SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

At the Southampton meeting of the British Association (1882) Schwedoft's theory of hail was brought forward by Prof. Sylvanus Thompson, and opposed by Sir William Thomson, who stated that a hailstone passing through our atmosphere would do as much work as would raise the water of which it is composed 13,000 centigrade degrees, or, otherwise stated, 13,000 times as much work as would raise it one degree. This being demonstrated mathematically, of course settles the question *mathematically.* To some people such demonstration is final, and therefore the idea that a lump of ice can enter our atmosphere as meteoric matter, pass through it and reach the earth as ice, is, as Sir W. Thomson said, "a manifest absurdity."

But we know that lumps of iron do thus enter the atmosphere, pass through it, and perpetrate the manifest absurdity by surviving in solid form this ordeal of fire.

In the case of iron the absurdity is even greater than that of water, as the *quantity* of heat demanded for the fusion of a given weight of iron is far greater than is demanded for the fusion and evaporation of the same weight of water. Note that we have here a question of *quantity* of heat corresponding to work done, not one of mere temperature.

The specific heat of water is nine times greater than that of iron, the quantity of heat demanded for raising a pound or any other weight-unit of water one degree will raise the same quantity of iron nine degrees, or nine times that quantity one degree. Therefore (assuming the figures of Sir W. Thompson to be correct) the heat generated as described would raise the iron nine times 33,000 degs., or 297,000 degs. But iron fuses at about 1,600° C. How, then, does it contrive to reach the earth in a solid state?

A simple experiment answers this question. Take a chisel or other hardened steel tool and press it against a rapidly rotating *dry* grindstone. Here work will be done in arresting the motion of the grindstone, and heat will be evolved in quantity exactly proportionate to the amount of mechanical motion arrested, *i.e.*, the motion of the grindstone. Both grindstone and steel will be heated; the temperature of the steel will be far higher than that of the grindstone because it is more concentrated on the smaller surface of the steel. The evidence of this high temperature will be supplied by the brilliant combustion of the particles of steel torn from the chisel, and by the softening of that part of the steel in contact with the grindstone. A chisel thus treated, as every practical workman knows, is spoiled by such softening, and therefore he always fits up his grindstone in a trough of water so that a film of cold water shall adhere to the rubbing surface. Itinerant grinders who sharpen other people's knives and scissors may omit this, as the softening of these is "good for trade;" the softened edges rapidly become blunt and require regrinding.

A further examination of the chisel, if fairly bright, will supply further instruction. It will show that the heat thus developed is generated at the surface whereon the force which did the work was applied. The well-known colours whereby the workman determines the temperature of heated steel will be displayed, the blue just beyond the ground face, then the purple, then the nut-brown and straw colour, etc. Two comparative experiments may be made, one in which the grinding operation lasts but a very short time, when it will be seen that the bands of colour will be very narrow; if in the other experiment the grinding be continued for a much longer time, the bands will be proportionately broader, showing that time be required for the heat to travel through the substance of the metal.

The case of the meteorite passing through the air is analogous, the air here representing the grindstone as regards its friction on the surface of the meteorite, which friction does the work of reducing the velocity of the motion of the mass. The effect is shown accordingly on the surface, as may be seen by an examination of the fine collection of specimens at the end of the mineral room of the British Museum (Natural History Department, South

Kensington). All of these are fused on their surfaces, but the work of the friction being completed in so short a time, the heat could not travel to the interior.

If so good a conductor as meteoric iron fails to carry the superficial heat to its interior, how much less able is so bad a conductor as ice to do the like. This may be easily illustrated by placing a lump of ice in the midst of a fire and watching the result. However fierce the fire may be, the time required for melting the ice is considerable, and proportionate to its size.

We must also remember that ice has the advantage of iron, not only in respect to specific heat, but also in that of its great latent heat of fusion and evaporation. Putting these together, those of my readers sufficiently interested in the subject may make the calculation for themselves, and will find that to melt and vaporize 1 lb. of ice demands about three times as much heat as to fuse 1 lb. of cast iron. Here, of course, I refer to the quantity of heat, or heat-work, not to mere intensity or temperature.

Besides this, Sir W. Thomson was wrong in assuming that all the work performed in retarding the motion of a meteorite, whether of ice or metal or any other substance, is directly converted into heat. It is evident that some of the motion of the solid body will be communicated to the air *as mechanical motion*; how much I will not attempt to calculate, but as the distance travelled in the mobile air is great, the amount of atmospheric commotion must be considerable. What may *finally* become of that motion does not affect the question under discussion, the hailstone being removed from the sphere of such action before it is completed.

I am aware that eminent men of science, whose views I am bound to respect, interpret the doctrine of the conservation of energy in such a manner as to assume that in every case where the mechanical motion of a body is arrested, *the whole mass* of the body is necessarily heated accordingly. I have discussed this question with scientific friends in literal table talk, and find that such discussion is instructive; it deals with one of the grandest, I may say the grandest, generalisation of modern science, the one which constitutes the philosophical basis of all our science, and which should be clearly understood by all.

I will therefore make it the topic of more table talk in this magazine.

THE THIRTY-SIX INCH TELESCOPE OF THE LICK OBSERVATORY.

MR. JAMES E. KEELER, one of the astronomers at the Lick Observatory, has recently communicated to the *Scientific American* an account of the great Lick telescope, from which we borrow the following particulars.

The pier of the telescope is a rectangular cast-iron column weighing 20 tons, built up of four sections rigidly bolted together. The thickness of the iron is about $1\frac{1}{4}$ inches. The lower section, which at the floor-level is 9 by 5 feet, expands into a broad base, 16 feet long and 10 feet wide, resting on the solid masonry foundation which forms the tomb of James Lick. This casting weighs 5 tons, and is the heaviest single piece hauled to the summit in the construction of the observatory. On top of the pier is a balcony, surrounding the massive head-piece which forms the support for the polar axis. The upper section of the pier, 4 by 8 feet at the top, contains the driving clock. A light iron spiral staircase, running from the base of the pier on the south to the balcony, gives access to the clock-room and n[illegible]y above, and adds greatly to the appearance of th[illegible]ing.

The weight of the pier is distributed over a number of heavy steel screws in the base, which afford means for the exact adjustment of the polar axis, but it is possible that, after this adjustment is perfected, the base will be set in cement, and the pier permanently fixed in position.

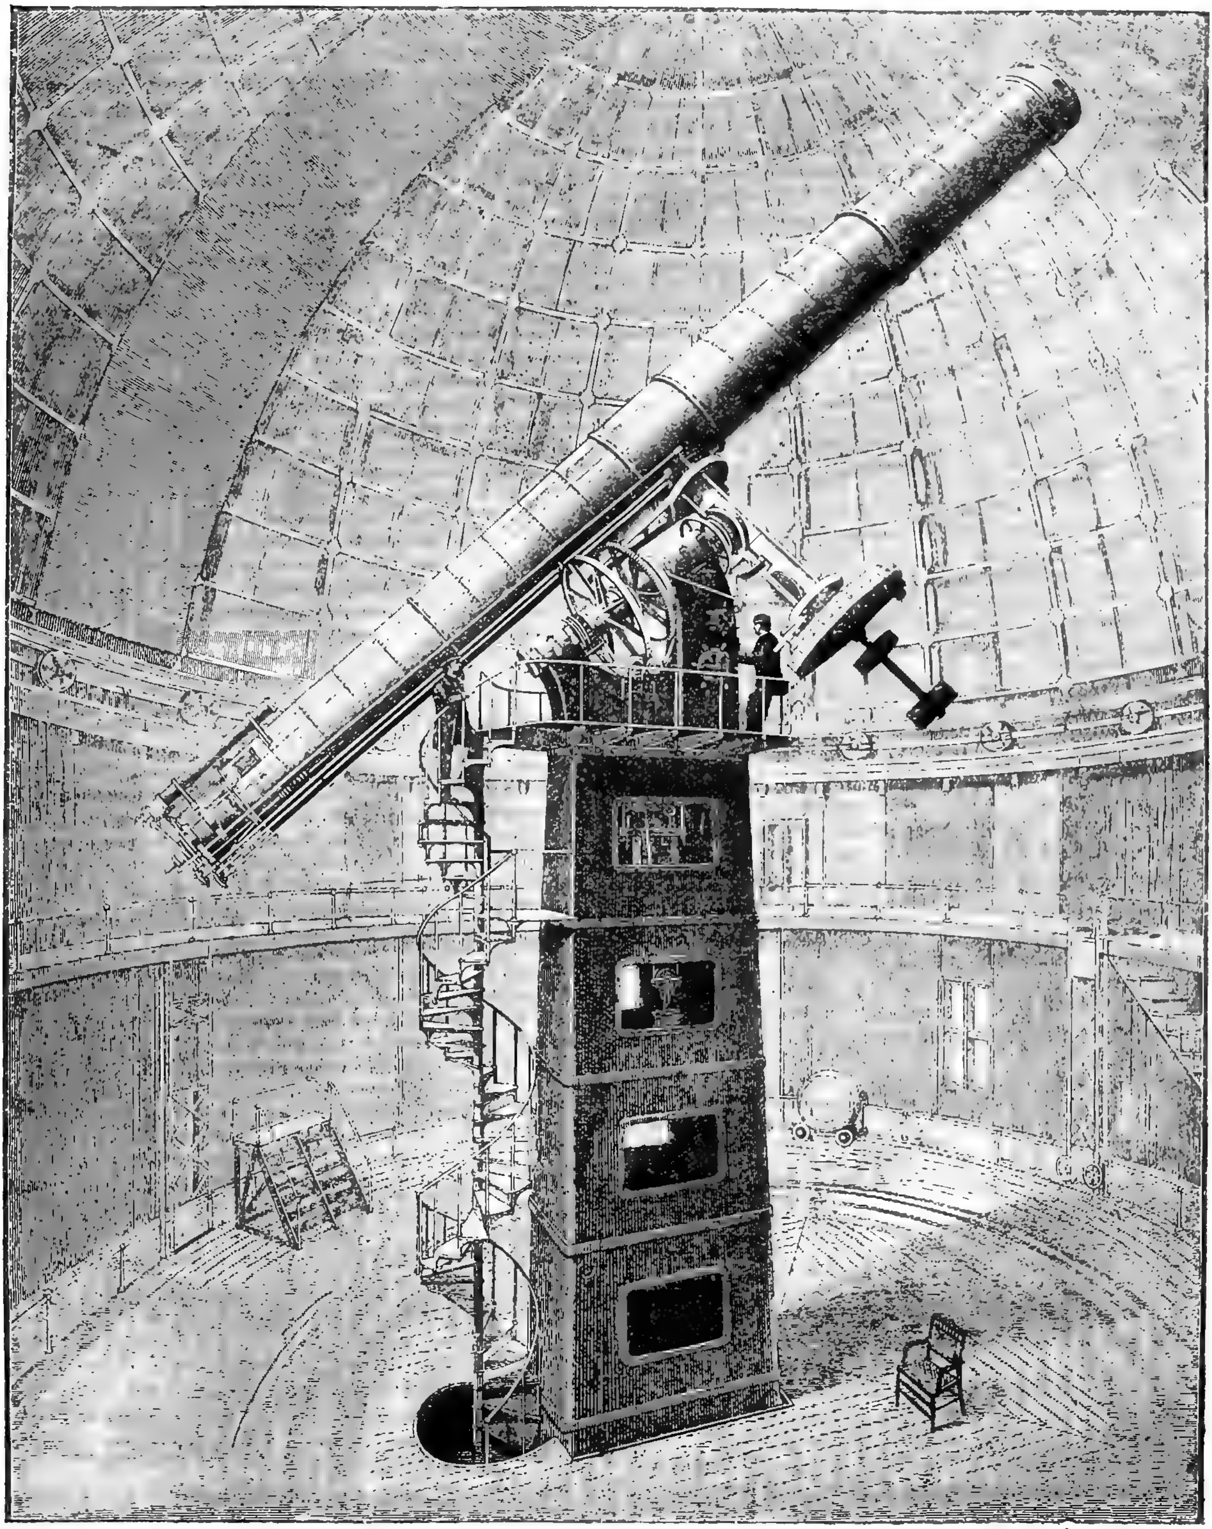
The telescope is intended to be moved by an assistant stationed on the balcony which surrounds the top of the pier.

The makers, Messrs. Warner and Swasey, designed the entire mounting, with the exception of the eye end, which was made essentially from plans prepared by Professors Langley and Holden. The telescope can also be moved quickly in the ordinary way by the observer at the eye end, although, as the whole train of gearing extending to the balcony must then be set in motion, this cannot be done as easily as if the quick motions had not been provided. A pressure of 10 lb. on the spokes of the quick motion wheel on the balcony will move the telescope in right ascension; a pressure of 20 lbs. is required for the motion in declination. The telescope can be reversed, or the same star brought into the field on opposite sides of the pier, in a little over two minutes.

The polar axis is a finely-finished shaft of steel, 12 inches in diameter and 10 feet long, weighing 2,800 lbs. It is pierced centrally by a 6-inch hole, through which passes a shaft for communicating the motions in declination to the telescope from the balcony. The polar axis turns in bearings of Babbitt metal, but the greater part of the weight on its upper end (some 14 tons) is supported by a collar containing hard steel rollers encircling the axis just outside of the upper bearing, and carried by a lever which leads down into the hollow head piece, and can be adjusted for tension. The lower end of the axis is turned to a flat surface, and the thrust of about 8 tons is taken by two rows of hard steel balls rolling in concentric grooves. To the upper end of the axis is bolted the cast iron cylindrical case, 9 feet in length, which contains the bearings of the declination axis.

The declination axis is 10 feet long and 10 inches in diameter, and is also made of steel. To one end is bolted the cast-iron central section of the telescope tube. The other end is just outside of the 6-foot declination coarse circle, and carries indices which point out the approximate declinations. The coarse circle is fixed to the declination axis case, and supports the rods which carry the weights for counterpoising the tube. This rod is made of a brass tube shrunk on to a steel core, and the weights, which are in the form of circular discs, travel on a thread cut in the brass. Each disc is 2 feet in diameter, and weighs 240 lb. Eight of these discs are required to counterpoise the telescope.

The bearing of the declination axis toward the telescope is relieved of the weight of the tube and its attachments (about $4\frac{1}{2}$ tons) by a double counterpoise lever, one end of which carries a collar with steel rollers, like that on the polar axis, the other an annular iron casting weighing 500 lb., which surrounds the sleeve of the declination axis just inside the coarse circle. The steel rollers embrace the axis close to the telescope tube, and as the counterpoise levers are always parallel to the axis, they relieve the same proportion of the pressure on the inner bearing in every position of the telescope.



TELESCOPE, LICK OBSERVATORY

The centre of motion of the telescope or intersection of the polar and declination axis is 37 feet 10 inches above the masonry foundation. The sight line of the telescope is $5\frac{1}{2}$ feet from the centre of motion, and the end of the rod for counterpoising the tube 12 feet.

The tube is made of hard steel plates rivetted together. It was shipped in four sections (besides the cast-iron central section), which are connected by bolts through flanges at their extremities. The plates near the middle of the tube are $\frac{3}{16}$ inch thick, and the thickness of the sheets diminishes towards the ends, where it is $\frac{1}{8}$ inch. The tube is 52 feet long, 4 feet in diameter in the middle, and tapers to a little over 3 feet at the ends. In the shops of the makers it was tested by placing a ton on each end when supported in the middle, and in other ways, the greatest deflection produced being about one-eighth of an inch.

The object-glass by Alvan Clark and Sons is secured to a flange on the outer end of the tube in the usual manner. Its clear aperture is 36 inches, and the distance of the focal plane from the back surface of the flint lens is 56 feet. The lenses are $6\frac{1}{2}$ inches apart, and the total thickness of glass, traversed by a ray of light, is about $2\frac{1}{4}$ inches. The weight of the objective in its cell is 530 lb.

The tail-piece at the eye end of the telescope is surrounded by a revolving jacket, provided with position circle, clamp, and slow-motion screws, for carrying the spectroscope and other accessory instruments. Clamps on opposite sides of the jacket receive two hollow brass rods 6 feet long and 3 inches in diameter, and any apparatus attached to these can be rotated easily and yet firmly about the axis of the telescope.

The draw tube at the eye end is 8 inches in diameter and is focussed by a wheel surrounding and concentric with the tube. This wheel acts upon three screws, parallel to the telescope axis, which move the draw tube in or out, and allow the heavy micrometer or other instrument to be adjusted to the proper focus with great ease and accuracy. The eye end is surrounded by a steel ring 39 inches in diameter to which lead all the clamps, slow motions, and other contrivances operated by the observer. The spokes of the right ascension wheels are notched, so that they can be distinguished from the declination wheels in the dark.

There are three finders of $2\frac{3}{4}$, 4, and 6 inches aperture, and in addition to these, brackets to which the objective and eye end of the 12-inch equatorial can be attached when a finder of great power is desired. The makers are providing a double slide micrometer eye-piece for this or the 6-in. finder, which will enable the great telescope to be pointed at a faint object by means of any neighbouring bright star—a contrivance especially valuable for photographic work.

The three microscopes for reading the finely-divided circles from the eye end (two for declination and one for right ascension) also pass through this ring. By turning a switch close to the eye-piece of the corresponding microscope, the circle to be read is illuminated by an incandescent electric lamp. Attached to the ring are also a small sidereal clock, a telegraph key for recording the time of an observation, and an electric switch for starting or stopping the driving clock.

The driving clock in the top section of the pier is, on a large scale, essentially the same as the clocks employed by Messrs. Warner and Swasey on their smaller equatorials and chronographs, except that it has an electric control, by which its rate is kept in agreement with that of a standard astronomical clock.

The equipment for photographic work is very complete. The photographic corrector is a meniscus of crown glass, 33 inches in clear aperture, and weighing in its cell 150 lb. When in use it is placed in front of the visual objective, and the focus of the combination thus formed is about 10 feet above the eye end. At this point a large aperture is cut in the telescope tube, giving access to a plate-holder capable of taking a dry plate 20 inches square, or any smaller size, and provided with all the necessary adjustments. An image of the moon formed here is about $5\frac{3}{8}$ ins. in diameter. Instead of a dry plate, a board holding an enlarging lens can be inserted in the plate-holder, and a magnified image of a planet projected into a small box camera, screwed to the draw tube at the eye end.

The steel dome, 75 feet 4 inches in diameter, was made by the Union Iron Works of San Francisco. The weight of its moving parts is 100 tons. It is rotated on the plan devised by Captain Floyd and Mr. Fraser, by an endless wire rope, which passes round the circumference of the dome, over grinding pulleys, and around a grooved wheel turned by a hydraulic motor in the basement. The dome can be turned completely around in nine minutes.

The slit for observing is $9\frac{1}{2}$ feet wide. It is closed by two steel shutters weighing 15 tons, which are opened by an endless rope hanging inside the upper gallery. A pull of 5 lb. is sufficient to move the shutters.

The hydraulic elevating floor weighs 26 tons, is $61\frac{1}{2}$ feet in diameter, and is movable between fixed galleries through a range of $16\frac{1}{2}$ feet. It is operated by four telescopic hydraulic rams, which have replaced the motors formerly employed for this purpose, their motion having been found inconveniently slow. The motors are retained, however, and can be connected in place of the rams whenever desired. By means of the rams the floor can be raised in a little less than ten minutes, and lowered in four, with an expenditure of 300 gallons of water. The floor is counterpoised by eight heavy blocks of iron, which slide in vertical columns and relieve the rams of all but two tons of the weight to be lifted.

PHOTOGRAPHY BY NIGHT WITH "LIGHTNING POWDER."

VARIOUS scientific journals and the special photographic organs have published formulæ for a mixture of magnesium and chlorate of potash, known as lightning powder, by means of which photographs may be taken in the night. We give, from *La Nature*, particulars of an improved process and apparatus devised by Mr. T. Sardnal, which prevents all risk of accidents, and obviates the escape of fumes from the burning powder. The inventor converts the powder into pastilles, which are then burnt in the apparatus shown in figs. 1 and 2.

The powder used is that of Dr. Fabre, and consists of:—

Pulverised chlorate of potash, very dry ..	6 parts
Sulphuret of antimony	1 part
Magnesium powder	3 parts

When these three materials are weighed out, the chlorate of potash and the sulphuret of antimony are very carefully mixed together, using for this purpose a slip of supple cardboard, or a *dry* finger. When the mixture is very intimate, the magnesium is added, and the whole is thrown upon a piece of coarse muslin of an open texture, placed upon a sheet of paper, upon which the powder may fall on shaking the muslin. When this operation has been repeated three or four times, the mixture is ready to be converted into pastilles in the following manner. The powder is placed upon a flat piece of glass, ordinary collodion is added enough to form a thin paste, which is mixed up with a wooden spatula or with the finger.

When the paste begins to set, it is at once formed into a flat pastille, and when half dry it is detached from the glass by passing beneath it the blade of a thin knife. It is then dried as quickly and perfectly as possible, since moisture would retard the combustion. The inventor has preserved such pastilles for two or three days by

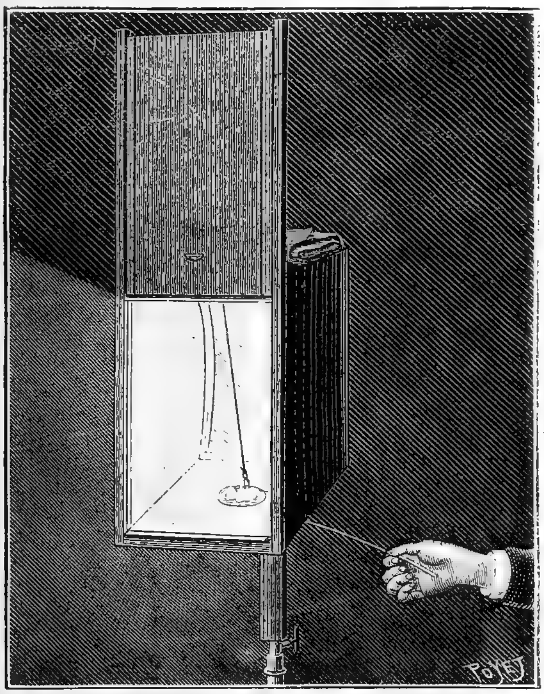


FIG. 1.

coating them with tin-foil paper, but he prefers to prepare each morning a quantity sufficient for use in the ensuing night. These pastilles have, as compared with the powder, the advantage of not scattering burning magnesium, and almost all the fumes remain shut up in the apparatus.

The following is the description of the apparatus in which the powder or pastilles should be burnt.

It is a box, placed vertically. The lid is replaced by a slide, and the bottom board by a plate of tin, sloped at 30° (fig. 1). In the middle of this tin plate there are pierced two small holes, to receive, the one a fuse of gun-cotton, and the other a nail which is introduced from below and which is twisted into a hook inside the box. The upper part of the box is partly removed, and this aperture is closed, at the moment of operating, with four folds of moistened linen. Lastly, the apparatus is lined with silver-paper, after the fashion of a passe-partout. To have a complete apparatus, it is merely necessary to mount the whole upon a sliding support, which can be raised or lowered at will (fig. 2).

After having focussed by means of candles, place the apparatus just described to the right or to the left of the camera, and so high that the light may fall upon the principal object at an angle of 15°. On the other side of the camera there is a small support set on a plate from which is suspended three or four ribbons of magnesium twisted together, and of a weight less, by fifteen times, than that of the magnesium powder employed in the apparatus. Care must be taken that the two foci are out of the field of the object-glass.

When these arrangements are made, the slide of the apparatus is fitted with a thread attached to the bottom of the trap, and which is fixed to the hook in the tin plate after having passed into another hook at the upper part of the box. There is then introduced through the other hole in the tin-plate a fuse of gun-cotton, the fibres of which are dusted over with the chlorate

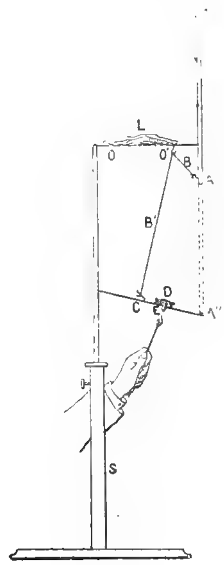

FIG 2.

and magnesium powder, and the pastille is placed upon it. The top of the box is then covered with the moistened linen, and the operation is commenced. The magnesium ribbons are ignited, the object-glass is quickly uncovered, and when the magnesium is almost consumed the wick of gun-cotton is kindled, taking care to keep behind the apparatus.

The pastille ignites and burns the thread which holds back the slide, but this takes place only when the explosion is complete, that is, after the explosion. At this instant the object-glass is closed, and the proof is developed as usual.

Fig. 1 shows the elevation of the apparatus, and fig. 2 the section. AA'A'' is the slide, BB' the thread serving to keep the slide raised, C hook to which the thread is attached, D the focus, E the fuse of gun-cotton, S the stand, L moistened linen placed over the openings OO.'

[It is essential that the chlorate of potash and the sulphuret of antimony should be powdered *separately*. Any attempt to pulverise them together, and even to mix them with mortar and pestle, would, in all probability, occasion a disastrous explosion.—ED., SCIENTIFIC NEWS.]

DIAMONDS FROM THE HEAVENS.

BETWEEN September 10 and 22, 1886, after the usual phenomena which accompany the arrival of meteorites, there fell three stones near the village of Nowo-Urei, in the government of Penza, in South-Eastern Russia. One of them was lost in a marsh; another was found by a peasant who, induced by a curious superstition, *ate* this wonderful substance arriving from heaven; the third was offered to the Mineralogical Cabinet of the Institute of Forests at St. Petersburg, where it has been carefully examined both mineralogically and chemically.

According to an account furnished to the Academy of Science by MM. Jerofeieff and Latchinoff, this stone, before being cut, weighed above four pounds. A part of its surface is remarkable for the deep piezoglypts which the mechanical action of the air has dug into it during its rapid flight. This surface is free from incrustation, as has been already observed in the case of several black meteorites, such as those of Tadjera. The fracture is almost black, but marked over with small particles, some of them white and others metallic. It is irregular and rough, but it does not present, as we find in many cases, a globular structure. Its specific gravity is 3·46.

By analysis it has been found that the meteorite of Nowo-Urei consists of fragments of peridote and pyroxene, between which is interposed a mixture of nickeliferous native iron and carbonaceous matter. There has also been recognised the presence of pyrrhotine and of chrome iron.

It will be understood that this is a mineralogical, not a chemical analysis, the ingredients mentioned being themselves complex.

The carbonaceous matter amounted to $2\frac{1}{4}$ per cent. of the entire stone. By successive treatment with aqua regia, hydrofluoric acid, and bisulphate of potash and by Brodie's process as adopted by Berthelot, it has been ascertained that the carbonaceous matter is a mixture of amorphous carbon and of diamond, perhaps of the variety known as carbonado, both in the state of microscopic grains.

The diamond has been recognised as such by its hardness, which is such as to eat rapidly into a polished surface of corundum which was rendered dull, and covered with fine scratches. The meaning of this test will be understood if we remember that corundum is, next to the diamond, the hardest substance known.

The mean specific gravity—of course, of the carbonaceous part—is close upon that of the diamond, 3·5.

When heated in a current of oxygen, the substance burnt yielding carbonic acid, and indicating a composition of 95·40 per cent. of carbon and 3·23 of ash.

In fine, the Russian mineralogists are led to conclude that the meteorite in question contains, in addition to 1·26 per cent. of amorphous carbon, diamond in the proportion of 1 per cent., but in very fine dust. The authors remark that, as the meteorite weighed 1,762 grammes, it contained 17·62 grammes of diamond, or 85·43 carats.

This discovery of diamond in a meteorite is not as unprecedented as it might seem at first sight.

The meteoric iron or holosiderite of Arva in Hungary is not only remarkable for its large proportion of phosphorus in the state of Schreibersite, a double phosphuret of iron and nickel, but also contains graphite in a cubic form. Hence Hardinger was of opinion that this crystal might be derived by pseudomorphosis, from iron pyrites, for which graphite had been substituted. But Gustav Rose remarked that these crystals present rather the form of the diamond, and that iron pyrites have never yet been recognised in meteoric stones.

M. Daubrée made the following remarks in addition:—In Brazil, the diamond in the sands in which it is sought for is accompanied by rutile, anatase, brookite, oligiste, tourmaline—that is to say an assemblage of fluoric and boric minerals, to the origin of which the diamond in this region seems to attach itself. In New South Wales, as Professor Liversidge has shown, the diamond is attended by the same minerals. Besides quartz, tourmaline is frequent along with brookite, ilmenite, topaz, corundum, and cassiterite (tin-stone), a mineral for which the intervention of the same fluoric or chloric agents is generally admitted.

In the important deposits of South Africa the diamond occurs in a very different manner, being associated with a serpentine brecchia in which the crystals are sometimes encased. But nothing shows that it has remained in its original matrix. It appears rather to have been torn away from the depths, and to have risen to the surface.

In the gangue of cosmic origin, which the meteorite of Nowo-Urei supplies, the diamond occurs in a manner different from the deposits on our globe. Its association with amorphous carbon is doubtless not accidental. Either the diamond, so refractory to the efforts of mineralogists for its artificial production, has separated itself by crystallisation from a carbonaceous medium, or, what is more probable, the diamond merely represents the residue of a partial transformation, which tends to change it completely into the state of graphite.

This last supposition seems particularly applicable to graphite in diamond-like forms, like that occurring in the meteoric iron of Arva. Seized and enclosed in a mass of iron, the high initial temperature of which is attested by the abundance of distinctly crystallised metallic phosphurets, it must necessarily lose its original state, and could not escape a change into the allotropic condition of graphite, with which we are experimentally familiar.

In the cosmic rock of Nowo-Urei the preservation of the diamond is surprising. It leads us to believe that the temperature of this rock, since the time when the diamond was developed, cannot have been very high, probably not reaching the melting point of peridote and pyroxene, in the midst of which it is found. Another proof is that nickeliferous iron could remain in the presence of free carbon without combining with it, as would probably have been the case at a high temperature.

Graphite abounds in meteorites, especially in Holosiderites, often isolated in nodules, as in the specimen from Arva, but more often in cylindrical cases around rods of pyrrhotine.

THE RELATIONS OF ASTRONOMY AND ASTROLOGY.—Professor Newcome (*Sidereal Messenger*) remarks that astronomy is often said to have been eagerly cultivated in the past because it served as a starting-point for the astrologers. But nothing in the writings of antiquity and of the middle ages supports this opinion. On the contrary, astrology must be regarded as an aberrant daughter of astronomy.

General Notes.

The Origin of Meteorites.—M. Faye seeks to revive the hypothesis of Lawrence Smith, according to which the meteorites are fragments hurled aloft by volcanoes in the moon and in the planets. *La Nature*, criticising this hypothesis, reminds its readers that meteorites very rarely present a volcanic character.

Baregine and Glairine.—These organised sulphur-compounds exert upon the sulphates of mineral waters a reductive action, the product of which is free sulphur. According to a recent communication of M. Olivier to the Academy of Sciences, these same organisms exhale ammonium sulphocyanide. In them sulphur seems to fulfil the ordinary chemical function of oxygen.

The Manufacture of Explosives.—The inspectors under the "Explosive Act" state in their annual report for 1887 that the number of accidents by explosion, and fires due to explosions in that year had been 130, causing forty-three deaths, and injury, more or less severe, to 105 persons. They mention as a serious fact, that a nest of young mice was found in a box of dynamite.

New Method of Embalming.—A certain Angelo Motta, of Cremona, invented, or thought he had invented, a process for preserving human bodies by gradually destroying the organic matter, and replacing it by metals. No possible good could result from the success of this process, and we may, therefore, rejoice that the inventor has carried his secret with him to the grave.

Royal Agricultural Society's Experiments at Woburn.—The annual excursion of members of the Royal Agricultural Society of England to the Woburn Experimental Farm took place on June 28th, when upwards of 100 gentlemen proceeded from Euston by a special saloon train, among those present being Lord Egerton of Tatton, the Earl of Macclesfield, Lord Middleton, Lord Northbourne, Sir J. Lawes, Dr. Gilbert, Sir John Shelley, Sir John Thorold, and Mr. Mark J. Stewart, M.P. At Woburn the party were met by Dr. Voelcker and Mr. Carruthers, who went over the various experiments and explained them.

Arsenic in Cretonne.—We publish in our correspondence column a letter from a well-known chemist, drawing attention to the use of arsenic in cretonnes and muslins, and we regret to learn that a draper in London has been compelled to return a large quantity of these materials to the manufacturer on account of cases of poisoning which have occurred. The use of arsenic in such materials is even more dangerous than in wall paper, and is strongly to be deprecated. We would advise our lady readers to be chary of buying bargains in these fabrics, unless a guarantee is given that they are free from this poison.

British Columbia.—The Rev. W. S. Green, who formed one of the expedition party for the recent deep sea explorations in the Atlantic, sailed on June 28th from Queenstown in the *City of Rome*, accompanied by the Rev. H. Swanzy, for New York. Their ultimate destination is British Columbia, where they are commissioned by the Royal Geographical Society to make a rough survey of the unexplored glacier regions of the Selkirk Range. The expedition will be assisted by the Canadian Pacific Railway Company. The two gentlemen are also commissioned by the Royal Dublin Society to collect information in the United States on the fish trade and fisheries, with a view to developing the home industry.

The Gramophone.—At a recent meeting of the Franklin Institute, Philadelphia, Mr. Emile Berliner, of Washington, read a paper on his lately invented apparatus for recording and reproducing musical sounds and speech, called the "gramophone." Mr. Berliner gave a historical sketch of the progress of invention in this field, and a detailed description of his own method and apparatus. He demonstrated its capabilities by recording on one of his prepared zinc plates several songs and speeches, etching the plate, and reproducing the songs and words then and there. Several etched record plates, prepared previous to the meeting, were likewise presented, and the reproducing apparatus faithfully emitted the songs and spoken words recorded upon them. The reproduction was loud enough to be distinctly audible all over the lecture-room. The music could be easily recognised. Speech, though not so clearly rendered, was for the most part intelligible.

Curious Cause of Action against a Medical Man.—An old Breton peasant, having met with a slight accident, sent for his doctor, who assured him that there was no serious injury and prescribed a draught, ordering at the same time leeches to be applied. As leeches were not easily procurable, the patient asked the doctor to get them for him. This he promised to do, and the next morning a bottle arrived containing half a dozen fine leeches. The farmer's wife being in doubt herself, applied to a neighbour for advice how to cook them. The result was that they were fried. The patient disliked the bitter taste of the first one so much that he declined eating any more. However, his wife insisted that as they had to pay for the "medicine," it ought to be taken, and so the poor man actually ate the whole of the fried leeches. He was afterwards seized with severe and fatal illness, which was attributed to poisoning by the leeches. The widow brought an action against the doctor, who, however, was exonerated from all blame by the court.

Compressed Gas.—It has been urged that the use of compressed gas for lighting cars is attended with the danger of the gas exploding in the event of a collision. The imaginary nature of this danger was shown by the recent accident on the Philadelphia and Reading, where an escape of compressed gas from a leaky hose simply burnt for a few moments without any explosion. Experience in Germany has been of a similar nature, and a recent collision near Birkenhead, England, between two trains lit with compressed gas, was unaccompanied by any explosion. At the time of the collision between the Hoylake and Mersey tunnel trains, the gas in the latter was alight. The gas cylinders of the smashed coaches were taken from the debris, and tested to a pressure of 150 lbs. per square inch, and they were found to be entirely uninjured beyond a few severe dents. The gas fittings of the remaining portion of both trains had not suffered in the least through the collision;

and, with the exception of those in the smashed cars, not a single lamp glass was broken in either train.

The University of Bologna.—On June 12th began the festivities in commemoration of the eighth centenary of the University of this name. *La Nature*, whilst admitting the impossibility of summing up all the illustrious men who have been connected with its history, makes an exception in favour of Galvani. The inauguration of a statute to his memory formed an interesting part of the festivities. On the proclamation of the "Cisalpine Republic" Galvani refused to take the oath of fealty to the new Constitution, and was deprived of his professorship. He died in 1798, without having been reinstated. It was at Bologna that the Ptolemean astronomy fought its last battle. Its most celebrated and most obstinate champion, the Jesuit Riccioli, occupied the mathematical chair at the University, and had published in 1651 a complete course of anti-Copernican astronomy in two bulky quartos. He had made some experiments on the fall of bodies from the top of the tower of Bologna, and believed that he had demonstrated the immobility of the earth.

The Life and Genius of Lavoisier.—By occasion of a new biography of Lavoisier, compiled by M. Edouard Grimaux, *Le Temps* pays an eloquent tribute to the memory of this illustrious savant, whose merits, we fear, are in these days not sufficiently estimated, even by a multitude of scientific men. The fact that he rendered chemistry quantitative by introducing the use of the balance should of itself be sufficient to cover his name with glory. We read here that when he became one of the "Fermiers Generaux," an occupation which cost him his life under the Reign of Terror, one of his colleagues in the Academy of Science exclaimed: "All the better! He will give us better dinners." It is to be regretted, however, that in the *éloge* in *Le Temps* there is no mention of Priestley as the first and true discoverer of oxygen, though he is duly credited with the discovery of other gases. It would have been both true and sufficient to have said that Lavoisier was the first to recognise the importance of oxygen, which Priestley utterly failed to do, and continued to advocate the phlogistic theory.

Observations on Saturn and Mars.—M. Perrotin informs the Academy of Sciences that he has examined the rings of Saturn at Nice with a magnifying power of 1,250 diameters. He has measured the distance from the margin of the ring to the body of the planet, and fixed the place, not merely of Cassini's division, but of the line which separates the bright rings from the dark enclosed ring. He finds that this dark ring, the existence of which has not been known for more than thirty years, presented an inner margin, not diffused, but perfectly distinct. M. Perrotin is continuing his studies on the planets which are at present in opposition, that is, in the most favourable position for observation. In Mars he has observed canals more vast than any of those previously mentioned. There are four which commence quite near the equator, and which extend to the white cap of the north pole. The region which recently seemed to have been inundated by the sea, judging from the greenish colour by which it had been overspread, seems about to resume its former continental condition, recognisable from the reddish colour which is gradually reappearing.

Liverpool Science Students' Association.—A large party of members and friends left on June 23rd for a field meeting at West Kirby and Hilbre Island. On arrival three sections were formed—a botanical party under the direction of Miss E. M. Wood and Mr. James MacKarell proceeding to Caldy; the biological and geological sections, under the guidance respectively of Messrs. William Narramore and I. E. George, making their way across the sands, first to the Little Eye, thence to Hilbre Island, for the study of the sandstone formations and interesting fauna of the happy hunting ground of local naturalists. The fine weather experienced proved highly favourable to the botanists, upwards of ninety-two plants in flower being obtained. Among the more interesting specimens found were *Thalictrum minus*, *Sedum Anglicum*, *Armeria maritima*, and *Ornithopus perpusillus*. The prize for the day was offered for the best-named collection of plants in flower belonging to the orders Compositae and Rosaceæ, and after a keen competition was awarded to Miss M. E. Clementson, who obtained twenty-two species. The geological features of the island were explained by Mr. Isaac E. George, who, in the course of his remarks on the peculiar "weathering" of the rocks, alluded to the great denudation that had taken place during the last century.

Aerial Voyages.—M. Faye writes to *La Paix* with reference to the projected expedition of M. Jovis (captain of the balloon *Horla*) from America to Europe. His remarks are suggested by a study of the more elevated atmospheric currents, in the midst of which tempests take their rise. "It is quite true that on setting out from a point like Caracas, situate in 10° north latitude on the northern coast of South America, and on rising very high into the air (about the region of the cirrus) there is the chance of meeting with a current flowing towards Europe. But these currents move at first very slowly, and only acquire a great speed more to the north, about lat. 20° or 25°. The voyage, in place of three days and three nights, will last at least ten or twelve days. Besides, these currents do not tend directly towards the northern coasts of Europe. From the parallel of 10° they move slowly westwards, declining more and more to the north. About 30° or 35°, according to the season, they move due northwards, then incline to the east, and finally take a north-easterly direction. Thus one of these currents, taken above Caracas will move first towards the Gulf of Mexico, enter upon the territory of the United States in Texas, leave the western continent at some point between Philadelphia and Newfoundland, cross the Atlantic obliquely, and arrive at the Bay of Biscay, the coasts of Ireland or of Norway. It is in these upper currents that cyclones are formed, a circumstance evidently dangerous for such a voyage. It would be better to select a starting point near New York, to enter into daily communication with the "signal service" and with the meteorological department of the *New York Herald*, and select, for, ascending, the moment when a depression, not dangerous, and well studied beforehand, was passing above the station. The voyage might then be completed in three or four days, and there would be at least the advantage that the departure of the *Horla* would be immediately telegraphed to all the European coasts. M. Faye, however, considers the undertaking rash, and advises its authors to weigh well the terrible risks to which they are exposed.

BUDS.

AMONG the many pleasing and wonderful effects of Spring, there is none more striking than the rapid expansion of buds into tender leaf. A few days of warmth causes them to swell and burst so suddenly that with many who have not thought about the matter their formation seems to be a thing of the moment. But, as will be presently shown, this is not so. Leaf and stem were there in the previous autumn, and indeed in a very rudimentary condition at an earlier period than that, and very little has been added to the organ besides water. In fact, buds may be made to develop into shoots with

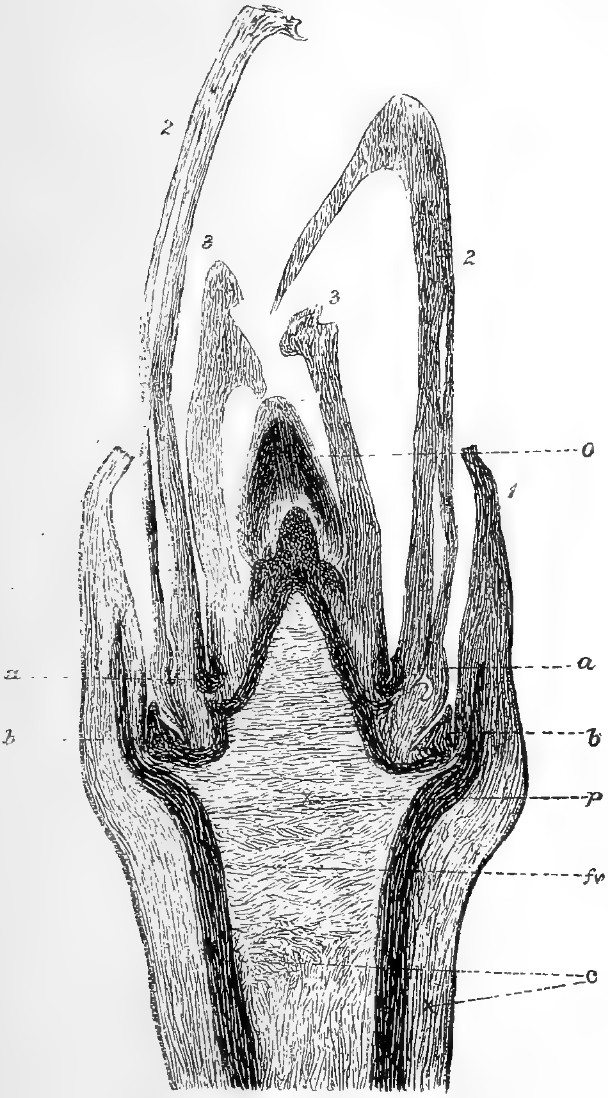

FIG. 1. SECTION OF LEAF BUD OF EUONYMUS.
a, *b*, axillary buds; *p*, pith; *fv*, fibro-vascular bundles; *c*, cortex, 1, 2, 3, young leaves. Magnified twenty times.

only warmth, water, and oxygen for respiration, care being taken in performing such an experiment to cut the branch bearing the buds under water, to render it more absorbent. It will contribute to a better comprehension of the matter if we imagine that we have before us a "winter-bud"—one from the spindle tree *(Euonymus)* will be a good example—which we have dissected through the middle, from base to apex. We shall then see a central axis tapering upwards from a thickish base to a fine point and along its sides a number of leaves, so closely set as to leave scarcely any interval, which tightly envelop the axis and overlap its tip, to which they act as a protection, but, it is important to note, do not, except in flower-buds, grow from it. This central axis afterwards becomes the stem, and the leaves which enwrap it will be noted to consist of two kinds, the inner or foliage-leaves, slightly succulent and light-green, the outer or scale-leaves dryish brown and often sticky and hairy. These latter usually fall away upon expansion, their function being the protection of the inner and more delicate parts. All these characters are visible to the naked eye, but if we now prepare a transparent section showing the same parts and place it under a low power of the microscope (or, in the absence of such, a good hand-lens will be helpful), we are able to make out the following important additional details. Proceeding as before, from the centre or axis, we observe first a lightish and, as a higher power shows, a cellular portion, which is the pith in a young condition, and this is bordered by two dark

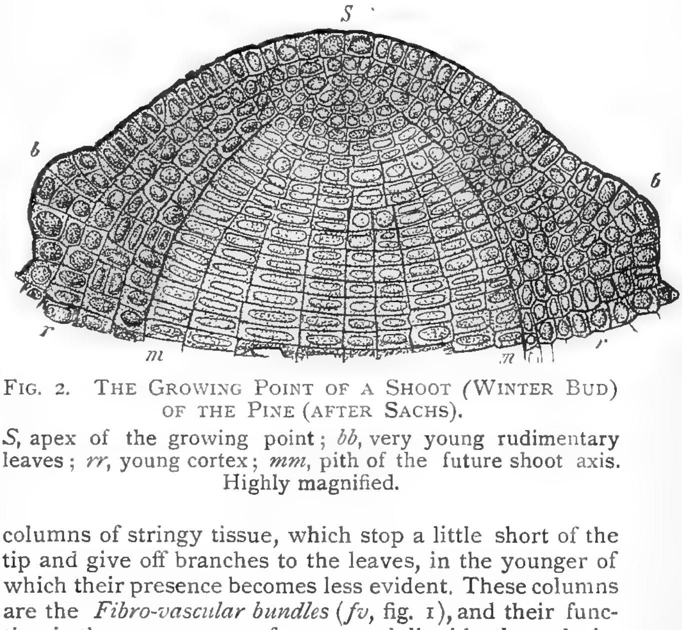

FIG. 2. THE GROWING POINT OF A SHOOT (WINTER BUD) OF THE PINE (AFTER SACHS).
S, apex of the growing point; *bb*, very young rudimentary leaves; *rr*, young cortex; *mm*, pith of the future shoot axis. Highly magnified.

columns of stringy tissue, which stop a little short of the tip and give off branches to the leaves, in the younger of which their presence becomes less evident. These columns are the *Fibro-vascular bundles* (*fv*, fig. 1), and their function is the conveyance of gases and liquids through the plant, and the maintenance of rigidity; they spread out into the leaves as the veins. External to these is another lighter cellular region (*c.*, fig. 1.), which is the bark in a young condition, and from it the leaves arise. The leaves (1, 2, 3, fig. 1) themselves are seen to be masses of cellular tissue, interrupted by strands of vascular tissue, and become smaller and less defined as they proceed towards the apex until they dwindle down to little roundish prominences on the upper part of the axis. But one of the most striking circumstances in connection with them is the existence in a very rudimentary condition (being less evident near the younger leaves) of next year's buds (*a*, *b*, fig. 1.), in the axils or angles which the leaves form with the stem. If we now raise the magnifying power to about 400 diameters, the vascular nature of the darker tissue and the cellular nature of the lighter will be rendered evident at once, whilst at their terminations the character of that most important part of the bud, the apex, or the *growing point* (fig 2), also becomes more clearly defined. It is seen to consist of cubical or polyhedral cells filled with protoplasmic matter of a solid or semi-fluid nature, and containing large nuclei which may be rendered more evident by staining with carmine. This is the most active part of the whole structure, and must be considered the beginning of the shoot rather than the end of it, as it is derived from the fertilized oosphere or single cell in the ovule of the mother-plant which gave rise to the present generation, and from its simple and but slightly differentiated condition has been formed all the complex structures of stem, leaf, and flower, its great activity being kept up by a continuous supply of nutriment from other parts of the plant. By way of illustration it may be mentioned that a similar mass of tissue is found close to the tip of every growing root and root-fibre, but here of course there is no bud.

(To be continued.)

POISONOUS DYESTUFFS.

A RECENT occurrence in Lyons has confirmed MM. Arloing and Cazeneuve's conclusions respecting the poisonous character of some aniline dyes and the harmlessness of others. Almost an epidemic happened last November with female spoolers working a particular yellow cotton yarn used for gold lace making. Dr. Carry, of the Lyons Medical Society, who was the first to notice the accidents, on being called to attend a spooler, found the patient suffering from a complication of obscure complaints. The most apparent symtoms were weakness, dyspepsia, and vomitings, coupled with a bluish-grey colouration of the gums, extending to the inside of the lips. As the yarn on winding emitted a considerable amount of yellow dust, and other working girls were similarly affected, the physician was soon on the right scent. He found that, while the accidents were caused by the dye, some yellows were very poisonous, others less so, and some quite harmless. One sort, giving out much dust, was so dangerous that one working girl had lost, within a short time, two canaries and one cat. The bird's cage hung near her machine, and the cat had probably swallowed the deadly dust with her food.

Next it was found that in a shop, where many girls were employed, no accidents were noticed last summer while the windows could be kept open, but the trouble began in November and December, when they had to be closed. With the new patients Dr. Carry had full opportunity to observe all the symptoms. Besides those already mentioned, which mostly relate to the digestive functions, others pertaining to the nervous system were noticed, such as persistent cephalalgia, insomnia, and an analgesis of the skin so complete that pin pricks could not be felt. At the same time the circulation was normal, there was no fever, and no albuminuria.

Some twelve or fifteen women were under treatment for the same complaint, and the recovery was in all cases very slow. But the accidents were too evidently caused by some poison to be thus dismissed without further investigation. Lead, the first that suggested itself, was looked for by a Lyons pharmacist, but proved absent. Three different specimens of dust were next given for thorough analysis to a specialist—Professor Pouchot, of the Martiniere school, who confirmed the absence of lead, but found traces of antimony used as a mordant.

The first specimen, the most poisonous, was found to have been dyed with sodium binitronaphthol, generally known in trade as Martius yellow; the second, less poisonous, with Poirier's light binitronaphthol; and the third, quite harmless, with the sodium salt of binitronaphthol sulphonic acid. Experiments on animals confirmed the chemist's report. Dr. Carry did not feel justified in concluding that goods thus dyed are dangerous to the wearers, but they are certainly to the weavers; and since yellows, equally good but harmless, can be obtained at a slightly higher cost, he thought the poisonous dyestuffs should be prohibited, or such ventilation enforced as to protect the working people from the dangerous dust.—*Therapeutic Gazette.*

THE CULTIVATION OF THE OSIER.

WITH reference to the judicious proposal of Mr. Mattieu Williams that the waste lands of this country should be re-forested, we lay before our readers some remarks on the cultivation of the osier in France, which have appeared in the *Echo Forestier* and in *La Nature.* The case is stronger in England than in France, for whilst France already exports osiers to a very considerable extent, both to Britain and to America, we do not produce sufficient for our own consumption.

There are in Europe not fewer than one hundred species of willows. Each of these species is well characterised from a botanical point of view, but for industrial purposes they may be divided into two sections, the respective types of which are the true osier (*Salix viminalis*) and the goat-willow (*Salix caprea*), the "*Saule marceau*" of the French. Both classes have a high importance in the art of basket-making, which is now a pursuit of importance. The coarse or brittle osier (*Salix fragilis*), sometimes known as the "crack willow," is grown to a great extent in France. It is planted along the streams and on the margins of marshy fields, and it is cut in pollards. The young shoots are reaped every year, and used for common baskets and hampers. Of this kind, as already intimated, France exports a large quantity. But of the fine osier used in ornamental basket-work, France does not produce sufficient for her home consumption, and imports it in large quantities from Germany and Italy.

We import this kind not so much in the twig as in the shape of manufactured articles. Now, there is certainly no good reason why the osier should not both be grown and worked up at home. Our climate is certainly not less favourable to its growth than that of any Continental country. It does not require great heat, but plenty of moisture, both in the soil and in the air.

The osier is a tall shrub, with upright long stems and very flexible branches of a greenish-grey colour, less commonly yellow. It prospers in soils which are too wet or too poor for most other crops, and it might, we think, be very appropriately planted to take up the moisture of sewage-irrigation fields. We have seen it, in fact, planted for this purpose at Leyton, where it seemed very flourishing. It grows rapidly, requires little attention, and by the third year (thirty-six months from the date of planting) it gives a net return, in the most suitable situations, of from £16 to £20 per acre; in soils of medium quality of £13 to £15; and in the worst and least suitable localities, £8 to £10. An osier bed, with due care, will continue productive for twenty-five to thirty years.

The expense of planting an osier bed may be as much as £9 or £10, and the annual cost £2 to £3 per acre. But it must be remembered that the land is generally suited for no other purpose, and is therefore, for the most part, lying waste.

Natural History.

A CURIOUS PARALLEL.

THERE must be few zoologists who have not been greatly struck by the manner in which types, so to speak, of structure are reproduced in groups of animals widely distant from one another. Thus we have beasts of prey, birds of prey, fishes of prey, and insects of prey; burrowing mammals, burrowing reptiles, burrowing insects, and burrowing crustaceans; swimming mammals, swimming birds, swimming reptiles, and swimming insects;

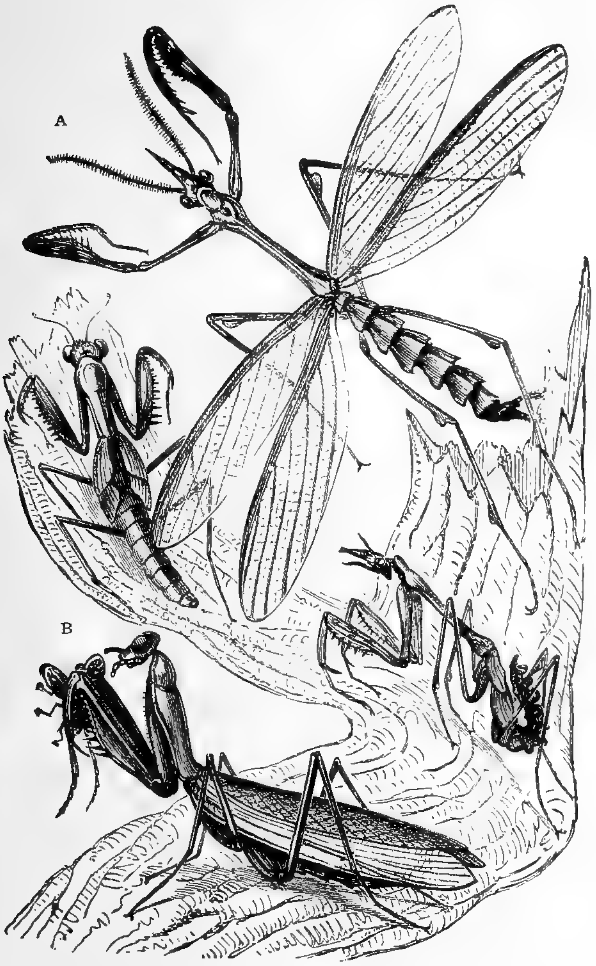

FIG. 1. A, *Mantis religiosa* and its larva. B, *Blepharis mendica* and its larva.

and similarity of habit implies similarity of structure, at any rate so far as general principles are concerned. And, very often, between individual species, though wide as the poles asunder in the scale of nature, we find the most startling similarity in bodily formation. Take, for instance, the mole and the mole-cricket. One is a vertebrate and the other an invertebrate; yet not even the most casual of observers can fail to notice the striking likeness which exists between them. Take, again, the whale and the fish: the similarity is so great that even now many of us find it almost impossible to believe that they do not belong to one and the same class of beings. And examples such as these might be multiplied *ad infinitum*. There is one very remarkable case of natural parallelism, however, with which very few of us are acquainted, and which is sufficiently remarkable to call for special notice; and that is the instance of the Praying Mantis and the Mantis Shrimp.

The former of these—a member of the vast class of the insects—is a fairly well-known creature. In some form or other—for there are many species—it abounds in all tropical and many temperate lands, and the curious attitude which it adopts while waiting for food, and which is referred to in its popular title, has rendered it familiar to many who would otherwise never have heard of its existence. This attitude, as most of us are no doubt aware, is very much that of prayer, the long fore-legs being clasped and raised aloft, as though in supplication to heaven. But, in reality, the insect is only holding those limbs in readiness for the fatal stroke to be delivered upon the first insect which ventures within reach; and, in order to understand the full utility of the

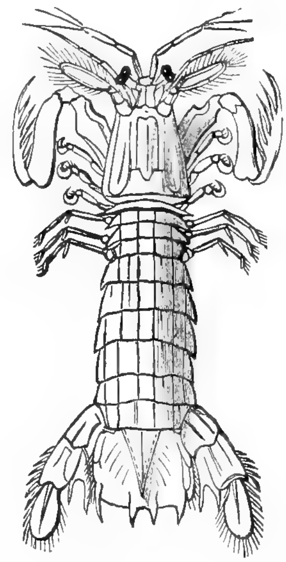

FIG. 2. The Mantis Shrimp. *Squilla mantis.*

position in question, we must examine the structure of the limbs.

In the first place, then, as may be seen by the illustration (fig. 1.), the *coxa*, or hip-joint, is greatly developed, and becomes not merely a joint—as in the generality of insects—but a veritable division of the limb, almost equal to the thigh in size, and furnished with an immensely powerful muscular system. The immediate effect of this prolongation, of course, is greatly to lengthen the limb, and at the same time to increase its power of folding. In the mantis from which this description is written, and which is a small one of its kind, the *coxa* is just three-quarters of an inch in length, while the thigh is one-eighth of an inch longer.

The thigh itself, which, like the *coxa*, is triangular, is armed upon its lower surface with two rows of strong and sharp teeth, one upon the outer edge and one upon the inner. In the specimen referred to the outer row consists of four tolerably large teeth, placed rather widely apart, and the inner of eighteen, varying in size, and situated quite closely together. The lower leg is also triangular, and is armed with a double row of teeth, the inner consisting of thirteen and the outer of ten, while the apex itself is developed into a very long, curved, almost fang-like claw, reminding one very much of that upon the tail of a scorpion, save and except that it is not perforated for the transmission of poison. The foot is quite small and insignificant, used in walking only, and never employed in the capture of prey.

These formidable limbs, as already mentioned, are raised high in air while their owner is lying in wait for prey. No sooner does a victim venture within reach, however, than they are thrown sharply forward and downward, and the insect, or whatever it may be, is seized between the thigh and the lower leg, the teeth upon which hold it securely imprisoned notwithstanding its struggles. The legs are then folded closely to the body, chiefly by the action of the *coxa*, the captive is brought into contact with the jaws, and there it is firmly held while its conqueror leisurely picks it to pieces and devours it.

The muscular system of these curious weapon-legs is exceedingly powerful, as is amply shown by the markedly triangular shape of every joint. And, as the lower part of the leg fits, when the limb is folded, into a groove upon the thigh, and as the teeth closely interlock, it is tolerably evident that a victim, when once seized, can have but very little hope of escape.

This structure is common to a large number of insects belonging to the group, whose slowness of foot is thus amply compensated for by the formidable character of their natural weapons. And their green colour and leaf-like appearance of course assist them very greatly, by assimilating them to their surroundings, and rendering their detection by their anticipated victims an almost total impossibility.

Now, in the mantis shrimp, strange to say, although a crustacean and a dweller in the water, we find a structure almost precisely similar in detail as well as in principle. And a most admirable illustration it supplies of the law that identity of habits produces identity of structure, even in creatures not in any way allied to one another, and existing under conditions of a totally different character.

Again we find the long raptorial fore-legs constituting weapons of offence, and armed, just as in the mantis, with a formidable array of strong and sharp spine-like teeth. Again we find the lower part of the limb fitting into a groove upon the upper, in order that the grip may be the more severe, the possibility that the victim should break away the less. And the chief, in fact the only, difference in the weapons of the two creatures is that in the crustacean the *coxa* is not prolonged, and that in consequence the teeth are set upon the foot; while it is the foot which is received into a groove upon the lower leg, and not the lower leg into a groove upon the thigh.

By those who have kept it in captivity, the mantis shrimp is said to use its raptorial limbs with wonderful address. Dr. Lukis, for example, speaking of his own specimen, tells us that "it placed itself in a menacing attitude, which would rather have excited the fear of exposing the hand to it. . . . . . I brought a silver tea-spoon near it, which was struck out of my hand with a suddenness and force comparable to an electric shock. This blow was effected by the large arms, which were closed and projected in an instant with the quickness of lightning."

In a smaller crustacean, also, popularly known as the Skeleton Screw, and scientifically as *Caprella linearis*, a very similar structure is found; but its efficiency is still further increased by a corresponding modification in the second pair of legs also, so that four raptorial organs are provided in the place of two. No groove is present upon the lower part of the leg, but that joint, which is enormously large, is armed with a double row of long and sharp teeth, between which the food is received, and which practically answer the same purpose. The foot itself, too, is sharply notched along the edge. And both attitude and action of the creature, when seeking for prey, are so singularly suggestive of those of the mantis, that it is quite difficult to realise that the two have absolutely nothing in common with one another.

Instances such as these are not uncommon, although seldom do we find the resemblance so complete in creatures so widely different. And yet, since the resemblance does exist, it is somewhat singular that the peculiar structure in question is not more common, seeing how great is the number of predacious beings, and how many of them, so far as we can tell, would benefit by the possession of raptorial limbs. Something similar we see in the water scorpion, the water gnat, and the stick-like *Ranatra linearis*, all of which capture their prey by the aid of modified fore limbs. But in none of these do we find the true mantis structure, which is so very pronounced in the creatures described. And we thus have a double and seemingly paradoxical source of wonder; firstly, that the similarity should exist at all, secondly, seeing that it does exist, that it is not far more common.

THE POISON OF BEES.—According to some investigations which Professor Carlet, of the Faculty of Sciences of Poitiers, has recently communicated to the Academy of Sciences at Paris, the poison-apparatus of bees comprises two quite distinct sets of glands, some yielding an alkaline secretion and others an acid product. For the full efficiency of the venom a mixture of the two liquids is required. The alkaline glands, which are highly developed in the bees and in all other Hymenoptera with a barbed sting, are merely rudimentary in insects of the same orders which use their stings not for defence against their enemies, but for paralysing a victim destined for the food of their larvæ. (If a bee is caused to sting into a piece of blue litmus paper, a red spot is produced, showing that the acid is in excess. The sting of a wasp, on the contrary, as it was first pointed out by Professor Church, and as we have since confirmed, has an alkaline reaction. It is very probable that all the animal venoms are of a complex nature. There is here evidently room for further research, which we recommend to persons in districts where the hornet is plentiful.—ED., SCIENTIFIC NEWS.)

APPLICATION OF SULPHATE OF COPPER TO FRUIT TREES. —M. Magny, President of the Horticultural Society of Coutance, writes to the National Horticultural Society of France as follows:—"Every year, about the months of February and March, when the fruit-buds on fruit-trees, of whatever species, begin to swell, birds (and especially bullfinches and tomtits) fall upon the fruit-trees and pick the buds to such an extent as greatly to compromise the hoped-for crop. Having in vain tried various methods, I had the idea last year of entirely covering my trees, especially the fruit-bearing branches, with the following composition:—4 lbs. of lime slaked in 6 pints of water, 1 lb. sulphate of copper (blue stone); dissolve in 67 pints of hot water, add then 1 lb. of soot and clay enough to give it a semi-fluid consistency. The result was good, as on all my trees, after being thus dressed, not a bud was damaged, and the blossom appeared in a normal manner. This composition has also the advantage of destroying the predatory insects which hibernate under the bark, and of preventing the spotting of the fruits by moulds and other fungi. The same mixture, with a little more sulphate of copper, has been employed against another enemy. All horticulturists know the decided taste of slugs and snails for nectarines (we may say for wall-fruit in general). In spite of hunting for them in the early morning, I had almost given up the hope of a crop, but now I have coated the walls, the stems, and branches of the trees with this composition, I have secured a full crop of sound nectarines." (We give this receipt on the responsibility of *La Nature*, but we consider it likely to prove both safe and effective.—EDITOR, SCIENTIFIC NEWS.)

AN ANOMALOUS MOVEMENT OF SWALLOWS.—The steamer *Abd-el-Kader*, which set out about the end of May from Marseilles, bound for Algiers, when at the distance of twenty-eight miles from land fell in with a large flight of swallows going *southwards*. They alighted upon all parts of the vessel, where they spent the night. At seven the next morning, when off the Balearic Islands, they left the steamer and all took flight in the direction of Algiers. A migration of swallows southwards at this season of the year has never before been witnessed. —*(Cosmos)*.

THE RAVAGES OF SILPHA OPACA.—This well-known carrion-feeding beetle has recently taken to prey on vegetable matter, and is indulging in the very pardonable freak of destroying the sugar-beet. Conjointly with this change in its diet it has begun to increase in a manner previously unknown. This prooceeding excites great wrath among the growers of betose, who are combating the enemy with sulphuret of carbon.

THE "CENTREING" OF THE HUMAN EYE.—Some years back Professor von Helmholtz showed that, optically speaking, the human eye was not a perfect instrument. M. Tscherning *(Comptes Rendus)*, who has re-examined the subject, finds that the adjustment of the eye is never exactly centred, but the deviation is generally inconsiderable. In most eyes the three centres are situate in the same vertical plane, but the centre of the cornea is below the axis of the crystalline lens. In other eyes the centre of the cornea lies in the same vertical plane as the axis of the crystalline lens.

OBSERVATION ON THE ARRIVAL OF THE SWALLOWS AT THE PARK OF BALEINE, IN L'ALLIER.—M. G de Rocquigny-Adanson gives in *Ciel et Terre* a table of the return of the swallows, from which it appears that the extreme dates over a term of forty-one years are from March 19th to April 11th. Half the returns took place between March 30th and April 3rd, the mean date being April 1st. The solitary, unusual date of March 19th, occurred after the severe winter 1879-1880.

BIRD MURDER.—As we learn, both from private sources and from contemporaries, the massacre both of hoopoes and of sand-grouse still continues. The possible penalties under the Wild Birds' Protection Act are ridiculously small.

POISONS IN THE WORKSHOP.

WE admit very generally that it is the duty, or at any rate the good policy, of the community to defend its members as far as possible from causes of disease or death. But we do not yet see that agencies which suddenly and swiftly strike down a man who might have previously been in robust health are, after all, less formidable than such as gradually undermine his vitality and enable him to leave behind an enfeebled posterity. We have yet to learn that the so-called "diseases of debility," phthisis, scrofula, albuminuria, affections of the brain and the heart, are as truly preventible as the various types of pestilence.

Among the causes of gradual decay and debility, we have at present to deal merely with the poisonous products employed in the arts and manufactures. We are too apt to connect the notion of poison exclusively with a sharp, sudden illness, ending in death, a *post-mortem* examination, and a coroner's inquest. But in the vast majority of instances there is no sudden death; the life of the victim is not so much shortened as rendered more or less useless and enjoyable. His strength fades away, he undergoes often extreme suffering without knowing the cause, and his death is finally attributed to some ordinary disease.

The number of poisons which enter into our industrial operations is great and increasing. We will accordingly take a glance at some of the most important, and consider how their evil action is to be avoided or overcome.

One of the most formidable, if its effects are viewed in connection with its trifling quantity, is mercury. The men engaged in mining for this valuable metal, and in separating it from the ore (generally cinnabar) often suffer severely. Among the ordinary effects are looseness and even entire loss of the teeth, and often formal salivation. Where it is constantly absorbed into the body in smaller proportions tremblings of the limbs, neuralgia, or other nervous symptoms are commonly observed. It is important to note that in proportion as the metallurgy of mercury has been improved by preventing the escape of the metal in the form of vapour, the health of the workmen has been greatly improved.

But much mischief is occasioned by mercury in the various arts in which it is employed. Probably the largest quantity is consumed in the so-called "amalgamation process," for separating gold and silver from their ores. In this process vapours of mercury are constantly given off, though not in striking quantity, and the men employed cannot entirely help coming in contact with the poisonous metal. The improvement devised by Mr. W. Crookes, F.R.S., *i.e.*, the use of an amalgam of mercury and sodium instead of pure mercury, has effected an improvement in this process from a sanitary point of view, since the quantity of mercury needed is reduced, and the time during which it has to be worked up with the ore is shortened.

The so-called silvering of mirrors is another extensive use of mercury, and is very detrimental to the health of those employed, the more so as the operation is not performed, like the amalgamation of gold and silver ores, in the open air, or in rough sheds readily traversed by the wind. The operation need not be here described in detail, but it consists substantially in applying to the glass, whilst in a horizontal position, sheets of smooth clean tinfoil, upon which a sufficient quantity of mercury is spread very evenly. This process requires careful manipulation; the hands of the men are often in contact with the metal, and the air is filled with mercurial fumes, which, it must be remembered, are given off even at the ordinary temperature of this country.

To do away with the evils resulting from this process, attempts have been made to "silver" mirrors with a thin film of pure silver deposited upon the glass, and thus entirely dispensing with the use of mercury. But these processes, though apparently successful, have disappeared from use. It is, indeed, rumoured that the inventors have been "bought off," lest the interests of the mercury trade should suffer loss.

A considerable quantity of mercury in the metallic state is used in the manufacture of thermometers, barometers, and hydrometers, in making Sprengel pumps, and in a variety of the operations of chemical and physical laboratories. For these purposes it is not likely to be superseded

Mercury is also employed in the preparation of vermilion, of corrosive sublimate, and of nitrate of mercury. The manufacture of vermilion and its use in the fine arts cannot be held injurious, since it is neither soluble nor capable of being volatilised at ordinary temperatures.

Nitrate of mercury is used to give hare and rabbit skins the power of felting. For this purpose it is dissolved in water, and brushed lightly over them with a sponge. In this process the hands of the workman are liable to absorb some of the poison.

The manufacture of corrosive sublimate without great care is very dangerous, as this compound may quickly prove fatal if inhaled in the state of vapour. Its use as a disinfectant also requires no little caution.

Antimony is one of the minor poisons from our present point of view. Its only manufacturing uses of any importance are in the preparation of so-called antimonial vermilion. This colour is less beautiful than the true, mercurial vermilion, but it finds a demand from its low price. Neither its preparation nor its use involves anything dangerous to health.

Of much more importance is the double tartrate of antimony and potash, commonly known as tartar-emetic. This substance was formerly employed only in medicine, but it is now used on a much larger scale, along with tannin, in fixing aniline dyes upon cotton wares. It has been often accused of producing irritation of the skin, and even erysipelas in persons wearing cottons which have been thus got up. It is, however, to be noted that men employed in the manufacture of tartar-emetic and in its use in dyeing and printing operations do not seem to suffer in the least. The same must be said of other preparations of antimony which have been tried as cheaper substitutes for tartar-emetic.

(To be continued.)

Reviews.

Betrieb der Galvanoplastik mit Dynamo-electrischen Maschinen zu Zwecken der Graphische Künste. Von Ottomar Volkmer. Vienna: A. Hartleben's Verlag.

This handbook, one of a series of technical works corresponding to the English series known as Weale's, relates to electrotyping as used in pictorial arts. It deals with the machinery used for eletrotyping, including gas engines and dynamos, the baths used, the solutions, and the methods of connecting them up and of regulating the current. We find descriptions of the installations in Vienna at the Imperial Institute of Military Geography, and at the Imperial printing establishment, of which latter the author is vice-director. The fourth section is really the most important in the book, as containing novel information, the rest being such as could be compiled from works already existing. It deals with the practical processes used for electrotyping, including the production of the original plate as a mould for electrotyping on, the deposition of electro-copies, the facing of these with steel or nickel or brass as a hardening process. The author next describes the processes of producing a plate fit for printing off, from non-metallic matrices, such as gelatine photo reliefs, wax and gutta-percha moulds, etc., and gives a detailed description of the production of the electro-plates from which the Government maps of Austria-Hungary are printed.

A descriptive list is given of the various chemicals and materials used by electrotypers, with their properties, tests for purity, etc.

It is a pity that in a book like this, intended to be written up to date, the author should have chosen for description those dynamos which are used in Austria-Hungary only, a rather antiquated Gramme machine, one by Schuckert, by no means his latest or best type; and one by Krötlinger, of Vienna, also containing no special features, when of late such very improved machines specially constructed for electrotyping have come into use. An illustration is given of a dissected Gramme ring, which at first looks like a very old friend, but we find that the author has substituted for the iron wire, of which the core is actually built, iron plates so placed that, in working, strong electric currents would be produced in them sufficient to damage the machine from over-heating.

In a chapter on the theory of the work done by electric currents, the author falls into a well-known fallacy in stating that "the maximum work is produced in the depositing baths when their conductor resistance is equal to the sum of the resistances of the source of supply (dynamo) and conducting wires." A dynamo of reasonable size would give its full output, absorbing only 10 or 15 per cent. of the total power internally, in which case the apparent resistance of the baths would be 8 or 9 times that of the machine, and by decreasing this resistance, to follow the author's rule, the dynamo would be carrying about 5 times the load it was constructed for, with results which can be imagined. Excepting, however, a few slips of this kind which are not peculiar to this work, we can certainly recommend this book as a practical guide to those engaged in any of the arts with which it deals.

A Manual of Orchidaceous Plants cultivated under Glass in Great Britain. Part III. *Dendrobium, Bulbophyllum, and Cirrhopetalum.* Chelsea: James Veitch and Sons, Royal Exotic Nursery.

The great genus Dendrobium possesses in the Eastern Hemisphere a rank and a varied development corresponding to those of Epidendrum in the Western Hemisphere. Each comprises a large number of species, and each displays the most gorgeous colouration.

The former genus, Dendrobium, has now been elevated to the rank of a sub-tribe, and includes the genera, Aporum, Rhizobium, Cadetia, Sarcopodium, Strongyle, Stachyobium, and Eudendrobium, the last being the most important.

Orchids of this group are found in south-eastern Asia, in the Malay Archipelago, Australia, and the islands of the Western Pacific outlying members occur in Southern India, Japan, and the Society Islands. An examination of the accompanying maps shows that the head-quarters of the Dendrobia are in Western Burma and in the Moulmein district. The eastern side of Australia, from the extreme north of Queensland, down to Cape Howe, is also fairly rich in species. New Guinea and Borneo are less abundantly supplied, having, probably, not been sufficiently explored.

Many of the species are so gorgeous that the careful descriptions here given, joined to the illustrations, fail to convey any adequate idea of their beauty. But many others, though botanically interesting, have no attractions for the horticulturists.

The closely-allied genus, Bulbophyllum, has also its principal seat in the Eastern Peninsula and the Malay Islands, but it spreads into Africa, and even South America.

One of the most remarkable species is the gigantic *Bulbophyllum beccarii* from Borneo. Its flowers emit so loathsome an odour as to exclude it from general cultivation. The function of this evil smell has not been ascertained.

Transactions of the Manchester Geological Society.—Vol. XIX., parts xviii. and xix.

Mr. Vaughan Cornish read a paper on the "artificial reproduction of minerals and rocks." Investigations of this kind have chiefly been conducted in France, and are important, not from the commercial value of the products obtained, but from the light which they throw on the natural formation of minerals.

Two communications "on the occurrence of boulders and pebbles in coal seams" were made by Mr. H. A. Woodward and Mr. W. S. Gresley, and were succeeded by a prolonged discussion. No theories in explanation of the presence of these masses were propounded differing in character from those mentioned in the SCIENTIFIC NEWS, p. 438. Mr. Wild, in the present discussion, suggested that the two theories of the formation of coal, viz., the drift theory and that of its growth *in situ* are not necessarily exclusive. "If a tract of country, 50 or 100 miles square, had a very rank vegetation upon it, and subsidence began to take place, say over the central half of that tract, water would begin to accumulate, trees there would cease to grow, and their remains would accumulate and decay, being augmented by the growth of mosses of low forms of moisture-loving vegetation. Streams flowing into this depressed area would bring in a lot of drifted vegetation, and a deposit would be formed, say 12 or 15 inches thick; then a flood might bring down a quantity of mud, which would be spread over the already formed deposit. Fresh growth or drift would again go on from the surrounding flattish land, and gradually there would be formed another deposit of moderately pure vegetable matter, which in course of years would be converted into coal." He considers that the boulders and pebbles have been liberated from some floating mass, such as ice or tree-roots, and let fall upon the submerged vegetable matter.

A curious fact mentioned is the occurrence of a water-worn pebble of lead-ore in a colliery in Shropshire.

In part xix., we find several papers on mine-rents and mineral royalties, of purely professional interest.

Abstracts of Papers, Lectures, etc.

MANCHESTER MICROSCOPICAL SOCIETY.

AT the meeting held on June 14th, the President, Professor A. Milnes Marshall, in the chair, Signor G. Platania, Acireale, Sicily, secretary of the Italian Microscopical Society, sent for distribution amongst the members a quantity of Tripoli, a fossil diatomaceous earth. Mr. W. Chaffers gave a short communication on Tripoli, explaining its character, and exhibited slides of the diatoms he had found after cleaning a small portion of the earth. The Society's annual volume was issued at this meeting.

At the February meeting of the Society Mr. Peter Cameron read a paper on Parthenogenesis in the Hive Bee, his object being to show that this doctrine, which has heretofore been accepted as correct, must at any rate be considered as open to question if not modification. Professor Marshall, who presided at that meeting, expressed a wish that some members of the Society would take the matter up.

Mr. E. H. Turner described the present position of an apiary, the owner of which, Mr. Tonge, had consented to make observations in this direction. Briefly the doctrine of parthenogenesis is this, that in some animals young are produced which are not the result of a sexual act, and in the case of bees that drones partake of the nature of the queen bee irrespective of the kind of drone by which she was fertilised. Consequently, if the doctrine be correct, such a thing as a hybrid drone is an impossibility. In the apiary in question a fertile Carniolan queen was introduced last summer, and from her it is intended to raise pure Carniolan queens, which will be placed in a hive of bees of the ordinary English type. Observations will be made as to the character of the young raised from her eggs. If the worker bees are hybrids, then if the doctrine of parthenogenesis be correct the drones ought to be pure Carniolan in spite of the fertilisation of the queen mother by an English bee.

An interesting discussion followed.

Professor Marshall made an interesting communication on Primitive Nervous Systems, illustrated by black-board drawings and preparation shown by means of the microscope. He defined a nervous system as a means of communication between one part of the body and another, and detailed the various uses which it served. Beginning with the Protozoa, the lowest forms of animal life, each individual consisting of a single cell, he took the Amœba as being typical of the group, and pointed out that although generally considered as being destitute of a nervous system, yet it possessed a certain amount of nervility or "nervousness," although no definite paths can be pointed out along which the impulses pass. In this case the whole surface of the animal is "nervous" as may be seen when examining an individual under the microscope. It moves by means of pseudopodia, long finger-like processes protruded from its protoplasmic body; and if it comes in contact with a foreign body, evidences of nervousness are given by its action. If the substance be good for food other pseudopodia are put out, and the animal slowly surrounds and absorbs it. If, however, the substance be unfit for food, the Amœba changes its course and passes it. Here we have the lowest form of nervous action. The nervous system follows the development of the other organs, and as we ascend in the scale of life the paths along which the impulses travel become more defined, and at the same time the results are quicker and more definite. In the Polyzoa (as illustrated by the Hydra) the sense organs are on the surface of the body, and are connected with the muscles in the interior. The outer cells of the Hydra are nervous, and are the most primitive form of a nervous system. The outer part of the cell is nervous and the inner part contractile, but there are no nerves, their place being taken by the medium part of the cell. The nervous cells are equally developed over the whole of the body, forming a nerve sheath, as from its habit the whole of the body of the Hydra is exposed equally to the environment. Where the parts of the animal are unequally exposed there is a variation in the development of the nerve cells. An example of this may be seen in the worms, where, from their habit of crawling on the ground, the nerve sheath is more fully developed on the ventral side. Turning to the Vertebrates he pointed out that in these the nerve sheath gives place to a localised nervous centre, the brain, from which nerves radiate to all parts of the body. He also described the development of the nervous system in the chick, and pointed out the important part the development of the nervous system plays in bearing out the recapitulation theory, in that, beginning as a single cell, it passes through the various conditions in which we find it in successive grades as we advance up the scale of life.

ROYAL SOCIETY.

At the meeting held on June 21st a paper on "Muscular Movements in Man, and their Evolution in the Infant: A Study of Movement in Man, and its Evolution, together with Inferences as to the Properties of Nerve-centres and their Modes of Action in expressing Thought," by Francis Warner, M.D., F.R.C.P., Physician to the London Hospital, and Lecturer on Botany in the London Hospital Medical College, was communicated by Professor J. Hutchinson, F.R.S.

Every one knows that children are fidgety, and babies smile, and crow, and move their thumbs and fingers. Many people do not know that seedling plants are also full of constant movement, but this has been demonstrated in plants of all the principal natural orders by Charles Darwin, in his "Movements of Plants." Dr. Francis Warner, while looking at infants, was struck with the fact that here, as in all other young living things, the parts are always moving in the young, but that older subjects present less movement. In fact, just as in the seedling it has been demonstrated that the constant spontaneous movements (circumnutation) result from healthful conditions of growth, and are succeeded by complex and highly important movements, such as bending to the light and away from the earth (heliotropism and apogeotropism), so in man this spontaneous movement becomes gradually co-ordinated and brought under the influence of surrounding forces, and the movements thus become so well fitted to the surroundings as to be considered useful, intelligent, and voluntary. The conditions of movement at ages from birth to ten years are described, and to do this much previous work on the part of the mother was needed. Dr. Warner has employed an apparatus which he invented (see author's "Anatomy of Movement") for recording movement of the child by lines on a revolving drum. It was also necessary to describe many kinds of movements and to classify them on physiological principles. The purpose in view in this study of spontaneous movements in infants is to report the first signs of the manifestation of mental faculty as seen when those movements are arrested or controlled by impressions made upon the child.

All expression of mind is by movements, and from observations made descriptions are given of the modes of action and properties of nerve-centres in adult age. Properties similar to those described in brain centres may be illustrated in modes of growth.

This part of his general work Dr. Warner illustrated in his work on "The Study of Nerve-Centres and Modes of Growth," which he delivered as Hunterian Professor of Physiology at the Royal College of Surgeons.

Graphic tracings were shown indicating the amount of spontaneous movement in an infant nine days old, and the controlability of such action in an older child by light and sound.

The author concluded by saying, "Intelligence is, then, not a property of the brain, *per se*, but for its manifestation certain modes of brain action are necessary.

LONDON MATHEMATICAL SOCIETY.

At the meeting held on June 14th, Sir J. Cockle, President, in the chair, the Vice-Chancellor of Cambridge University read a paper "On the Determination of the Circular Points at Infinity." Professor M. J. M. Hill followed with a paper "On the c and p Discriminants of Integrable Differential Equations of the First Order." Mr. Tucker (Hon. Sec.) communicated the following papers by Lord Rayleigh, "On Point-line and Plane-sources of Sound"; by Mr. H. Fortey, "Note on Rationalisation"; and by Prof. G. B. Mathews, "Applications of Elliptic Functions to the Theory of Twisted Quartics." Prof. Greenhill read a paper on "Coefficients of Induction and Capacity and Allied Problems." The following were taken as read:—"Electrical Oscillation," by Prof. J. J. Thomson, and a demonstration of the theorem that the equation $x^3 + y^3 + z^3 = o$ cannot be solved in integers, by Mr. J. R. Holt.

ROYAL METEOROLOGICAL SOCIETY.

The concluding meeting of this Society for the present session was held on the 20th ult., Dr. W. Marcet, F.R.S., President, in the chair.

The following papers were read:—

(1) "First Report of the Thunderstorm Committee." This report deals with the photographs of lightning flashes, some sixty in number, which have been received by the Society. From the evidence now obtained, it appears that lightning assumes various typical forms, under conditions which are at present unknown. The Committee consider that the lightning flashes may be arranged under the following types:—1. Stream; 2. Sinuous; 3. Ramified; 4. Meandering; 5. Beaded or chapletted; and 6. Ribbon lightning. In one of the photographs there is a *dark* flash of the same character as the bright flashes, but the Committee defer offering any explanation of the same until they get further examples of dark flashes. As the thunderstorm season is now coming on, the Committee propose to publish their report at once, along with some reproductions of the photographs by the autotype process, in order that observers may be prepared to notice the various forms of lightning.

(2) "The Cold Period from September, 1887, to May,

1888." By Mr. C. Harding, F.R. Met. Soc. The mean temperature for each of the nine months from September, 1887, to May, 1888, was below the average, whilst in the case of October there has been no corresponding month as cold during the last half century, and only three colder Aprils. In London the mean temperature for the period was only 42·4 degs., and there has been no similarly low mean for the corresponding period since 1854-5, which will be remembered as the time of the Crimean War, and only three equally cold periods during the last fifty years. The temperature of the soil at Greenwich at 3 feet below the surface was below the average in each month from October to April; in October and April the temperature at this depth was the coldest on record, observations being available for the last 42 years, and in November it was the coldest for 37 years.

(3) "Observations on Cloud Movements near the Equator; and on the General Character of the Weather in the 'Doldrums,'" by Hon. R. Abercromby, F.R.Met.Soc. The author gives the results of observations made during four voyages across the Equator and the "Doldrums," with special reference to the motion of clouds at various levels. Two voyages were across the Indian Ocean during the season of the north-west monsoon, and two across the Atlantic in the months of July and December. The nature of the general circulation of the atmosphere near the "Doldrums" is discussed as regards the theory that the trades, after meeting, rise and fall back on themselves; or, according to the suggestion of Maury, that the trades interlace and cross the Equator; or as following the analogy of Dr. Vettin's experiments on smoke. It is shown that the materials at present available are insufficient to form a definite conclusion, but details are given of the general character of the weather and of the squalls in the "Doldrums," with a view of showing what kind of observations are required to solve this important problem. The old idea of a deep trade—with a high opposite current flowing overhead—is certainly erroneous, for there is always a regular vertical succession of the upper currents as we ascend, according to the hemisphere.

HAWICK SCIENTIFIC AND PHILOSOPHICAL SOCIETY.

The annual general meeting of this Society was held on June 21st, the President (Mr. John W. Lamb) occupying the chair. The first session extends over sixteen months. During that time twenty papers, lectures, etc., had been brought before the Society. Excluding the President's introductory address on "The Constitution of the Matter," the first subject discussed was "Atmospheric Pressure," a paper on this subject, illustrated with experiments, having been read by Mr. Berry. Mr. W. E. Wilson gave the second physiographical paper on "Meteorology on Ben Nevis." Geology was represented by three papers, one by Mr. Rorrison on "Palæolithic Man," and two by Mr. Miles—viz., "Fossils, what they are and what they teach," and "Climate and Time." Astronomy was represented by Mr. Brown's paper on "Shooting Stars." Chemistry had its exponents in Mr. Dechan and Mr. W. C. Goodfellow, the former in a lecture on "Some Aspects of Modern Chemistry," and the latter in a paper on "Carbon Dioxide." Mathematics also received the attention of the Society, the subject being presented by Mr. Blackwood in his "Mathematical Treatment of the Rain Guage," and in a paper on "The Equation of Time." Botany was presented in a very attractive and interesting form by Mr. Robert Turnbull in a lecture on "The Fertilisation of Flowers" and "Insectivorous Plants." "Notes on the Moa Bird," illustrated with a femur of that gigantic biped, by Mr. Gowans, "Notes on some Shells from Pentland Firth" by Mr. Irving, and a paper on "The Hydra" by the President, were the contributions to the science of biology. Mr. James Jackson treated of "Musical Sounds," Mr. Thomas Welsh of "Vaccination," and Mr. W. S. Irving of "Soils, their classification and physical properties." Only two papers were, strictly speaking, philosophical, these being Mr. Sinclair's "Function of Reason" and the first of a promised series by Mr. Gowans on "Introduction to Psychology."

THE SOCIAL CONDITION OF THE BABYLONIANS.

Abstract of a Course of Lectures delivered by Mr. G. Bertin, M.R.A.S., at the British Museum. Third Lecture—Civil Life.

There was very little political life in ancient Babylonia, though the citizens had, to a certain extent, the direction of the private affairs of their own town or village. The municipal council, named by the most influential people of each town, was not to be envied, for in case of trouble the councillors, or the ancients, as they were called, had often to suffer for the conduct of the inhabitants. The absence of political life gave perhaps a greater impetus to the energy displayed by the Babylonians in their private undertakings.

On account of the fertility of the soil, agriculture was naturally the most important of the occupations of the Babylonians. As the great rivers of Mesopotamia do not overflow the country periodically, like the Nile, the agriculturists had to apply to the land an extensive system of irrigation. Canals were so important that an ancient king, Hammurabi, placed among the most important deeds of his reign, the construction of a canal. These irrigation canals were probably the property of the State or of the towns, and each agriculturist had to pay a fixed sum for so many hours, during which the water of the public canal was allowed to flow in his private canal; this mode of distributing the water for agricultural purposes, and of charging for it, is still practised in the East, and especially in Cyprus. When the ground was not level with the canal, a very rudimentary hydraulic apparatus was used to draw up the water, and pour it on the field.

There were several systems of land-tenure. In the first kind, called the double tenure, the landowner played the part of the sleeping partner, but he had to provide the farmer, or active partner, with implements beasts of burden, and seeds, and could claim half the crop for his share. The other tenures were called third, fourth, fifth, and sixth, from the proportion claimed by the landowner, and the smaller that share the less the landowner had to contribute to the expenses of the farm. The usual term of profit claimed by the landlord in the later period of the Babylonian Empire was ten per cent. of the crop; this answered to the ordinary letting. This system of tenure, and the custom of calculating from the crop and giving to the landlord a proportion of it, introduced the practice of paying in kind, which had sometimes a disastrous effect on the farmers. These were often obliged to borrow grain in the worst season to pay taxes, and had to repay, as is shown by many contracts, practically twice as much as they had borrowed. Some landowners cultivated their estate themselves by means of slaves, or their land was divided in small portions among a number of serfs, who had to give up the whole of the crop, keeping only enough for their bare existence.

The fertility of the land allowed the agriculturists to cultivate any kind of plants, the chief being that of the date-tree, for dates were such an important article that the word for date came to mean any kind of produce. Wheat, barley, oats were also cultivated, as well as several sorts of vegetables. Farmers also reared cattle, either as beasts of burden or to provide for butcher meat.

The geographical position of Babylon made it, at an early period, a great centre of commerce. The export and import trade was done either by caravan or by water. Goods were brought from the north on rafts, but, once in Babylon, the rafts were pulled to pieces and taken back on donkeys, or oxen, to the countries from whence they came, as it would have been difficult to go up the river against the current. The Babylonians never were good sailors; it is, therefore, probable that the sea-trade of the Persian Gulf was carried on by foreigners. The caravans radiated from Babylon in all directions, in Media, Elam, Assyria, and Armenia. The Syrian desert was avoided; as a rule, the merchants wishing to go to Syria and Egypt, went towards the north, crossed the Euphrates, turned southwards into Syria, and so into Egypt. The principal articles of export were grain, dates, cattle, and slaves, for the Babylonians were not manufacturers. The import, on the contrary, brought to the great city manufactured objects from Phœnicia: cloth, linen, carved ivory, and amber. Skins and hides were brought from Media and Armenia. Asia Minor was the principal country which provided horses for the Babylonians. We have several tablets of commercial agents informing their employer of the number of horses they had bought, and were sending from divers localities in Asia Minor.

When the goods were brought to Babylon, they were generally unloaded in the large markets held between the two walls, and sold wholesale to the small traders or commercial agents. There were many impediments to trade: tolls were numerous, not only on bridges, and through or near towns, but also near temples; the travelling merchant had besides to submit to the exaction of kings or governors through whose states he had to pass; but what he had most to dread was the highway robbers, and, in order to resist these, merchants often associated together, and travelled with a numerous, well-armed escort.

In some cases the merchant did not possess the necessary capital to buy the goods; he had then recourse to capitalists or bankers, who in that case played the same part of sleeping partner as the landowner in the double tenure, and received a certain percentage of the profit.

The retail trade was done on the same principle as the small land tenure. Large proprietors or capitalists had a number of shops which they farmed under certain conditions. Sometimes the owner merely placed in his shop a manager, who received from him all the goods, but had to give up all the profits, keeping only a fixed amount as his salary. Sometimes the shop was simply rented for a fixed sum; in other cases the landlord entered into partnership with the shop-keeper. The shops in Babylon were not like ours, with their great display of show-windows, but the goods were generally kept inside the houses, into which the customers had to enter to make their purchase. If people wanted to have more choice, they had to go to the bazaar, which answered to our retail markets; retailers there held stalls either on their own account, or in partnership with or as simple manager of the capitalist, who advanced the money to buy the goods. The articles sold in the bazaar were most varied: not only ornaments in gold, silver, amber, or ivory, but utensils of all sorts, clothing materials, and also eatables. The slave market was, it appears, held at a different place, as also was the horse and cattle market.

There was in Babylonia a branch of trade which hardly has its equivalent in modern time, that is that of the lender; it was an important and most lucrative industry. The lender let out on hire every possible article, tools to the workman, cart to the tradesman, horses, oxen, or grain to the agriculturist, or even furniture to people starting in life, but the most important article was the slaves: these were let for short or long periods as workmen of all kinds. We have in the British Museum several contracts referring to transactions of this sort, and it is generally specified that the hirer shall pay a fixed sum in case of death or disablement of the slave. The slave-owner did not always conduct a business of this kind himself: he often left it in the hands of a manager, who was sometimes himself a *galla*, or chief slave.

We see by that and by the same practice in other branches of commerce, that the middle-man was an important person in Babylon. Not only were there those employed as agents by the merchants, but there were also independent middle-men, who bought the goods in the wholesale market and sold them in small quantities to the retail dealers, and the independent agent who canvassed for the large slave-owners and lenders.

The profession of banker, money lender, and even usurer was generally in the hands of the scribes. In nearly every circumstance of life the Babylonian had recourse to the bankers: if a young man was on the point of being married he often borrowed in order to buy a house; in other cases a man borrowed money to create a capital and begin business, either by himself or in partnership with another. The money lender generally took as security houses or other landed property, or, like the modern pawnbroker, objects of value, rings, bracelets, etc.

Retail dealer and small agriculturist had often to appeal to the usurer, the former to buy the goods necessary to his trade, and the latter to buy either seeds or implements. The money was generally lent for a year or six months, repayable by monthly instalments at the interest of one-sixtieth per month, which is not so exorbitant for usurers. But when a man had borrowed, without giving any property as security, his creditor had claim on his person, and, as in ancient Rome, could seize his debtor and sell him as a slave.

Connected with trade is the interesting question of the means of exchange. There was no stamped money: the Babylonians used gold-dust, or bars of metal, gold or silver, weighed in scales; every article for sale was esteemed so much gold or silver in weight. Coined money appears to have been introduced by the Greeks at the time of Nabonidus; even the *darick*, so long supposed to have been invented by Darius, and its name derived from that of this king, is found mentioned in a tablet eighty years before his accession, and cannot, therefore, have been invented by him. The Babylonian name of this coin, *dariku*, is probably derived from the Greek *doru*, a lance, on account of its having on it the representation of an archer.

THE CHEMISTRY OF FIRE AND FIRE PREVENTION.

Abstract of a Lecture delivered by Mr. W. Lascelles-Scott, before the Balloon Society, on June 8th.

FIRE, or, to use a more appropriate term, combustion, is simply the result or accompaniment of chemical action, be it combination or the reverse, of so intense a kind that the substances immediately concerned are raised and maintained for a time at an exceedingly high temperature—the temperature of flame, or, popularly, that of a white heat.

"Combustion," however, may be very slow or extremely rapid according to circumstances, the former being well illustrated by the rusting, or oxidation of masses of iron, lead, zinc, etc., in the air, and the latter by the oxidation of the same metals when reduced to a state of fine division, as by powdering or filing, and then subjected to heat.

If a piece of sheet lead be scraped clean we know perfectly well that the surface will soon become dull again on account of the formation of a film of oxide thereon, and the same thing happens with iron, zinc, and many other substances; combination takes place with a little of the oxygen of the air (or of water, as the case may be), an oxide is formed, and "combustion" occurs. Of course the heat produced is quite inappreciable, but it is produced all the same, and we have only to accelerate the oxidation in order to render this quite evident. It is difficult to oxidise a bar of zinc or an iron rod with sufficient rapidity in the flame of a candle or spirit lamp to cause it to burn, because the heat communicated to any one particle of metal is conducted away by the mass so quickly that that particle does not rise to the temperature at which the oxidation can proceed with sufficient rapidity to produce light and heat. If, however, this cooling be prevented by exposing to heat and oxygen enormously increased surfaces of these same metals, with comparatively little mass, rapid oxidation, even to the extent of energetic combustion, takes place. This may be well shown by sifting iron filings into the flame of a spirit lamp.

This question of relative "surface" is worth a little more consideration; it is, of course, quite impossible that a block or sheet of bright metallic lead when exposed to the air should oxidise so quickly as to become heated to to the point of ignition, and the same remark applies to carbon or charcoal, but if either or both of these elements be so prepared as to exhibit, so to speak, an infinitely large surface and an infinitely small mass, exposure to oxygen, or even to air, at the normal temperature, causes immediate ignition of the whole. Phosphorus, again, when exposed to the air, at low temperatures, although it oxidises more quickly than the substances we have just been considering, seldom accumulates so much heat as to inflame; but by dissolving it in a certain manner and applying the solution to a porous substance—such as a bit of blotting paper, for instance—the menstruum would quickly evaporate and leave the phosphorus so minutely divided that the heat resulting from its rapid oxidation speedily causes it to burn. It is perhaps to such causes that some of the "suspicious fires" referred to lately by Mr. Peter McLagan are due.

The lecturer then referred to the modifications in the properties of bodies by the substitution of some other element or group of elements for one of the constituent elements of the compound, and instanced the case of cellulose and its three nitro-derivatives. He said nothing done in this direction had succeeded in making fabrics uninflammable, but it has long been known that by impregnating timber, textile fabrics, and other inflammable substances superficially, or throughout their substance, with certain chemical salts, they could be rendered less easy to burn, and a variety of salts have been recommended for this purpose. Hitherto these compounds have not proved very successful in practice. These chemical salts render canvas, muslin, etc., less inflammable in several ways dependent either upon the water they contain, the vapours they give off when heated, or the manner in which they surround the particles or encrust the fibres with incombustible mineral matter. As typical examples of salts of this kind he cited silicate of sodium (the so-called "water glass"), tungstate of sodium, phosphates and carbonates of sodium and ammonium, borax, and ordinary alum. Some of these—and particularly certain mixtures of two or more—give fairly good results—for a time. Then comes the reckoning. Mr. Scott said probably many of his audience had noticed that if a piece of damp linen be hung out of doors during a sharp frost it speedily gets stiff, and is so extremely brittle that it may be easily broken in pieces like a sheet of glass, or rather like the sheet of ice or crystallised water it really is. Well, something very like this happened when fabrics were impregnated with some of the chemical salts he had mentioned; if enough be used to make the stuff what is called fireproof, the salt is deposited in the pores and between the fibres of the material in the crystalline form. These tiny crystals have very sharp angles, and they act just as myriads of little knives or saws would do, speedily weakening the fabric and rendering it as brittle as the frozen linen mentioned before. Other varieties of these salts are prone to absorb moisture from the air, so that a lady's dress prepared with any of them, and got up, as the laundresses say, to be "very nice and stiff," would, in the course of a very few hours—the time varying with the material, and with the state of the weather—become quite limp and unwearable. Again, some salts are unsuitable by reason of their caustic properties, which, whether they be of the acid or of the alkaline class, tend to destroy the substance of the linen or cotton fabric, and to render it rotten. Many compounds of this class, even if giving apparently good results at the outset, develop acidity throughout the interstices, and, as it were, in the heart of the fabric, when a little time has elapsed. Increase of temperature greatly facilitates the decomposition of these salts, and enhances their destructive influences. Therefore in selecting a compound intended for the treatment of theatrical scenery or properties exceptional caution should be taken. In theatres and other places of public amusement the warmer regions are always near the top. In such hot places some salts—like phosphate of ammonium, and like common alum, as examples of a class—soon develop acidity, with the inevitable result that any fabric impregnated with them gets very tender after a time, and actually falls to pieces sooner or later.

In conclusion, Mr. Scott said: I believe I have made myself well acquainted with everything, or at least nearly everything which has been accomplished in the direction to which I refer, but until recently I knew of nothing actually in the market calculated to answer and to stand the practice and of time. I am, however, bringing under your notice a compound, of French invention, called "Ignifuge," which really seems to leave little or nothing to be desired. This compound has attained to something like a reputation in France, having been rewarded with a prize of 1,000 francs and a gold medal, after a series of exhaustive trials under a committee of experts appointed by the Prefecture. It is non-poisonous, does not destroy or even weaken any fabric impregnated with it, nor does it injure the colour of any dye of fairly good quality. Ignifuge will, however, render all kinds of fabrics and combustible materials absolutely incapable of sustaining flame

How is this accomplished? M. Martin, the inventor, does not really employ any one thing which is precisely novel, but he so mixes and combines two or more different fire-resisting salts that they neutralise each other's objections to a great extent. Further, by the employment of certain peculiar compounds of the salts with glycerine and lactic acid, all fear of their crystallising or efflorescing, on the one hand, or of becoming too moist on the other, seems to be avoided.

A number of experiments were then shown to prove the efficacy of the compound.

A discussion followed, in which the Chairman, Mr. F. D. Dixon-Hartland, M.P., Mr. P. McLagan, M.P., and others took part, and a committee—consisting of the above gentlemen, Mr. P. L. Simmonds, the Marquis de Leuville, Mr. Mr. W. J. Bull, Mr. Lewis Appleton, Captain Heath, Mr. W. H. Lefevre, M. A. Louis, and Mr. W. Lascelles-Scott—was appointed for the purpose of impressing upon Government the necessity of taking "prompt and improved measures to secure public safety and relief by increased numbers of fire escapes, relays of firemen, and other efficient means, and for the purpose of diffusing information and accurate knowledge respecting the prevention and extinction of fires and the safety of human life."

THE DURATION OF SUNSHINE.

A FACTOR of much interest has of late years been added to the science of meteorology by the introduction of the sunshine recorder, an instrument reflecting much credit to the inventor, although, as is usual, the first introduced, known as Campbell's burning recorder, was followed by Jordan's photographic. The first is simply a globe of glass of some three or four inches diameter, throwing a focus of the solar rays at about two inches from its surface, the focus being of sufficient power to burn through comparatively thick card paper; hence it may easily be conceived, if a strip of prepared card paper be made to encircle the globe at the right distance for the focus, and precisely opposite the path traversed by the solar orb in its daily journey, upon a clear day a small black line will be burnt along the strip of card paper; and, further, if the card paper be divided into hours and tenths, the number of hours of sunshine will be registered upon the paper for the day; after sunset the card paper can be removed from its proper receptacle and a new one inserted ready for the next day; such in outline is the instrument by which a measurement of the solar value is now being obtained in many parts of the kingdom. At Eastbourne one of these instruments completed its first three years' work on the 31st of May last, having been set to work on the 1st of June, 1885. The record thus obtained is bringing to light many features of considerable interest independent of the record of the actual number of hours registered, the most important being its testimony in favour of there being in every month of the year, certain days that are annually bright and sunny, and others that appear annually to be nearly or quite sunless; holding out to us the hope that in future we may be empowered to select our sunny days for picnics or holidays, and avoid the more cheerless ones. Again there are other days that appear to be bright and clear in the morning but cloudy during the afternoon, others wherein the solar orb shines forth during the middle of the day only, and others wherein the afternoon is reserved for solar favours. Indeed, the facts of interest that reveal themselves at every step are many and various, clearly showing this branch of meteorologic science will, in the near future, form by no means the least interesting.

In the following table is embodied the five most sunny, and the five most sunless days for each month of the year, as revealed from a three years' daily average:—

JANUARY.

Most Sunny Days.		Least Sunny Days.	
26th	6·1 hours.	31st	0·0 hours.
28th	5·6 "	22nd	0·0 "
17th	5·0 "	15th	0·0 "
20th	4·7 "	11th	0·0 "
30th	4·3 "	4th	0·0 "

Total for the month, 66·6.

FEBRUARY.

26th	6·5 hours.	21st	0·5 hours.
10th	4·5 "	11th	0·3 "
2nd	4·3 "	19th	0·2 "
27th	4·2 "	3rd	0·1 "
28th	4·1 "	29th	0·0 "

Total for the month, 65·0.

MARCH.

7th	6·2 hours.	5th	1·9 hours.
29th	6·0 "	3rd	1·8 "
6th	5·2 "	17th	1·4 "
2nd	5·0 "	18th	1·0 "
9th	4·7 "	27th	0·9 "

Total for the month, 105·0.

APRIL.

26th	10·0 hours.	15th	3·3 hours.
21st	9·3 "	14th	3·3 "
3rd	8·8 "	2nd	3.2 "
20th	8.5 "	7th	1·9 "
27th	8.3 "	29th	0·5 "

Total for the month, 169·0.

MAY.

15th	13·0 hours.	25th	4·7 hours.
9th	11·1 "	11th	4·6 "
14th	10·4 "	17th	3·8 "
5th	9·3 "	19th	2·0 "
20th	9·2 "	16th	1·0 "

Total for the month, 216·0.

JUNE.

10th	12·0 hours.	6th	4·6 hours.
11th	11·3 "	2nd	4·2 "
12th	10·3 "	3rd	4·2 "
28th	10·0 "	26th	3·8 "
20th	9·5 "	8th	2·7 "

Total for the month, 224·3.

JULY.

6th	14·0 hours.	19th	5·6 hours.
3rd	12·9 "	31st	5·6 "
22nd	12·2 "	25th	5·4 "
1st	12·2 "	30th	4·3 "
4th	11·0 "	12th	1·4 "

Total for the month, 263·3.

AUGUST.

Most Sunny Days.		Least Sunny Days.	
15th	10·8 hours.	26th	4·0 hours.
25th	9·6 "	18th	2·3 "
22nd	9·2 "	19th	2·2 "
10th	9·0 "	28th	1·9 "
6th	8·9 "	7th	1·3 "

Total for the month, 199·7.

SEPTEMBER.

8th	9·1 hours.	25th	2·1 hours.
1st	7·9 "	12th	1.3 "
18th	7·5 "	2nd	0·9 "
3rd	7·3 "	11th	0·8 "
6th	7·3 "	30th	0·6 "

Total for the month, 143·3.

OCTOBER.

11th	5·5 hours.	6th	2·0 hours.
1st	5·4 "	27th	2·0 "
25th	5·3 "	30th	2·0 "
16th	4·4 "	31st	1·2 "
21st	4.3 "	23rd	0·6 "

Total for the month, 101·0.

NOVEMBER.

16th	5·4 hours.	11th	0·1 hours.
17th	4·8 "	9th	0·0 "
6th	3·7 "	10th	0·0 "
15th	3·4 "	13th	0·0 "
1st	3·5 "	26th	0·0 "

Total for the month, 55·0.

DECEMBER.

1st	4·1 hours.	24th	0·6 hours.
25th	3·7 "	4th	0·4 "
7th	3·5 "	17th	0·2 "
27th	3·5 "	13th	0·0 "
30th	3·4 "	21st	0·0 "

Total for the month, 59·2.

Herein therefore, it appears the 6th of July is the most sunny day of the whole year; the month of July likewise registers more sunshine than any other month, but this is not the case at many other places in the kingdom; as might be expected, the month of November registers the least.

Among the singular facts revealed throughout the year is the apparent partiality of the solar orb to shed forth his favours at certain periods of the day. Take, for example, both the 27th and 28th of January; on each of the three years upon these days the sun commenced to shine about 8.30 a.m., and shone on brilliantly till 1 p.m. Precisely the same is observed on the 26th of February, with the exception that the sun commenced to shine each year precisely at 8 a.m.; whilst on the 15th of March each year the sun commenced to shine between 11 a.m. and noon, and afternoon became the chief recipient of solar favours. April furnishes a day, the 16th, when solar favours are abundant between the hours of 9 a.m. and 3 p.m. May contributed two splendid days, the 14th and 15th, when each year the sun commenced to shine before 6 a.m., and shone on without a break till close upon 7 p.m. Can this be chance or periodic? June had the honour of contributing the greatest amount of sunshine in one single day, this being the 13th of June, 1887, when no less than 15½ hours of sunshine was registered. July, the month *par excellence* for sunshine, yet presented us with one day, the 12th, whereon only at rare intervals in either year did the solar orb shed upon us his gladdening rays for a few minutes; on many a November day the sun has been quite prodigal of his favours compared with this singular July day. August presented us with a lovely afternoon on the 9th, with a bright morning and afternoon but cloudy midday on the 21st, and with a cloudy morning and afternoon but bright sunny midday on the 26th. September presented the least number of singular days of any month, but on the 12th we find between 7 and 9 a.m. is always a sunny period, the rest of the day, except between 2 and 3 p.m., is dull and cloudy. October entered with a lovely sunny day, and again solar favours are abundant on the 11th, upon this latter date between the hours of 9 a.m. and noon, not a cloud passed over the sun during either year. November is the first month of the year presenting us with sunless days, commencing with the 8th and 10th; thus we find both sunny days and sunless days, like birds of a feather, flock together. The last sunless day of the year is the shortest day, the 21st of December, wherein never a gleam has been observed on either year, but Christmas Day shines forth grandly; between 10 and 11 a.m. on Christmas Day not a cloud passed over the sun in either year, and each year the sun has commenced to shine between 8 and 9 a.m., with but very few clouds before noon, generally clouding over about 2 p.m.

The mean annual value is 1,667 hours, an amount of sunshine equalled by but few other places. R. SHEWARD.

Eastbourne.

THE COMMON SPARROW.

Passer domesticus.

The peculiarities relating to the eggs of this bird appear to have been overlooked by ornithologists, namely, the peculiar formation of each clutch of eggs and their great infertility.

The eggs forming a set or clutch are generally four or five, occasionally six are met with, but not more than one set in ten has that number, very probably not more than one set in twenty.

In every set or clutch containing four, five, or six eggs, one egg, occasionally two, will be found of quite a different type. This egg I shall call or name "the odd egg," and the first peculiarity of this odd egg I shall mention is, that with very few exceptions it is of a lighter coloured ground to the others of its set, with the colouring matter laid on in spots and blotches instead of being diffused in specks and speckles more evenly over the whole surface of the shell. An odd egg of a darker colour than the others of the clutch is rarely met with, and in the ninety sets I have now before me there is only one set in which the odd egg has a ground of a slightly darker shade.

The ninety sets of eggs to which I refer were all taken under my own supervision, and all blown by myself, so that I know them to be genuine sets and not made up. In every set containing four or five eggs, the odd egg appears, excepting in one clutch of four and one clutch of five. In these clutches the odd egg may have been dropped when the bird was from home.

I will now mention the extreme infertility of "the odd egg," which I find this breeding season to be about sixty per cent. In the season of 1886 I found it to be seventy-five per cent. This egg is, I believe, as a rule, to be the fourth egg laid, for in clutches of five eggs I have found an egg of the usual type laid after the odd egg has appeared.

In one set of four, with two eggs of the usual type, and two of the odd type, I found the two of the odd type infertile, in the other two incubation was far advanced.

In another set of four, similar to the last mentioned, I found the two eggs of the usual type infertile, and the two bearing the character of the odd egg on the point of hatching. The two sets just mentioned are quite exceptional, and the only two I have at present met with.

In a set of five having one egg dark in colour, another of a rather lighter ground with dark markings, and three of a very light ground and very uniform in size and shape, I thought I had found a set with the odd egg the darkest, but upon examination I found in the two darkest incubation advanced, and the three light coloured eggs without the slightest signs of incubation having set in.

Again, in a set of six, with four rather dark and uniform eggs, and two of a lighter colour, the rule of the lightest coloured eggs being the infertile ones did not stand good, for in this set the two light ones were far advanced in incubation, and the four dark coloured ones showed no signs of it whatever. This being a very exceptional set I have preserved the shells; unfortunately one of the dark shells got broken, so the set shows but five.

During the past two breeding seasons I have had a very great number of clutches of eggs and also broods under my notice, taken over a considerable area in Herts., Cambs., and Essex, and I find the average clutch to be $4\frac{1}{2}$ eggs, and the average brood to be only $3\frac{1}{8}$ young birds; these figures show that about 30 per cent. of the eggs to be unproductive.

From these observations, which I have carefully made, the sparrow is not so prolific as it is generally supposed to be, and it may be quite possible for the "British Farmer" to kill them down too close, and to their present troubles they may add worse enemies than the sparrow to eat their crops.

I believe the foregoing peculiarities have no parallel.

Royston. JOSEPH P. NUNN.

P.S.—There were not more than half the number of sparrows breeding in this neighbourhood last season that there were in the season of 1886, neither were the eggs of last season so well coloured as those of 1886. Five per cent. only of the broods contain five young birds.

ARSENIC IN CRETONNE.

I wish to bring to the notice of your numerous readers a fact that appears to have escaped observation up to the present time. I allude to arsenic poisoning by means of cretonnes, imitation Indian muslins, etc. Dr. Giffard, the medical officer at Coopers'-hill, has brought some cases to me in which he thought he detected symptoms of arsenic poisoning, and in every case the source of the poisoning was traced either to a cretonne or an imitation Indian muslin that had been used as a decoration by the student. As, during the last twelve months, four unmistakable cases of arsenic poisoning have been brought to my notice, I have recently been investigating the subject. The samples upon which the experiments have been performed were supplied by a local tradesman. The results obtained on analysis are as follows: 44 samples of cretonne have been analysed, and of these none were found absolutely free from arsenic, three contain only the very faintest trace, and 21 contain larger traces. The remaining samples all contain arsenic in poisonous quantities; in my analyses I have grouped 11 of them as "very bad," and the other nine are bad and distinctly dangerous. It may be mentioned that one of the worst specimens has been examined quantitatively and yielded an amount of arsenic equivalent to rather more than $19\frac{1}{2}$ grains of white arsenic As_2O_3 per square yard. As a dose of $2\frac{1}{2}$ grains of white arsenic has been known to prove fatal, I should like to point out the extreme danger that exists from the indiscriminate use of these materials. It is quite a common occurrence to have enough of these substances in a room which would contain sufficient arsenic to give one hundred people a fatal dose. As far as the analyses have gone at present they do not show that any one colour is more poisonous than another, as, strange to say, the greens and blues, that would be first suspected, have until now proved purer than reds, browns, and blacks. In the case of imitation Indian muslins, five samples only have been analysed, but they all contained arsenic in poisonous quantities. That such a state of affairs should be allowed in this country at a time like the present seems scandalous, and I would recommend no person to use any of these fabrics for decoration unless either the vendor guaranteed the absence of arsenic or that they had first been analysed by some trustworthy chemist. F. E. MATTHEWS.

Cooper's-hill, Staines.

RELATION BETWEEN THE WAVE-LENGTHS OF LIGHT AND ITS INTENSITY.—Professor Ebert (*Ciel et Terre*) is examining if the speed of light is in any relation to its intensity. He employs interference-gratings, and shows that by this method changes in the wave-lengths amounting merely to the 1-200,000th of their value, or changes in the speed of light amounting merely to $\pm$ 1·5 kilometre per second, may be indicated. Different sources of light were submitted to experiment, and it was proved that the wave-lengths and the speed of light were not changed by one millionth of their value, whilst the intensity of the light varies by 1 to 250.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

TELEGRAPHS.—A type-printing telegraph has been patented by Mr. G. A. Scott. This invention consists essentially of a series of magnets, having their armatures so arranged relatively to a flexible connection secured to the type wheel, that the part of the wheel bearing any required character may be turned round to the printing point by opening or closing the circuit of a battery through the coil of one or all of the magnets.

PIPE.—Mr. C. J. Coventry has patented a tobacco smoking pipe. The bowl of the pipe is constructed in the usual manner with a hole at the bottom in line with the stem. Into this hole is placed a solid metal tube, having slots cut in it. When the mouthpiece is screwed on to the bowl of the pipe it pushes the perforated tube into the hole in the front part of the bowl, and renders it air-tight. When it is necessary to let out the nicotine, the stem is partially unscrewed, which thus releases the perforated tube and allows the nicotine to escape.

KNIFE-GUARD.—Mr. A. L. Mora has patented a guard for use with carving forks. The guard or stop proper consists of a piece turning upon centres in the fork shank. The stop is made of a springy nature, so that when it is raised the springing action causes the lower parts of the stop to enter the recesses provided for the purpose, and to be supported thereby. To release the stop it is pressed against the springing action, and so the lower parts leave the recesses, and the stop can be turned out of its raised or effective position.

EXTINGUISHER.—An automatic lamp-extinguisher has been patented by Mr. A. Breden. This invention relates to that class in which two spring-clacks are used, which, when in nominal conditions, are under the upper edge of the wick-tube, but when the lamp is inclined, rise and unite together above the flame, but sometimes fail to put out the light. According to this invention one of these spring-clacks is replaced by rigid plates, which enclose the wick on three sides, the remaining clack being articulated between the lower ends of the lateral walls of these rigid plates, and penetrating between the same under the action of its spring, when the extinguisher is actuated. Thus the tight casing is provided, which effectually extinguishes the lamp.

TYPE-WRITERS.—Mr. H. A. Gruhl has patented a type-writer. The invention relates to that class of type-writers in which the printing mechanism is caused to move above the sheet of paper to be printed upon, and the object is to facilitate the alternate use of two or more sets of type. This is effected in the following manner. Two or more sets of type are made use of, arranged concentrically on the lower side of a segment, the pivot of which can be moved in a rectangular direction, whereon the letters have to appear upon the paper. Controlling rows of letters, which correspond with the types at the under side of the segment, but in the reverse arrangement are attached to the upper side of the segment, and appear alternately according to the position of the type-bearing segment in a segmental slot of a plate fixed above the said pivotted segment.

LAMP.—A velocipede lamp has been patented by Messrs. W. P. Burt and S. B. Edmonds. The object is to prevent the lamp from being affected by the jolting and oscillation of the vehicle to which it is attached. Two metal tubes are fixed to the lamp, in each of which works a metal rod attached to the socket-piece, by which the lamp is held to the vehicle; at the upper portion of each is fixed a washer of leather, through which the rod passes, and at the lower end of each rod is a leathern plunger; at the bottom of each tube is an indiarubber buffer. Between the fixed upper plugs of leather in the tubes and the plungers—upon the rods—are fixed spiral springs, so that, when the oscillation takes place, any movement to the lamp is at once counteracted by the springs. In order to secure a perfectly steady and noiseless action, two wing-pieces lined with leather are attached to the socket, these wing-pieces clipping the outside of the metal tubes which act as a guide.

ELECTRIC MEASURING.—Messrs. W. T. Goolden and G. Evershed have patented a compensating electric measuring instrument. The object is to make the reading of voltmeters independent of temperature, and is attained by winding the coils of such instruments with wires, having different resistance temperature co-efficients. For example, the coil of a voltmeter is wound partly with a wire having a small co-efficient, and partly with a compensating wire having a large co-efficient, the latter wire being coupled in shunt to a portion of the former wire in such a way as to cause the current to flow in opposite directions in the two wires. The resultant magnetic field of the combination coil will then be equal to the difference of the fields due to the two wires, and, by observing certain proportions between the resistances and number of turns of the two wires and the resistance of the shunted portion of the wire having the small co-efficient, this difference may be made constant for constant pressure on the terminals of the coil, throughout a large range of temperature.

RELEASING HORSES.—Mrs. A. D. Durell, London, has patented means for releasing runaway horses from vehicles. To apply the invention to a pair-horse carriage, a rock-shaft is mounted in bearing secured to the splinter-bar of the vehicle. This rock-shaft is provided with short arms projecting horizontally, and to these arms are pivotted bolts, which slide vertically through sockets on the front of the splinter bar. The shaft is actuated by a hand-lever placed near the driver's seat. Plates with holes through them corresponding with the holes in the sockets, and provided with a trace-block, fit into the sockets, and are held in place by the vertical bolts. The pole fits into the chop block in the usual manner, and is kept in place by a metal plate secured to the pole. This plate fits over the sockets on the splinter-bar, in which position it is held by two of the vertical bolts. Should the horses become unmanageable, the driver pulls over the hand-lever, and thereby draws up all the vertical bolts, when the pole and trace-blocks become detached, and the horses are freed from the carriage.

TECHNICAL EDUCATION NOTES.

CENTRAL INSTITUTION OF THE CITY AND GUILDS OF LONDON INSTITUTE.—During the month of July, 1888, the following summer courses of lectures and laboratory instruction for technical teachers and others will be held in the Institute's New buildings in Exhibition Road: 1. Elementary principles of machine-designing—By Professor W. C. Unwin, M.I.C.E., F.R.S. A course of lectures and drawing exercises to be given daily, Saturdays excepted, from 6.30 to 8 p.m., and extending over a fortnight, commencing on Monday, July 2nd. 2. Practical lessons in organic chemistry, intended mainly for teachers of technological subjects—By Professor Armstrong, F.R.S., Ph.D. This course will extend over two weeks, from 10 till 4 daily, commencing on July 2nd. 3. The construction and use of electrical measuring instruments.—By Professor Ayrton, F.R.S. This course will include experimental lectures and special laboratory work. The lectures will comprise the principles and practice of the construction, calibration, and testing for faults of ammeters, voltmeters, ohmmeters, wattmeters, coulombmeters, and ergmeters as used for direct and alternating current systems. The students' practical work will be conducted in a laboratory specially fitted with accumulators, standard instruments, etc., for electrical instrument testing, and they will have the opportunity of examining and practically trying all the more important electrical meters at present in ordinary use. It will extend over two weeks, and will consist of six lectures, from 8 to 9 p.m., on Mondays, Wednesdays, and Fridays in the fortnight commencing on Monday, July 16th; and also of practical work in the physical laboratories, daily from 2 to 5 p.m., Saturdays excepted. 4. Experimental mechanics—By Professor Henrici, Ph.D., LL.D., F.R.S. This course will consist of lectures and practical work in the mechanical laboratory, and will extend over two weeks, from 10 to 4, commencing on Monday, July 16th. 5. The principles of bread making —By William Jago, F.C.S., F.I.C., Examiner to the Institute. This course will consist of lectures and practical demonstrations, and will extend over two weeks, from 10 till 4 daily, Saturdays excepted, commencing on Monday, July 16th 6. Photography—By Captain Abney, R.E., F.R.S., Examiner to the Institute. A course of six lectures, at 8 p.m., on Monday, Wednesday, and Friday in the fortnight, commencing on Monday, July 2nd. 7. Mathematical and surveying instruments—By Arthur Thomas Walmsley, M.I.C.E. A course of six lectures, illustrated by large scale diagrams and instruments lent by various makers, at 8 p.m., on Monday, Wednesday, and Friday in the fortnight commencing on Monday, July 2nd. 8. Gas manufacture—By Lewis T. Wright, engineer to the Nottingham Gas Works. A course of four lectures, at 8 p.m., on Tuesday, July 17th; Thursday, July 19th; Monday, July 23rd; and Tuesday, July 24th. 9. The Application of modern geometry to the cutting of solids for masonry and other technical arts—By Lawrence Harvey, Medallist of the Ecole des Beaux Arts, Paris. A course of six lectures, practically illustrated, at 8 p.m. on Monday, Wednesday and Friday, in the fortnight commencing on Monday July 16th. 10. The craft of the carpenter —By John Slater, B.A., Examiner to the Institute in Brickwork and Masonry—A course of four lectures, at 8 p.m., on Tuesday, July 3rd; Friday, July 6th; Tuesday, July 10th; and Friday, July 13th. Further particulars and a syllabus of each course may be obtained at the Central Institution, Exhibition Road, S.W., or at Gresham College, London, E.C.

ANNOUNCEMENTS.

IRONMONGERS, IRON AND METAL TRADES' EXHIBITION.—An exhibition in connection with these trades is to be held in the Agricultural Hall, Islington, in November next. The exhibits are to include household ironmongery of all kinds, lighting, heating, and sanitary appliances, machinery, implements, and tools.

SALES.

EXCHANGES.

SELECTED BOOKS.

The Laboratory Guide; a Manual of Practical Chemistry for Colleges and Schools. Specially arranged for Agricultural Students. By A. H. Church, M.A., F.R.S., Professor of Chemistry in the Royal Academy of Arts. London: Gurney and Jackson, 1, Paternoster Row. Price 6s. 6d.

Metalliferous Minerals and Mining. By D. C. Davies F.G.S. With 148 Engravings. Fourth edition London: Crosby, Lockwood, and Co. Price 12s. 6d

Rock History: a Concise Note-Book of Geology, having Special Reference to the English and Welsh Formations. By C. L. Barnes, M.A., Science Master at Bromsgrove School. With coloured maps of strata and illustrations of fossils. London: E. Stanford. Price 6s.

The Flora of West Yorkshire, with an Account of the Climatology and Lithology in connexion therewith. By Frederic Arnold Lees, M.R.C.S., L.R.C.P. London: L. Reeve and Co. Price 21s.

Botanical Tables for the Use of Junior Students. By Arabella B. Buckley. Table of Common Terms used in Describing Plants, comprising those usually required in the Cambridge Local Examinations for Juniors. Also a Table of the Chief Natural Orders of British Plants, arranged according to Bentham and Oliver. New and revised edition. London: E. Stanford. Price 1s. 6d.

The Mechanic's Workshop Handy-Book: a Practical Manual on Mechanical Manipulation, embracing information on various handicraft processes, with useful Notes and Miscellaneous Memoranda. By P. N. Hasluck, A.I.M.E., Author of "Lathe Work," etc. London: Crosby, Lockwood and Co. Price 2s.

An Elementary Geography of the British Isles. By Archibald Geikie, F.R.S., Director-General of the Geological Survey of the United Kingdom, and Director of the Museum of Practical Geology, Jermyn Street, London, Author of "The Teaching of Geography," etc. London: Macmillan and Co. Price 1s.

Electro-Plating: a Practical Handbook on the Deposition of Copper, Silver, Nickel, Gold, Aluminium, Brass, Platinum, etc., with Descriptions of the Chemicals, Materials, Batteries, and Dynamo Machines used in the Art. By J. W. Urquhart, C.E. London: Crosby, Lockwood and Co. Price 5s.

An Atlas of Anatomy; or, Pictures of the Human Body. In 24 large Coloured Plates, comprising 100 separate figures, with descriptive letterpress. By Mrs. Fenwick Miller, late Member of the London School Board. Third edition. London: E. Stanford. Price 12s. 6d.

METEOROLOGICAL RETURNS.

For the ten weeks ending on Monday, June 25th, 1888, specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	47·6 degs., being 1·9 degs. below average.	5·1 ins., being 0·2 ins. above average.	448 hrs., being 28 hrs. above average.
England, N.E.	48·7 „ „ 2·5 „ „ „	3·8 „ „ 0·8 „ below „	357 „ „ 47 „ below „
England, East	51·3 „ „ 2·3 „ „ „	3·3 „ „ 1·1 „ below „	390 „ „ 76 „ „ „

Scientific News

FOR GENERAL READERS.

FRIDAY, JULY 13th, 1888.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

In my last I referred to a discussion with a friend whose views I greatly respect. We were perfectly agreed respecting the truth and universality of the great induction usually described as "the conservation of energy," though I may add, by the way, that I heartily agree with Mr. Herbert Spencer's objection to the form of expression that is generally accepted. He objects to it on the same ground as that of his objection to the term, "preservation of the fittest," for which he has successfully substituted "survival of the fittest." "Conservation of force," or "conservation of energy," as he says, implies "that energy would disappear unless it were taken care of, and this is an implication totally at variance with the doctrine enunciated" (*Nature*, vol. v., page 263). I do not remember whether he has proposed an alternative term.

Indestructibility of energy and indestructibility of force appear to me far better terms. They are more correct and more expressive, besides corresponding with the earlier-accepted description of what is virtually the same, viz., the "indestructibility of matter."

The difference, between myself and friend, referred to the fate of the hailstone supposed to enter our atmosphere with planetary velocity, and having its planetary velocity arrested by atmospheric resistance. According to his view of the doctrine of the conservation of energy the mass of ice—whatever be its size—must be heated throughout, seeing that the motion of the whole mass is arrested throughout. My view is that the whole of the heat into which the mechanical motion is converted is primarily evolved at the place where the arresting force is applied.

It is evident from Sir W. Thomson's slashing criticism of Schwedoft's theory, that my friend's view is shared by others, and I have reason to believe that I am not alone.

To illustrate the difference between these views let us take an imaginary case. Suppose that two bodies of equal mass, both solid, perfectly rigid, inelastic, and incompressible, and both non-conductors of heat, are moving with equal velocities in exactly opposite directions, and then come in collision. The visible motion of both will be arrested, and then what will happen? According to the first view each body will be instantly heated throughout. According to my view, they will be heated only at the colliding surfaces.

We cannot actually make this experiment, because we can find no substances having the perfect rigidity, etc., demanded, therefore the reader may fairly ask why I make such demands in my ideal case. This will appear as I proceed.

According to my view, the arrest of motion is only apparent. I regard the conservation or indestructibility of motion as the fundamental fact, and the conservation or indestructibility of what we call energy as merely the outcome or sensible expression of this. In all practical cases of collision the mass-motion is converted into several motions, a part of it directly into heat motion, another part into mechanical vibration, another possibly into electrical or chemical motion, etc., as the case may be.

As an example of such communication of motion in other form than that of heat, I may mention that when in Sheffield I was consulted concerning damage alleged to be done by certain steam-hammers in shaking the foundations of surrounding houses, and devised a simple instrument—a sort of seismometer—which proved that a hill about 200 feet high, half a mile long, the summit of which was about one-third of a mile distant from the hammers, was bodily shaken by the concluding strokes of the hammer upon blooms of puddled iron. When the steam-hammers were very busy the crockery ware placed on shelves in the houses around was endangered, as the general vibration caused it to travel gradually to the edge of the shelves and then topple over.

In this case a considerable proportion of the arrested mechanical motion of the hammer was merely transferred as mechanical motion to the body of the earth, and thence to the houses, etc.

A further examination of the doings of such steam-hammers is instructive. When the glowing, spongy ball of iron receives its first few blows, it crushes down, and at each compression its temperature is visibly increased.

In the case of the tilt-hammer, when applied for welding a "faggot" of steel strips together, the success of the proceeding is dependent on the fact that the blows are dealt in such rapid succession that the steel is maintained at a welding heat, which it would lose if exposed for the same length of time without the hammering.

In these cases the hammer-head itself, although it is the moving body whose motion is arrested, is but slightly heated. The inner portion of its mass, its centre of momentum, is practically unaffected, the only actual effect on this being due to vibration communicated by its elasticity and imperfect rigidity. The main heating occurs within the mass of the yielding metal, where the mechanical motion is arrested by internal friction. When it becomes more rigid, and ceases to supply this internal resistance, we have the well-known banging thuds that shake the foundations of the solid earth.

Die-sinking and coining afford another example. The die is of hardened steel, and its descent is suddenly arrested. Heat is thereby generated, but where? Certainly not in the mass of the die. If so, the vigorous proceedings at the Royal Mint would soon soften the hard steel of which the dies are made. The coins are heated considerably, and the metal of which they are composed flows into the device on the face of the die. The weight of metal thus heated in the course of a day's work is many hundred times greater than that of the die itself.

When the blacksmiths of olden times lighted their forge fires by converting the mechanical motion of their hammers into heat-motion, it was not the hammer-head that they applied to the brimstone match, but the piece of soft iron that arrested the motion of the hammer. An instructive experiment may be made by taking a leaden bullet and a corresponding piece of iron, hammering each on an anvil, and comparing the temperature of the victims. Both will be warmed, but the lead will be found to become much hotter than the iron, and the hammer itself not sensibly warmed.

I contend that these facts, and a multitude of others that might be specified, teach us that it is not the negative arrest of visible motion of the moving body, but the positive conversion of this kind of motion into another kind of motion, that effects the rise of temperature, and that in all cases such conversion must and does occur where the effective resistance occurs, whether that be on the surface or within the substance or outside the mass of the colliding bodies. (For further illustration of this, see chapter 5 of my "Simple Treatise on Heat," published by Chatto and Windus.)

In the imaginary bodies of perfect rigidity it would be all superficial, producing superficial fusion, volatilisation, or dissociation according to quantity. In a perfectly compressible and perfectly elastic body it would be all internal, as is proved when we drive a close-fitting piston into a closed cylinder of air or other gas, or, what amounts to the same, if the piston be at rest and we drive the gas in the cylinder towards it. Here the resistance occurs internally, and the heat is therefore internal.

If we apply a friction break to arrest the motion of a solid fly-wheel, the heat appears on the surface where the break is applied. If the fly-wheel be fluid, as a vortex of gas or liquid, and the break be applied by a resisting paddle within the fluid, the heat will appear within the fluid, commencing at the place of impact with the paddle, the heat being simply the other motion which is there set up in exchange for the mechanical motion.

THE "VOLTAIC BALANCE."

A NEW and simple lecture experiment has recently been devised by Dr. G. Gore, F.R.S. It is conducted in the following manner: Take two small clean glass cups containing distilled water; simultaneously immerse in each a small voltaic couple, composed of either unamalgamated magnesium or zinc, and platinum, taking care that the two pieces of each metal are cut from the same piece and are perfectly clean and alike. Oppose the currents of the two couples to each other through a sufficiently sensitive galvanometer, so that they balance each other and the needle does not move. Now dip the end of a slender glass rod in a very weak aqueous solution of chlorine, bromine, iodine, or hydrochloric acid, and then into the water of one of the cups. The voltaic balance is at once upset, as indicated by the movement of the needle, and may be shown to a large audience by means of the usual contrivances.

The chief circumstance to be noticed is the extremely great degree of sensitiveness of the arrangement in certain cases; this is shown by the following instances of the minimum proportions of substance required to upset the balance, with an ordinary astatic galvanometer of 100 ohms resistance, and with a Thomson's reflecting one of 3,040 ohms resistance.

1. *Zinc and Platinum with Iodine.*—With the astatic galvanometer between one part of iodine in 3,100,000 and 3,520,970 parts of water.

2. *Zinc and Platinum with Hydrochloric Acid.*—With the astatic galvanometer between 1 in 9,300,000 and 9,388,185 parts; and with the reflecting one, between 1 in 15,500,000 and 23,250,000 parts.

3. *Magnesium and Platinum with Bromine.*—With the astatic galvanometer between 1 in 310,000,000 and 344,444,444 parts.

4. *Zinc and Platinum with Chlorine.*—With the astatic galvanometer between 1 in 1,264,000,000 and 1,300,000,000 parts.

5. *Magnesium and Platinum with Chlorine.*—With the astatic galvanometer between 1 in 17,000,000,000 and 17,612,000,000 parts; and with the reflecting one, between 1 in 27,062,000,000 and 32,291,000,000 parts of water.

Every different soluble substance requires a different proportion, and with unlike substances the difference of proportion is extremely great. With solutions of neutral salts, the proportion of substance required to upset the balance is large; for instance, with chlorate of potash, a zinc platinum couple, and the astatic galvanometer, it lay between 1 part in 221 and 258 parts of water.

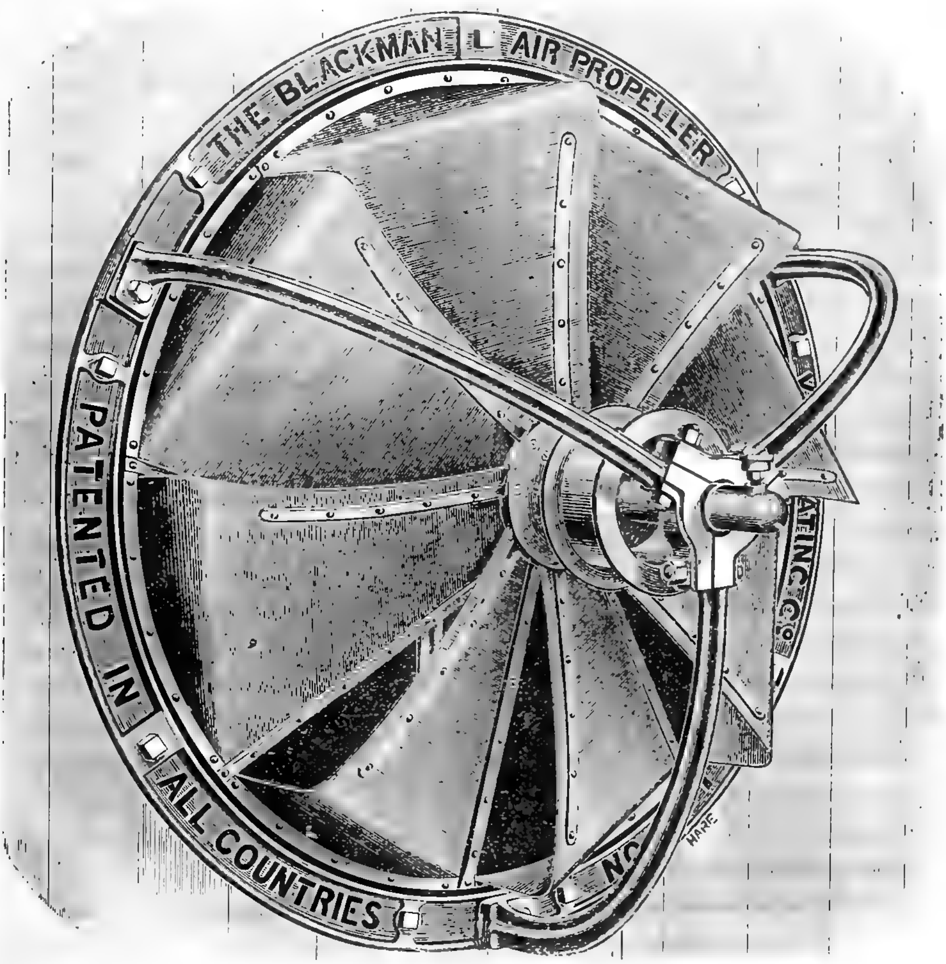
The degree of sensitiveness of the balance is usually greater, the greater the degree of chemical affinity the dissolved substance has for the positive metal, and the less it has for the negative one.

By first bringing the balance with a magnesium platinum couple and the astatic galvanometer nearly to the upsetting point, by adding 1 part of chlorine to 17,612 million parts of water, and then increasing the proportion to 1 in 17,000 millions, the influence of the difference, or of 1 part in 500 millions, can be distinctly detected.

THE SENSES OF INSECTS.—Franz Ruland (*Zeitschrift fur Wissenschaftliche Zoologie*) considers that insects possess in their antennæ a series of different olfactory organs, specifically perceptive of different odours.

THE BLACKMAN AIR PROPELLER.

THE importance of ventilation as one of the hygienic conditions necessary for health should be a truism. We regret to say it is far from being so, especially in crowded workshops and places of public resort, such as theatres, concert halls, churches, etc., and even when the need for ventilation is recognised, how inadequate are the means often adopted for effecting it. In the majority of cases it is admittedly difficult to ventilate efficiently, *i.e.*, to produce a constant supply of fresh air without inconvenient draughts, and without occasional reversals of current or downdraughts, caused by wind, or by the temperature of the external air being higher than that of the air inside the building to be ventilated.



Without doubt, the most sure and efficient way of ventilating large buildings is to forcibly exhaust the hot and vitiated air by mechanical means. This is usually effected by rotary fans driven by water or engine power. Much, however, depends on the shape of the fan, and although the Blackman is doubtless known to many, it has some distinctive features which some of our readers may be glad to have brought to their notice. In the first place it exhausts or delivers a large volume of air without materially raising its pressure, whereas the other fans in use generally drive in air at a considerable pressure. The latter system is the best when a strong current of air is required as for instance in the ventilation of the complicated working of coal-mines, where the resistance to be overcome is considerable. Blast fans are also very useful for producing the currents of great intensity required for smiths' forges, foundry cupolas, etc. The Blackman propeller is specially designed to move large volumes of air at low speed, and is therefore well suited for the ordinary purposes of ventilation. The eight blades of this air propeller, as will be seen in the accompanying figure, are curved in a special manner, not only to catch the surrounding air, but to draw it towards the centre, and then finally to push it forcibly through the propeller itself. Their peculiar construction also prevents the escape of air radially, which is a common defect in most other rotary fans

The following table, supplied by the makers, gives the work done, and the power required to do it, for the different sizes of the propeller, when there is a free inlet as well as a free outlet for the air.

Diameter in inches.	Revolutions per minute.	Cubic feet of Air moved per minute.	Actual horse power required
14	1,000 to 1,500	1,500 to 2,500	Fractional.
18	700 „ 1,200	2,000 „ 4,000	Ditto
24	500 „ 900	3,000 „ 6,000	¼ to 1
36	400 „ 650	7,700 „ 14,000	½ „ 1½
48	300 „ 600	13,500 „ 30,000	1 „ 2½
60	240 „ 450	21,000 „ 43,000	1½ „ 3½
72	200 „ 350	30,000 „ 58,000	2 „ 5

When driven within the limits of speed best suited for ventilating buildings, the air is moved at the rate of about 15,000 cubic feet per minute per horse power, and this is certainly an excellent performance. The higher the speed the greater is the power required for a given volume, and a large size run slowly is better than a smaller size driven quickly, unless considerable resistance has to be overcome.

Besides ventilation, the Blackman propeller is largely used in many industries for drying purposes, such, for instance, as the drying of cloth, timber, paper, wool, glue, etc. In many cases the heated air drawn from one part of a building may be used for drying or warming in another, or the air to be used for drying may be made to pass over heated pipes. One firm of furniture makers have four drying chambers, in which about twenty tons of timber are dried weekly by means of heated air drawn through them by two Blackman propellers. The temperature of the chambers is maintained at about 80° Fahr., and the timber is said to be in good condition for working when taken out, and free from cracks or warps. Rooms through which heated air is drawn by propellers, are also used for the drying of leather and card, or mill-boards, these materials being hung as nearly edgewise to the air-current as is practicable.

The dust and fumes produced in many factories are highly injurious to health, and it is most important that they should be removed from the workrooms. In white-lead works the fumes are poisonous, and in the grinding of steel and iron in the cutlery and other trades, the fine metallic particles are a fruitful source of lung disease. Again, the dust from wool often gives rise to the dreaded wool-sorter's disease, which generally ends fatally. It is caused by a minute organism called the *bacillus anthracis*, which is conveyed by the skin or wool of animals which have died of splenic fever. All these dangers may be minimised by a proper system of ventilation, but, although this is well understood, it is surprising to find it neglected, even in some of our best appointed factories.

It has been suggested that much of the fruit which is lost in this country, where there is not sun enough to dry it, may be preserved by air-drying. In warmer climates raisins, currants, apples, plums, etc., are dried by the sun after being gathered, and are then sent to England for sale. In our less favoured and uncertain climate this cannot be done, and fruit growers will do well to try thoroughly the above suggestion of drying their fruit in chambers by means of an air-propeller.

THE AUDITORY ORGAN OF THE GNAT.

LOVERS of minute anatomy will find this a curious subject for microscopic study. Capture a male gnat, known by the beautiful plumose antennæ, moisten with alcohol, and afterwards dissect out with fine needles in a drop of water. One of the antennæ is to be cut off, and the large basal joint is the special subject of investigation. This is seen to be of almost spherical shape, but flattened on its free surface, to which the second joint is attached. When the second joint is removed a sunk circular space is seen upon the large first joint. To the bottom of this cavity the second joint was attached, and the radiating muscles, by which it was moved this way or that, can be made out in a successful preparation. A fortunate cut will now and then reveal the true character of the basal joint, which we shall describe by comparison with a more familiar object, viz., a common paraffin lamp. In this the flame is screened by a chimney and a globe. Suppose that the upper edge of the globe is turned downwards, so as to form an inner and much smaller globe, to the bottom of which the chimney is fixed: the double globe thus formed represents the large basal joint, while the chimney corresponds to the rest of the antenna. We must next suppose that the space between the inner and outer globes is filled with fluid. A cylindrical wick passing up the chimney would indicate the position of the antennary nerve, but to complete the resemblance we must further suppose that a circular fringe of filaments, beautifully regular in disposition, passes off from the outer surface of the wick, and penetrates the closed fluid-containing chamber. The essentials of an auditory organ have now been brought together. We have the closed cavity filled with fluid, the numerous nerve-filaments, and the modified hairs (?) in which these end. It is easy to imagine that the nerve-endings may be of various lengths, each responding to a particular kind of sound-wave, but we have no direct proof that this is actually the case. The organ just described will furnish an interesting and not too difficult subject to the microscopist who has a little skill in manipulation. The external features of the antenna of the male gnat were figured more than 200 years ago by Swammerdam in his "Biblia Naturæ." Its internal structure was well described by Dr. Christopher Johnston, of Baltimore, in vol. iii. of the "Quarterly Journal of Microscopical Science" (1855).

DYE COLOURS FROM PLANTS AND SHRUBS.

A VARIETY of very useful colours and dyes may be obtained from very common plants, growing in abundance almost everywhere. The well-known huckleberry, or blueberry, when boiled down with an addition of a little alum and a solution of copperas, will develop an excellent blue colour; treated in the same manner with solution of nut galls, they produce a clear dark-brown tint, while with alum, verdigris, and sal-ammonic, various shades of purple and red can be obtained. The fruit of the elder, so frequently used for colouring spirits, will also produce a blue colour when treated with alum. The privet, boiled in a solution of salt, furnishes a serviceable red. The shoots of the common burning bush, "euonymus," when treated with sal ammoniac, produce a beautiful purple red. The bark of the currant bush treated with a solution of alum produces a brown. Yellow is obtained from the bark of the apple tree, the box, the ash, the buckthorn, poplar, elm, etc., when boiled in water and treated with alum. A lively green is furnished by the brown corn.—*Scientific American.*

THE USES OF SACCHARINE.—According to the *Medical Press and Circular*, the Seine Council of Hygiene has received a report presented by Dr. Dujardin-Beaumetz, which declares saccharine to be not an aliment but a medicament. They are moreover convinced its main use in industry will be in adulterating alimentary products. The report was unanimously adopted by the Council, and the probable result will be the prohibition of saccharine in all articles of food.

EXTRAORDINARY ESCAPE FROM LIGHTNING.

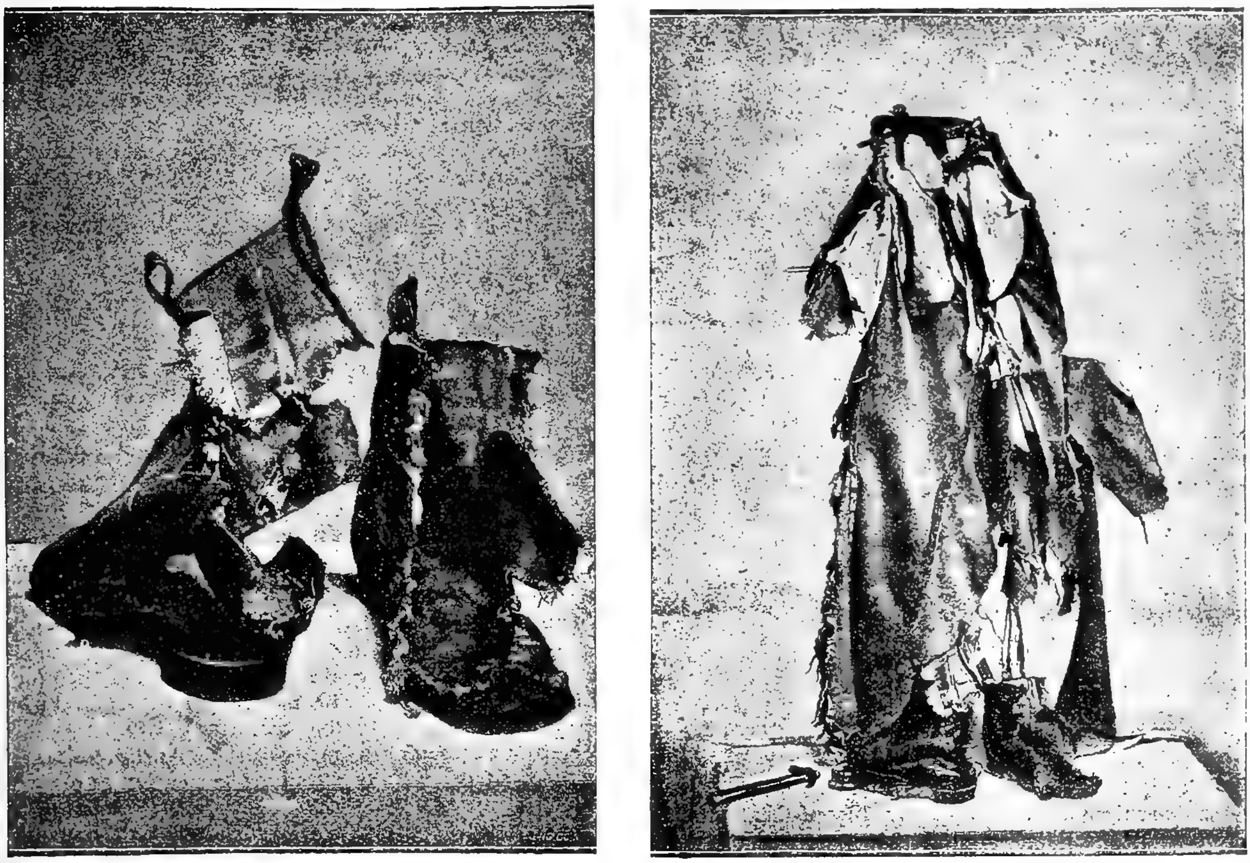
IN a letter to the *Scientific American*, Mr. J. B. de Motte, of De Pauw University, Greencastle, Ind., describes an extraordinary escape from lightning. He writes:

The narrowest escape from death by lightning of which I have ever heard came to my knowledge while lecturing a few weeks ago at the Florida Chautanqua. The drug store, which is used as a post-office by the good people of De Funiak, stands between the railroad station and their beautiful little lake. At the time to which I refer it was "protected" by a common-sized-twisted copper-band lightning rod, with iron core, fastened to the house by glass insulators in the old-fashioned way. Several houses in the town were "rodded" in the same way, but after this one was so badly shattered they were torn off by their owners, "to lessen their chances of getting struck, you know," they explained. About a hundred feet back of the post-office stood two fine specimens of the tall pines which grow so abundantly in that region.

On the afternoon of the 18th of last August, at about one o'clock, a number of boys and men had collected under the post-office porch, thinking, on account of the lightning rod, that they would be safe from the lightning, which was playing rather freely from an only partially cloud-covered sky. Among them was John Chisholm, a merchant of De Funiak, who was sitting about halfway between the corner post of the porch and the nearest window.

The lightning struck the two high pines, and after shattering their tops, leaped to the rod, completely melting its points, and then ran along the comb of the roof to the gable and down a corner. Mr. Chisholm's only recollection of the stroke is a sensation like that of a heavy blast of hot air striking him between the shoulders. He was thrown forward upon his face, and taken up for dead. His shoes were new and his trousers nearly so, yet they were left looking very much as if they had been attacked by an army of hungry rats. The engravings, which are made from photographs which I had taken for the purpose, give a fairly good idea of their condition. How a man could have his clothes chewed off from him by lightning in that style and still live, is a mystery. His shirt was torn entirely in two. His body was badly blistered, especially from the knees down. Becoming conscious, he experienced a terrible feeling of suffocation and "heartache, as though it would burst." He remained helpless for four months, suffering terribly from aching in the bones and a stinging sensation, "as though a thousand needles were being stuck all over my body."

Now, after a lapse of over nine months, Mr. Chisholm has gradually recovered the use of his limbs, only suffering from an occasional violent involuntary jerk in the back. He attends to business, and has recovered much of his former sociability.



MR. CHISHOLM'S NEW GAITERS AND CLOTHING AFTER THE STROKE.

THE NATURALIST AT THE SEA-SIDE.

1.—The Tow Net.

On a fine sunny day the naturalist at the sea-side can get many treasures by working a tow-net. This is a long tapering bag, from three to five feet long, made of stout and fine muslin. The open end is sewn to an iron hoop from six inches to a foot in diameter. The other end is open, but fitted with tape so that it may either be tied up or have a glass tube inserted. The hoop is held by means of three cords knotted into one. For special purposes one side of the hoop may be weighted, and the opposite side buoyed up with cork, but the tow-net should never be made so light as to float. When the net has been plied on the surface of the sea for half an hour, it is turned inside out into a clear vessel of sea-water. The captured animals float out and are either examined on the spot, or preserved for future study. Glass dipping-tubes of different sizes are needed to pick up small objects, and "concentrators" are useful for getting rid of the great mass of superfluous water. The concentrator is a lacquered cylindrical tube, made of fine gauze above, but capable of holding a small quantity of water below. If a gallon of water be poured through it all the visible organisms which it contains will be strained out into an ounce or two of fluid in the bottom of the tube. In working the net, a rowing-boat, or anything that moves on the sea, can be used, provided that it does not go too fast. A speed of two or three miles an hour is suitable.

So much for the tackle and mode of working. We will now suppose that our naturalist is at sea. Since it is just as easy to wish him good luck as bad, we will further suppose that he has a bright day and still water. If he is in a small boat he should have two or three wide jars at his feet, each to serve for a separate haul. If he be in a large craft and out for the day he must further be provided with a portable microscope, collecting tubes, and a supply of preservative fluid.

The things that he will find depend upon season and locality. To name all the likely things would be to empty a zoological text-book upon our readers. Let us be moderate then and notice only three kinds of animals, which are commonly met with and well worth study. The tow-net is pretty sure to bring up (1) small swimming crustacea, microscopic shrimps we might call them; (2) medusoids, and (3) echinoderm larvæ.

The surface crustacea will afford endless occupation in the determination of species, but this is work for the specialist. It will be enough for the beginner if he can recognise two orders which are sure to be met with, leaving details to others. The orders in question are the amphipods and the copepods. The amphipods are generally flattened from side to side, and provided with a crowd of legs beneath. At the tail-end are three pairs of tail-fins, which are used to make a sudden leap in the water. The legs next in front are very small. The copepods may be recognised with a pocket-lens as small, many-jointed crustacea, having four or five branched swimming legs on the fore part of the abdomen, and behind these a five-jointed tapering tail, without appendages. Far more interesting than these to the young biologist are the many larval crustacea which swim on the top of the summer sea. Look up, for instance, in any good manual of zoology, the larval form known as a *Nauplius.* The nauplius is an ancestral crustacean type, which was no doubt in its day an adult stage. In these later ages of the world's history it is usually a transitory phase of crustacean life, generally turning into something else, and ending up as a barnacle, a copepod, or a shapeless parasite. The zoæa, or larval stage of many crabs, is another and more advanced embryo, whose form should be studied beforehand. There is a world of interesting speculation opened out by these crustacean larvæ. Anyone who has examined under a microscope a nauplius and a zoæa in a watch-glass of sea-water will know what to make of those discussions of Darwin, and Haeckel, and Fritz Müller which seem so hard and dry to those who seek to master zoology by mere reading and thinking.

The tow-net often brings up medusoids, which at first sight look like brown or red spots entangled in a clear jelly. Give them plenty of water to swim in, and watch them under the microscope until you can make out the eye-spots and the tentacles, and the polyp hanging down in the middle of the transparent bell. These medusoids are detached from tree-like colonies, and will in turn produce such colonies again.

If your curiosity is capable of being roused by strange transformations you will find echinoderm larvæ very fascinating. The Bipinnaria of the star-fish, and the Pluteus of the echinus or sand-star are common forms. Utterly unlike the adult animals, into which they are transformed, these larvæ are well adapted for locomotion. They have long arms, ciliated bands, and a delicate skeleton of calcareous spicules. Elaborate figures would be needed to give even a rough notion of their various shapes. Sometimes the rudiment of the permanent body may be seen budding out from the larva.

The zoologist who has become familiar with the crustacean, hydrozoan, and echinoderm larvæ may exercise his thoughts profitably upon the great number of marine animals which develop with conspicuous metamorphosis. It is quite otherwise with animals of high grade, and with all the inhabitants of land and fresh waters. These, as a rule, develop directly. In the waters of the sea locomotion is very easy and advantageous, and at the same time enemies abound. These conditions favour the production of a vast brood of tiny embryos, which disperse at once in search of food, and only attain the adult condition by an entire change of structure and mode of life. In fresh waters, on the other hand, locomotion is limited by the small size of the area, while life is a less difficult struggle than in the sea. Fewer embryos are produced, and these are cared for by their parents, if only to the extent of having a good supply of food-yolk laid up for them in the egg. They hatch out in a comparatively advanced condition, resembling the parent, except in size. Terrestrial conditions are unfavourable to metamorphosis, owing to the difficulty which the immature animal finds in moving about on dry land. Lastly, all big and strong animals of high intelligence find it best to bring up a few young at a time, and to feed and protect these few until their development is far advanced.

We must add a few words about preservatives. Picric and chromic acid solutions are of great use in special cases, and have the merit of being extremely cheap. The picric acid solution should be saturated, the chromic acid one quarter per cent. For general purposes nothing is better than Haentsche's fluid, viz., a mixture of glycerine (two parts), methylated alcohol (one part), and distilled water (one part). After placing in the fluid, sort out the organisms by means of a dipping tube into little bottles, and be careful to label each with time and place of capture.

General Notes.

Stellar Studies.—We learn that Mr. J. Ellard Gore, F.R.A.S., etc., has in the press a volume entitled "Planetary and Stellar Studies: papers on the Planets, Stars and Nebulæ." It will shortly be published by Messrs. Roper and Drowley.

Manufacture of Aluminium.—A new company for the production of this metal is being formed in London. It holds a number of valuable patents and improved processes, and hopes to produce aluminium, not in small globules, but in ingots weighing above one cwt., and at the price of 1s. per lb. If these expectations are realised the metal will meet with an immense demand.

Scientific Training.—We are glad to learn that in one at least of the four Inns of Court there are being delivered lectures on mechanics, electrical engineering, toxicology, and psycho-pathology. Much time, trouble, and perhaps failure of justice will be avoided in patent-cases, complaints of nuisances, and charges of poisoning if counsel can thus be rendered competent to appreciate the evidence of experts.

The Origin of the Diamond.—Professor Simmler, supposing that the liquids occasionally found enclosed in diamonds are liquefied carbonic acid, suggests that the diamond may be formed by the crystallisation of a solution of carbon in such liquid carbonic acid. It is certainly known that diamonds have exploded without ostensible cause, a fact so far in harmony with Professor Simmler's supposition, but it has not yet been proved that carbon is soluble in liquid carbonic acid. The experiment is worth trying.

Curious Phase of Combustion.—M. Hirn sent lately to the Academy of Sciences an account of a very remarkable phenomenon which came under his observation. Having extinguished a spirit lamp, he saw a luminous point remaining for more than eight hours on the charred part of the wick, and finally traced it to a little block of carbon, the sides of which did not exceed a millimetre in size. This little block played the part of a platinum coil heated to whiteness, and remaining incandescent in the vapours of alcohol.

Petroleum in the Punjab.—According to *Indian Engineering*, quoted in *Invention*, Mr. Noble, of Canada, a great "oil" man, has obtained a concession from the Government of India to prospect for three years in the Punjab for mineral oil, and at the end of that time the right to take up 50,000 acres in case of success, with the privilege of supplying the whole of the North-Western Railway system with lubricating oil. His men and machinery are going out in September to begin operations. Mr. Noble is a brother of Colonel Noble, R.A., Superintendent of the Government Powder Works, Waltham Abbey.

The Permanence of Climate.—It has been lately asserted on theoretical grounds that the northern hemisphere reached its maximum temperature in the thirteenth century, and that the climate has since been growing progressively colder. A fact recorded in *Cosmos* does not agree with this supposition. On demolishing an old house at Thil, on the banks of the Rhône, there has been found a tablet of wood bearing the inscription in an old patois, "Le Rone a iele, 1670," which can only mean "the Rhone has frozen." Now as this exceedingly rapid river has never been frozen in the subsequent 218 years, we can scarcely admit that the climate of France has been deteriorating.

The Properties of Aluminium.—MM. Friedel and Crafts have determined the melting-point, the boiling-point, and the vapour-density of aluminium, and have laid the results before the Academy of Sciences. The vapour-density had been previously determined by MM. Sainte-Claire Deville and Troost at the boiling temperatures of mercury and of sulphur, and found to agree with the formula Al_2Cl_6. Recently MM. Nilson and Petterson have made a series of observations at a higher temperature, and deduced the formula $AlCl_3$. It results from the experiments of Friedel and Crafts, made between 218° and 440° C., that the density is constant for more than 200°, and answers to the formula generally admitted.

Research.—We have received the first number of a new monthly journal, published in Liverpool, called *Research*. In the introductory programme it is stated that a careful digest will be given of what has been and is being accomplished by workers of the first order. Also that the special value and bearing of this knowledge will be pointed out, as well as how such work may be supplemented, and how new lines of inquiry may be started. Such a programme is comprehensive, if not a little too ambitious, but we shall cordially welcome the fulfilment of what is promised. It is true that in the first number there is a total absence of the digest and of the teaching above referred to, but we cannot but suppose that this inconsistency will disappear in the next number. We notice also that most of the information given, under various headings, is essentially of a local character.

Anti-Science.—In a book bearing the strange title of "The Anointed Seraph; the Last Made First," written by G. H. Pollock (Sherry, Washington), may be read the following passage:—"The earth which we inhabit, and of which we are a part, was made up through involution of all the various products and qualities of the disturbed solar lights. Water came from Taurus, oxygen from the Great Bear, amativeness from Capricornus, copper from the Whale, steel from the Little Bear, gems from Scorpio, black hair from Aquarius, gold from the Crown, salt from Orion, mercury from Mercury, sulphur from Jupiter, alkaline substance from Venus, diamonds from Andromeda, verdigris from the sun spots, iron from Hercules, silver from the Pleiades, soapstone from the Hydra, loadstone from the Pole Star. The life of the world was the nature and personality of the digressor from the seventh sun, who through the progress of involution became inverted, passing from the divine to the material state." Leaving our readers to ponder over this jumble, we can only express our sorrow that men can be found to write, to publish, and, we fear, to read such productions.

THE MOVEMENT OF THE EARTH AND THE LENGTH OF THE DAY.—Mathematicians have exercised their ingenuity in calculating the gradual lengthening of the day in consequence of a progressive retardation of the Earth's rotation on her axis. Professor Young, in a lecture recently delivered in Princeton, and noticed in *Astronomie*, argues against the data on which their calculations are founded. He shows that the retarding influence of the tides is compensated by the fact that the Earth gradually contracts, owing to progressive refrigeration, which tends to accelerate its rotation. Geological causes seem also to neutralise each other reciprocally. An accumulation of matter in the equatorial regions, would have the effect of retarding the motion of the Earth, and such an accumulation is being effected by the Mississippi, which conveys its deposit into the Gulf of Mexico. The rivers of India also work in the same direction. But the rivers of Siberia, the Mackenzie, and other rivers produce an opposite effect by conveying their *débris* towards the pole. The Nile, La Plata, and Orinoco also convey matter away from the equatorial regions, whilst not a few of the longest rivers, such as those of China, the Amazon, and the Congo, flow in a west-easterly direction. Hence we may here fairly assume a compensation. The accumulation of ice at the poles must also compensate the loss of velocity due to the tides.

FURTHER OBSERVATIONS ON MARS.—The condition of this planet has been made the subject of further observations by M. Fizeau in a communication to the Academy of Sciences. It is an error to compare the condition of Mars with that of our Earth. Mars is more remote from the sun than are we in the proportion of three to two. The heat and light which it receives from the sun are about four-ninths of our allowance. Hence there is a mean climate comparable to that of our polar circles. Further the atmosphere of Mars is not like ours, which, as every one knows, absorbs and stores up the solar heat on the surface of the ground. Mars has no equatorial bands indicating the presence of clouds, that is, of watery vapour suspended in the atmosphere. It follows that about two-thirds of the proportion of gases forming our atmosphere, and serving as a storehouse for the heat, are wanting on the surface of Mars, which is consequently undergoing a state of glaciation. Besides, the seasons of Mars are about twice the length of ours; the long summers melt the foot of the glaciers a little, but the prolonged and severe winters which follow restore to these colossal masses what they have lost. In short, Mars is an immense glacier. M. Janssen agreed with the views of M. Fizeau on the constitution of the atmosphere of Mars, which he considers to be a planet geologically older than our Earth.

THE PUBLIC HEALTH.—The Registrar-General's return for the week ending June 30th shows that the deaths registered during that period in twenty-eight great towns of England and Wales corresponded to an annual rate of 15·9 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Brighton, Huddersfield, Sunderland, Bristol, Birmingham, and Blackburn. In London 2,289 births and 1,238 deaths were registered. Allowance made for increase of population, the births were 446 and the deaths 261 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 14·2, 14·2, and 14·5 in the preceding three weeks, rose last week to 15·1. In the thirteen weeks of last quarter the death-rate averaged 16·9 per 1,000, which was 3·0 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,238 deaths included 20 from measles, 19 from scarlet fever, 28 from diptheria, 27 from whooping-cough, 10 from enteric fever, 36 from diarrhœa and dysentery, 2 from cholera and choleraic diarrhœa, and not one from small-pox, typhus, or any ill-defined form of continued fever; thus 142 deaths were referred to these diseases, being 124 below the corrected average weekly number. In Greater London 3,032 births and 1,530 deaths were registered, corresponding to annual rates of 28 6 and 14·4 per thousand of the population. In the outer ring 4 deaths from scarlet fever, 4 from whooping-cough, and 3 from diphtheria were registered. Two deaths from scarlet fever occurred in Willesden sub-district and 2 from wooping-cough in Wimbledon sub-district.

A GERMAN ANTARCTIC EXPEDITION.—The exploration of the Antarctic regions is to be taken out of our hands and those of Australia. It will be remembered that some time ago a half-hearted proposal came from Australia that the Home Government should contribute £5,000 towards an Antarctic expedition, to which Australia would contribute a like sum. A discouraging reply was returned. It was represented, and rightly, that £10,000 would go a very little way towards the exploration of this enormous area of unknown surface; but that it was the intention of Her Majesty's Government "at a future time" to take up the undertaking, and then Australia would be invited to co-operate. But the few persons in Australia really interested in Antarctic exploration were not satisfied with this, and since then have been casting about to find some means of carrying on the work independently of the mother country. But so far their success has not been great. By the time Her Majesty's Government is ready to consider the subject the work will have been done by Germany, and as in recent colonial enterprises our enthusiasm will be kindled when it is too late. It is intended to place in the Prussian estimates a very considerable sum for an Antarctic expedition. A large staff of the best men obtainable will be engaged, naval and scientific, and the organisation of the expedition has been placed in the hands of Dr. Neumayer, of the Hamburg Observatory, who is, perhaps, the greatest authority living on Antartic matters. It is intended, we understand, that the expedition will stay out until our knowledge of this almost unknown region has been substantially extended. At present it is believed that within the Antarctic Circle there must be a very large area of land. We know that there is a long range of high mountains, and at least one great volcanic peak. It will be stipulated that the members of the expedition shall exert themselves to their utmost to explore the region, so that within a very few years we may expect to have another great blank in the globe filled up, and that not by the country of Ross whose Australian colonies have a practical interest in the physiography of the Antarctic, but by a nation whose interest in the subject is of a purely scientific character. The expedition, we believe, will sail in a few weeks.—*Times.*

BUDS.

(*Continued from page* 10.)

IN order to understand clearly the formation of a bud, whether lateral or terminal, it will be necessary to briefly trace its development from this conical mass of embryonic tissue. The earliest differentiation has been detected in the growing point itself, where in the almost homogeneous tissue the three layers of cells which form the various structural systems of stems and leaves are very faintly marked out. These three layers are the *Plerome*, which produces the pith and fibro-vascular system; the *Periblem* from which the cortex or bark arises; and the *Dermatogen*, from which the epidermis or skin is formed. The mode of growth by which these three layers arise is that of *cell-division* and in flowering plants it is confined to the growing point and to another region of similar tissue known as the cambium. The further we proceed downwards from the growing point, which seldom amounts to more than the hundredth part

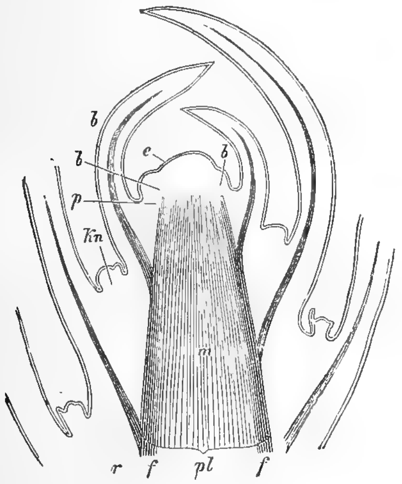


FIG. 3 (after Prantl).—Diagram of a longitudinal section of the stem of a dicotyledonous plant. *m*, pith; *f*, fibro-vascular bundles, both developed from the plerome *pl*, the bundles sending branches to the leaves; *r*, cortical tissue; *e*, epidermis; *bb*, young leaves, two showing their origin from the protomeristem, *p*; *kn*, axillary bud.

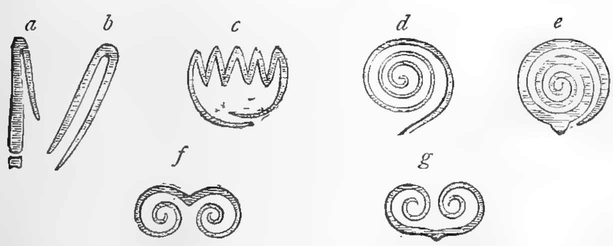

FIG. 5 (after Bentley).—*a*, vertical section of a reclinate leaf; *b*, transverse section of a conduplicate leaf; *c*, transverse section of a plaited or plicate leaf; *d*, vertical section of a circinate leaf; *e*, transverse section of a convolute leaf; *f*, transverse section of a revolute leaf; *g*, transverse section of an involute leaf.

of a millimetre, the more clearly defined do these three layers and the systems subsequently developed from them become, until they attain the readily recognisable cellular and vascular distinctions of form previously described. The leaves are always developed in a regular order, viz., *acropetally*, or from base to apex, as may be easily observed on expansion—and they always take their rise from the outer layer or layers of the *sides* of the growing point before the epidermis is formed, and in their earliest visible condition appear as little roundish or conical swellings, as shown, in figs. 1 *a* and *b*, 3 *b* and *kn*. As before stated, they never arise from the actual apex of the growing point, because their so doing would stop further growth in that direction, as is the case when a stem ends in a flower (lilac and horse-chestnut, fig. 4.) As they form they carry out with them in continuity the

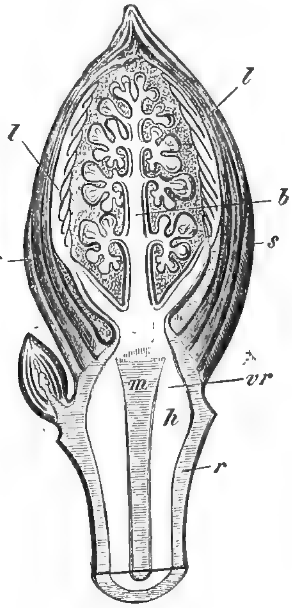

FIG. 4 (after Sachs).—Median longitudinal section through a vigorous winter bud of the Horse Chestnut (*Aesculus hippocastanum*). *m*, pith; *h*, wood and *r* cortex of the shoot axis (*vr*) of the preceding year; *ss*, bud scales; *ll*, young foliage leaves—in the middle are the flower buds. Woolly hairs fill the dotted space.

vascular, cortical, and epidermal tissues of the stem. Thus in our bud we have pith, fibres, and vessels surmounted by an apex of dividing cells from which rudimentary leaves proceed, whilst lower down the leaves

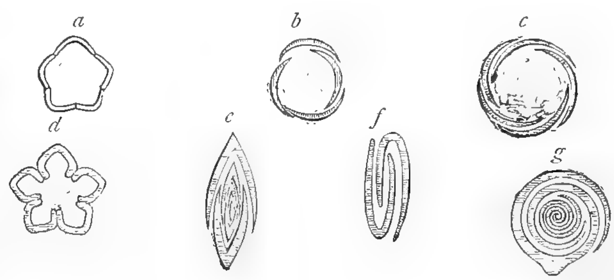

FIG. 6 (afte· Bentley)—Transverse section of buds: *a*, to show the leaves arranged in a valvate manner; *b*, to show imbricate vernation; *c*, to show twisted or spiral vernation; *d*, to show induplicate vernation; *e*, to show eduitant vernation; *f*, to show obvolute vernation, and *g* to show supervolute vernation.

are in a more advanced condition with vascular, cortical (modified) and embryonic systems of their own and embryonic buds in their axils. This is the condition of the structure in autumn, and such it remains during the dormant period of winter until the warmth of spring causes the sap to rise till the plant is gorged by it, and the protoplasm to resume its activity, the whole apparatus of vegetation being again set in motion. The embryonic tissue at the growing point and at the apices of the younger leaves now begins to divide, whilst those cells which have ceased to divide become watery and enter upon the period of elongation by which they receive their outward form and size and which causes that rapidity of growth which is so striking. The older parts commence to undergo that internal differentiation which results in certain alterations in the cell-walls and other partly formed structures—pittings, lignification, etc., and the formation of stomates in the epidermis—that complete growth. Then it is that the leaves rapidly expand, reversing as they do so the order of growth followed when forming in the bud when they curved upwards and inwards closely enveloping the axis, whilst now they curve downwards and outwards. This diversity is due to a curious property of plants known as *Bilaterality* which under certain conditions plays a very important part in their life-history and displays itself in an unequal growth of the sides of different structures, as in the leaves of the bud which when first forming grew more rapidly on their outer and under sides (*hyponasty*), the tension on the opposite side causing them to bend upwards, whilst in expanding they grow more rapidly on their upper and inner sides (*epinasty*), causing them to bend outwards and downwards. The mode in which they are arranged or packed in the bud is interesting, and varies greatly with the species, and is termed *vernation.* If a leaf-bud of any kind—the larger the better—be cut transversely and examined carefully with a hand-lens, each individual leaf will be seen to be folded in a certain way upon itself and also placed in a certain position with regard to the leaves nearest it. In the single leaf the vernation varies from the simple *inflexed* (fig. 5, *a, b*), or folding of the upper half of the leaf upon the lower (Tulip-tree), to the more complex *convolute* (fig. 5 *e*), or rolling of the leaf laterally from one margin to the other, as one would roll paper (apricot and banana), and in the relative position of one leaf to another from the *valvate* (fig. 6 *a*), where the leaf-margins merely touch, to the *supervolute* (fig. 6 *g*), where one convolute leaf is rolled round another (apricot). A most beautiful form of vernation of individual leaves is the *circinnate*(fig. 5 *d*), as seen in the tender coils of the fern. The examination of a series of buds would with a little care and patience be a pleasing exercise, and one calculated to increase knowledge of vegetable form. The folding of the sepals and the petals in flower-buds, known as *æstivation*, is, with a few modifications, very much upon the same plan as that in leaf buds.

Returning to the expansion of the leaves, it may be easily observed that the scales, which are mostly brown and dry, do not expand, except in the forms intermediate between the scale and the ordinary foliage-leaf—but rapidly fall away, leaving scars in the form of small, hard, closely-set rings on the stem. They have admirably fulfilled their purpose of sheltering the "winter-buds" from the severity of the colder months (being absent from the buds of plants growing in warm climates and from those which are formed during the more genial parts of the year, as in herbaceous plants) by many an ingenious contrivance, such as hairs and gummy exudations which render them bad conductors of heat and insoluble in water. Nowhere is this object of protection more beautifully carried out than in the bud of the ordinary Plane, which is completely covered by the hollow base of the leaf-stalk at its junction with the stem, and is only revealed when the winds of autumn bring down the leaves. It will then be found to be wrapped in three coverings, an outer of a gummy waterproof nature, a middle of furry scales, and an inner of silky down. These scales may be compared to those found on tubers and on underground stems; and are in reality rudimentary leaves, transitional stages, between their own form and that of the complete leaf, being of common occurrence. According to Goebel, they consist of chiefly of that portion of the leaf which first arises from the growing point, and is known as the "foliar base," which in an ordinary leaf develops so slightly as to be hardly distinguishable from the fully developed "upper leaf," and if a stalk be present it is generally interposed between the two. This "foliar base shows vigorous growth in the scales of the maple and the horse-chestnut, the ordinary "upper leaf" being sometimes so small as to require the microscope to make it manifest, whilst other forms occur in which the latter is easily distinguishable. To prove the origin of the scale from the "foliar base" Goebel took several young plants of the bird cherry (*Prunus padus*) on the 14th April and lopped off their apexes and part of their leaves. By the 10th of May the axillary buds, which should have expanded next spring, stimulated to premature growth by the excess of unused nourishment, began to develop vigorously and normally; the "foliar base," which usually became scales, being transformed into foliage leaves. This interesting experiment he afterwards confirmed upon the horse-chestnut, the maple, the rose, and the oak. The scales of certain plants are formed from stipules—small foliaceous appendages often found at the bases of leaves —as in the tulip-tree and many species of alder, where the two stipules of the lowest leaf are modified into scales.

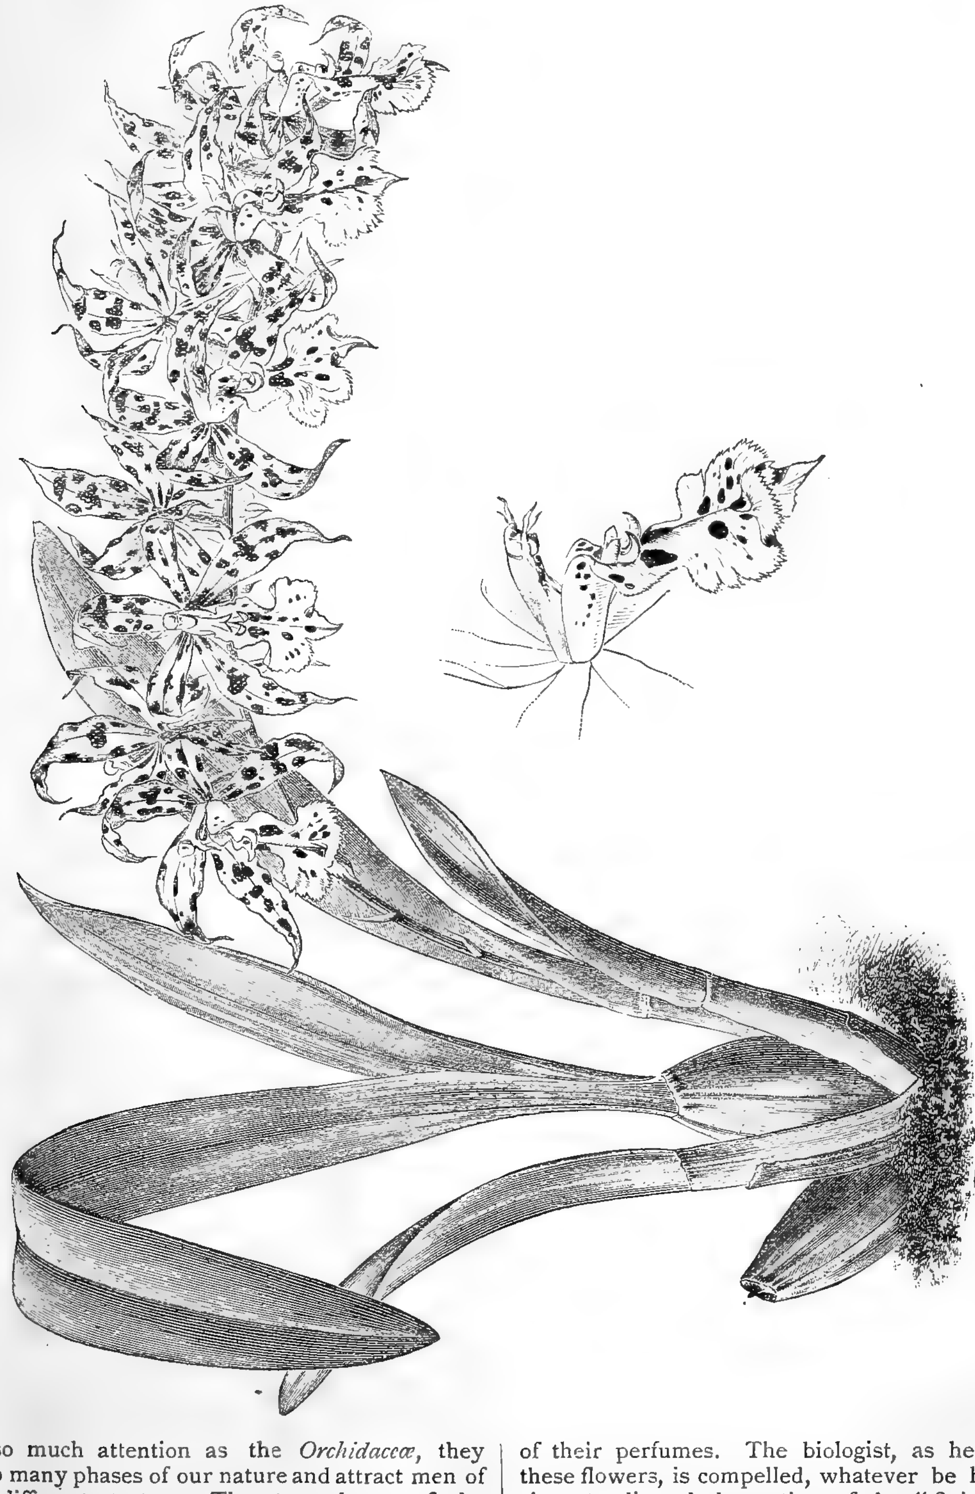
Resuming our study of the development of the foliage-leaves, it will be found that their growth is much more rapid than that of the stem, indeed the *internodes*, or spaces between the *nodes* or attachment of the leaves, in many plants remain as they generally are in the bud, in an undeveloped condition, as in *Nephrodium filix-mas*, or they may be so extremely short as to be apparently wanting, as in plants which exhibit rosettes of leaves (palms, etc.). In other cases, where the leaves are in distant whorls, the internodes are formed immediately after the leaves in the bud. In general, however, the internodes in the fully-formed shoot are well-developed, the nodes having sometimes a constricted and sometimes a swollen appearance, owing to the internal tissue passing off into the leaves, complete rings being formed when these encircle the stem, as in the bamboo and grasses generally, and in some cases the node becomes a separable joint, as found in the common pink.

MIDDLESEX NATURAL HISTORY AND SCIENCE SOCIETY.—This society held its first field-meeting of this summer on Saturday last, assembling at Northwood Station. The members walked through field paths to Batchworth Heath, then skirting Bishop's Wood into Moor Park the walk was continued into Rickmansworth. In the course of the excursion Mr. Thomas Blashill instructed the members on the methods of collecting and keeping wild plants to form a herbarium. Dr. Wharton, who was associated with Mr. Blashill as botanical mentor, contributed in like manner to the instruction of the members.

Natural History.

THE ORCHIDS: WHAT ARE THEY?

THERE are probably no plants, not directly subservient to our bodily wants which, in the present day, win so much attention as the *Orchidaceæ*, they appeal to so many phases of our nature and attract men of the most different tastes. The true lover of the beautiful—we do not here speak of that pseudo-esthetic sect who bow down to sunflowers and dandelions, to marigolds and dog-daisies—when he gazes on an orchid in flower is smitten at first with wonder, which rapidly passes into something verging upon affection. He is simply fascinated by their graceful forms, the purity and the exquisite harmony of their colours, and the delicacy of their perfumes. The biologist, as he contemplates these flowers, is compelled, whatever be his prepossessions to discard the notion of the "fixity of species" as a dream of the past. He sees here hybridism as



ODONTOGLOSSUM BLANDUM (AFTER VEITCH).

much the rule as the exception; he witnesses forms shading away into each other like the colours in the solar spectrum, and he asks at last vainly, What is a species? If he passes from such generalities to details he sees how, as Darwin has shown us, the most wonderful structures are employed for effecting the reproduction of the plant.

The horticulturist finds the management of these flowers in a European climate a task which at once stimulates him by its difficulties and delights him by the success with which his skill is often crowned.

Lastly shall we say that orchids have a particular fascination for the millionaire, and especially for him who has recently arrived at this envied position? A well-stocked, well-managed orchid house, and a constant supply of these lovely flowers for domestic and personal ornament, is proof of wealth even more striking, because more frequently producible, than an overflowing picture gallery. The prices paid for single plants of the rarer and more beautiful species are very high; £500 have been paid for a single plant of *Cattleya mossiœ*, and small shoots of a *Cypripedium* have fetched half that sum. These prices may remind some of our readers of the "tulip mania" which once prevailed in Holland, when fabulous sums were sometimes paid for a single root. There is, however, an essential difference. The "tulip mania" was a development not of horticulture or of flower-worship, but simply of gambling. Bulbs were sold which had no existence, and which were not intended to be delivered. The man who, *e.g.*, bought 100 bulbs of "Semper Augustus"—though, perhaps, not half that number could have been met with in all Holland—expected or hoped that he could in a few hours re-sell them at a profit to some other speculator.

Now in the high prices paid for orchids there is nothing similar. At sales the plants are actually produced, examined, and, when sold, duly delivered. Their costliness is due to their wonderful beauty, and to the difficulty of procuring and preserving many of the finest kinds. If the nurseryman is to send out experienced plant-hunters to the forests of Burmah or Borneo, and to pay for all the appliances needful for conveying home to England the precious booty safe and sound, he must naturally demand a fair profit on his outlay. Nor do we think that the passion for orchids is a mere temporary freak. If it be true in the somewhat hacknied words of Keats, that "A thing of beauty is a joy for ever," these gorgeous plants will always be cherished by all who have the means to acquire them, or the skill to keep them in healthy growth.

We must remember that we are here speaking, not of a single genus, but of a whole family of plants, including many genera and a whole multitude of species. If we make no attempt at their enumeration it is because, as we have already intimated, the task of drawing a definite line between species and species puzzles even the most eminent botanists. But so widely do they differ in their structure and habits that a non-botanist would scarcely think of referring them to the same group. Who, for instance, would think that the common spotted meadow-orchid—as abundant in the pastures of "flowery Suffolk" as is the daisy in the neighbourhood of London—could be a near ally of the magnificent *Odontoglossum blandum*, of which we give an illustration? Yet such is the case. The orchids of Europe, North America, and the temperate parts of Asia grow in the soil after the normal fashion of plants. The orchids of the tropics and of certain exceptional temperate regions, such as the eastern coast of Australia, Tasmania, New Zealand, and Japan, are *epiphytous*, that is, they grow, not in the soil, but upon the trunks of trees or rocks to which they attach themselves. It is curious that the species which thus maintain themselves should be larger and more luxuriant than the kinds growing in the soil, and the most absurd theories have been broached in explanation. Some have even suggested that these plants have the power of manufacturing the mineral matter which they, in common with all plants, require out of air and water! The fact is that the tree-trunks and the rocks themselves supply such matter. Decaying leaves, and other vegetable *débris*, and, above all, the dust of the earth, which can nowhere be excluded, lodge among the root-stems of these plants and supply all the mineral mattter which they need.

The more splendid orchids, therefore, are parasites. Unlike the common run of parasites, however, they are beyond comparison more beautiful than the beings upon which they feed. This may teach us the danger of making sweeping assertions, based, perhaps, upon a number of facts, but leaving others out of account.

In our next article we shall notice some of the more important groups of this wonderful family.

(*To be continued.*)

Bifurcated Palm-trees.—M. A. E. Göldi writes from Rio de Janeiro to *La Nature* to this effect:—"You published, on March 3rd of this year, an article on a bifurcated palm-tree at Cayenne. Such cases are not so rare as you seem to indicate. Here, at Rio, of ten specimens of an ornamental palm, very common in the gardens of the Brazilian capital, four are certainly bifurcated. It is a palm of the genus Areca, probably *A. arundinacea*, known colloquially as '*palmeira bambu*.' In the genus *Oreodoxa*, of which there are many splendid specimens in Brazil, bifurcation is less common, but more than one instance is known. Professor Haeckel, of Jena, on his return from Ceylon, spoke of a bifurcated cocoa-nut tree which had been shown him there as something remarkable."

Natural Food for Young Trout.—A writer in the *Field*, who uses the unpardonable signature of "Detached Badger," cautions trout-breeders against introducing into their tanks any of the parasitical forms of Entomostraca. One of these, *Argulus foliaceus*, he pronounces the most prevalent and deadly enemy of fresh-water fish. Unfortunately, it has the power of leaving the fish upon which it is feeding and swimming freely in the water; hence, when once introduced into a pond containing young fry, it produces a great spread of disease. The same writer points out that the Entomostraca require a due supply of food in the tanks.

Curious Case of Mimicry.—Mr. J. B. Steere (*American Naturalist*) observed in Southern Mindanao a very curious case of mimicry. Among the lizards was a flying species (*Draco*), very abundant on the cocoa-nut trees. On opening the wing-membranes one could not help noticing a likeness to a butterfly both in the shape of wings and in the colouring of blue with red spots. This peculiar colouring may aid the lizard both in escaping its enemies, the hawks, and in capturing its own insect prey.

NOTES ON THE BLACKBIRD.—Mr. H. Kerr (*Newcastle Weekly Chronicle*) mentions, in proof of the imitative disposition of the blackbird, that a wild one was found mimicking the crowing of a cock, and flapping its wings in the style of chanticleer. Mr. Kerr scarcely puts the case fairly when he blames the "ignorant gardener" for his displeasure at this bird's "helping itself to *a little* ripe fruit." Like many other species, the blackbird spoils not "a little," but a great deal, by pecking at the sunny side, when earwigs and flies creep into the holes and complete the mischief. For all this, we would spare every bird except the sparrow.

SWIFTS FLYING BY NIGHT.—Correspondents both of *Nature* and of the *Field* record instances of swifts remaining on the wing through a considerable portion of the night, if not through the whole.

A TRUE TAIL IN A HUMAN SUBJECT.—A case of this rare phenomenon of reversion is stated on the unimpeachable authority of Professor St. George Mivart. He was called in to a consultation on the safety of amputating this superfluous member, which was duly effected. The tail was 2½ ins. long, and was no tumour, mole, or other morbid excrescence, but had true joints, like that of a baboon.

POISONOUS HONEY.—Certain species of bees in Boliva are said to collect a poisonous honey, gathered doubtless from dangerous plants. Others are said by a writer in *Cosmos* to yield a honey endowed with strengthening properties, but in return their black and hard wax has the "the most fatal properties." What is the exact nature of these "fatal properties" the writer does not say, but as we do not eat wax it can be of but little consequence.

THE SERPENT CHARMERS OF THE EAST.—F. Mocquard, writing in *La Nature*, suggests that cobras and other venomous serpents may possibly be thrown, by the manipulations and the monotonous music of the jugglers, into a hypnotic crisis. They are said to become stiff and inflexible like a rod—a state, doubtless, of catalepsy. M. Mocquard suggests that these phenomena deserve a serious scientific investigation.

THE ACTION OF PATHOGENIC MICROBIA ("DISEASE GERMS").—M. Arloing had previously observed that the development of the microbe of the contagious pneumonia of cattle determines the production of a special substance, the most striking properties of which are those of the diastases. He has just announced to the Academy of Sciences that he has obtained the matter in question in a state of purity by precipitating it with absolute alcohol. It is soluble in water, and the solution, on injection into a vein, occasions the same symptoms as the disease germ itself.

THE HESSIAN FLY.—This pest has been again noticed in our cornfields, and on Wednesday Miss E. A. Ormerod received some infested stalks of barley from Mr. George Palmer, jun., of Revell's Hall, Hertford, the gentleman who was the first observer of the pest in England.

THE AQUARIUM OF BANYULS.—According to a paper read before the Academy of Sciences by M. de Lacaze-Duthiers *Murex trunculus* and *Eledone moschata* have deposited ova, a fact never witnessed before in captivity. He exhibited a photograph of a colony of little *Alcyonia*.

THE CANON WREN.

LONG ago, when our country was comparatively new, and naturalists few and far between, hundreds of birds whose notes had never been heard by men of science flitted through the woods, and whose songs, when heard for the first time, were a source of pleasure seldom equalled, and occasioned a feeling akin to idolatry.

Owing to the efforts of ornithologists, this state of affairs no longer exists. True, there is still much to be accomplished in the study of the singing of our birds, but to hear something comparatively new, something not constantly heard of and talked about, it is necessary to enter the more remote and isolated portions of the country, and to traverse the mountains and valleys seldom trodden by man. It is in such localities as this, in the southwestern part of the United States, that the cañon wren (*Catherpes mexicanus conspersus*) is to be found. Here, no matter how lonely, darksome, or dreary the vale, no matter what dearth of life is otherwise to be found, the clear, melodious song of this bird breaks forth from the gloom and thrills the very soul of the listener as with something holy. This is entirely different from the song of any of our birds, and is as marvellous for its character as for its clearness and strength, consisting of a series of eight or ten notes, descending regularly as does the musical scale until the lowest note is reached, each clear and distinct, but prolonged, so as to glide smoothly into the next.

I remember well the first time I heard it. I had been climbing the "Bee Rocks" near Meridian, Texas, and on reaching the summit paused a moment for breath and to rest. From a considerable elevation I looked across the Bosque Valley to the hills on the opposite side, and along the river, for a distance of twenty miles in either direction. The bed, owing to a three years' drought, was dry, save for a few stagnant pools of water, and the valley, although still of a sickly green, contained but little animal life.

In the air above circled countless numbers of vultures, while on the edge of the cliffs perched swarms too gorged to fly, but at times dispelling the monotony by shifting their location in long, awkward hops. The whole presented a scene similar to some of those described by Dante, and a more gloomy and desolate spot would be hard to find. While comparing it with a landscape viewed from a similar location in central New Hampshire, the wonderful note of the cañon wren burst upon the air. It was repeated several times at intervals of about three minutes, when it was answered by another lower down on the cliff. Both sang for some moments, then all was hushed as before. That the rocks had now a new interest, and had assumed a different aspect, can be readily imagined. For some time I waited in vain for it to be repeated, when of a sudden it burst forth again, seemingly directly beneath me. Crawling to the edge and peering over the cliff, the author was discovered some distance below flitting from rock to rock, pausing occasionally to give utterance to its song, then resuming its occupation. To descend to a point about on a level with the bird and conceal myself was the work of a few moments. Presently, with a "chip" and flutter, the little songster entered my retreat, visiting every nook and cranny, peering into every crack and crevice in search of insects. Yet it never for a moment lost sight of me. Coming at times to within a few feet of my hands, it would dart to the opposite side of the cavern and view me from another quarter. Whether it possessed that peculiar, hoarse, chattering note common to most of the family, I was at a loss to know, until, by accident, I moved slightly, when, with a sudden movement, it dashed across the open space, plunged into the bushes, and descended gradually to the bottom of the valley, scolding to itself all the way. During the next half-hour a dozen or more individuals were heard, and many others were undoubtedly in the vicinity. Descending now some fifty feet to a shelf which runs the entire length of the rocks, I followed it for some distance, and was pleased to note a number of the birds in question clinging to the walls, darting into the air and seizing insects in the manner of the tyrannidæ, disappearing from view for a time, while they searched the interior of some dark retreat, and appearing again often where least expected; on one occasion I observed one enter an orifice in the rocks some twenty feet distant, and, while watching closely for its return, was amused to have it dart from a hole directly before my face. The bird was fully as surprised as myself, and considerably more frightened, for it dashed around a neighbouring bluff and went some distance down the cliffs.

This closed my experience with them until later in the season, when I again met a few in the vicinity of Comanche Peak, in Hood country, and again, a week later, on Paluxy Creek; but it was now late in the fall, and their voice had lost much of its melody and richness. They are never, I believe, to be found at any great distance from the gorges and cliffs, which are their favourite haunts, and while the beauty of other localities is enriched by the songs of hundreds of musical little throats, it is reserved for the present species to lift in part and to cheer the gloom which for ever overshadows some of Nature's mightiest and grandest works.—*Scientific American.*

Reviews.

Notes on Inorganic Evolution. By E. A. Ridsdale. London: H. K. Lewis.

If evolution is in truth a primary law of the universe, we should be able trace it, not merely in stars and in living beings, but in the materials of which both stars and living beings consist—that is, in chemical compounds, or, perhaps, even in those elements from which such compounds are put together. Just as at present scientific men are seeking to trace out among organisms the counterpart of the periodic law of Newlands and Mendeleeff, so they are also searching for evidences of evolution in the chemical sphere. Now, here Mr. Ridsdale seems to us to have thrown a new and valuable light upon the question. It is generally admitted that the flora and fauna of the world consist of those plants and animals which have survived as being most fully in harmony with the totality of the circumstances among which they are placed. But can we find anything not identical but corresponding in the mineral world? Mr. Ridsdale tells us that the ruling principle here is the "survival of the most inert." Says the author: "When any new compound is formed, it is produced by reason of the greater affinity of the constituents of the new compound for each other than for the constituents of the older bodies of which they formerly made a part. . . . Bodies whose constituents have little affinity for each other tend to be broken up, and those compounded with stronger affinities to persist." Hence bodies held together by strong affinities will accumulate, whilst those held together by feeble affinities will gradually disappear. But it is further remarked that bodies having for each other very strong affinities may have still stronger ones for some other body or bodies, so that a body thus compounded may have in the long run a smaller chance of remaining unchanged than a body less strongly held together with weaker elemental affinities. Hence the body which is, as a whole, the most inert, is most likely to survive. The author shows—what will scarcely be controverted—that any such gradual "selection of the most inert" must have been exceedingly slow. He thinks that the evidence to be found is, upon the whole, favourable to this supposition. He reminds us that there is a constant tendency for barium salts to become sulphates; magnesium and aluminium salts to form oxides and silicates; silver salts, chlorides; lead salts, sulphides, etc. The inert salt, when once formed, except under abnormal conditions, remains, whilst any other salt, how often so ever it may be formed, is sooner or later broken up.

From these facts—for so far, at least, what he advances may be accepted as fact—certain striking conclusions follow as being, though not demonstrated, yet analogically probable. What are those bodies which we call simple or elemental? Are they not possibly—even probably—compounds which under the existing conditions of things are, *as wholes*, more inert than any other class of bodies, and thus persist? Says Mr. Ridsdale very happily:—"Every chemical body is 'elemental' to some set of conditions, or it could not exist, and an element *may* only be a body stable under more extreme conditions than usual"—in other words, more inert. Pointing out that in any group of the elements, the most active are those with the lowest atomic weights, and *vice versa* (*e.g.*, fluorine as compared with iodine) he suggests as possible that in each group of the elements those with the lowest atomic weights were formed first, and then those with higher atomic weights. Here, as the author intimates, we find ourselves running, not merely parallel to the law of Newlands and Mendeleeff, but to the more recent work of Mr. Crookes, F.R.S. On comparing the workings of this principle of the "survival of the most inert" with those of organic evolution, we can scarcely fail to find a number of very instructive resemblances. Many more passages in this pamphlet, brief but pregnant, deserve careful consideration. But we will merely quote the author's concluding remarks:—"That the various forms of matter are not radically distinct has long been supposed; that the early condition of the universe was fiery and gaseous, has almost passed the domain of theory; that our solar system at least is gradually tending to an inert or dead condition, is generally believed. Any hypothesis that can correct and explain such varied beliefs without running counter to evidence is worthy, at any rate, of a hearing."

Journal of the Franklin Institute of the State of Pennsylvania. Vol. cxxv., No. 6. June, 1888.

By far the most interesting paper in this issue is the report on water-spouts off the Atlantic coast during January and February of the present year, drawn up by Mr. Everett Hayden. These alarming and sometimes dangerous phenomena have been unusually plentiful, both on land and sea. Our readers will remember that two water-spouts—perhaps the German term "Wolkenbruch," or, as it may be rendered, "cloud-burst, is more applicable to such cases when they occur on land—have been recorded in Yorkshire (SCIENTIFIC NEWS, page 583). These spouts Mr. Hayden considers as special cases of whirlwinds and tornadoes, but on a much smaller scale. The general underlying principles he considers to be as follows:—A layer of warm moist air at the surface of the ocean happens to have above it a layer of cooler, drier air. This condition of things is one of unstable equilibrium, and sooner or later the warm light air at the surface rises through the cooler air above. This process sometimes takes place gradually and over a large area, but at other times it is more local, and there seems to be formed in the upper layer a break or opening through which the air of the lower stratum drains upwards, as through a funnel. When the differences of temperature and moisture, and the supply of warm moist air at the surface are very great, this action becomes intense, and this intensity is increased by the fact that as the air rises its moisture is condensed, the latent heat thus liberated adding to the energy of the rising column of air. As this surface air rushes in and escapes upwards through the opening thus formed in the upper layer, it takes up a whirling motion, the velocity of which is greatest towards the centre of the funnel, and a suction or partial vacuum is created, as indicated by the low reading of the barometer towards the centre of a cyclone.

When a whirlwind is thus formed over the ocean, water is often drawn up the centre of the whirl some distance, owing to the suction created, and at the same time the moisture in the air is condensed as it rises, so that the name "water-spout" is very applicable. Indeed, sometimes a spout will burst over a vessel and flood her decks with water, as a cloud burst does on a mountain side. The damage done, however, may exceed flooding. Captain Strandt, of the American bark *Reindeer*, as here stated, reports that on February 11th a heavy water-spout passed over his vessel, when under full sail, and dismasted her to below the heads of the three lower masts. This catastrophe happened near the "still vexed Bermöothes." But how would the ship have fared had the spout been like the one at Langtoft, which bored through the soil down to the solid rock?

During the two months of January and February, and within a comparatively short distance of the American coast, spouts are here recorded as having been seen on fourteen occasions, in one instance nine being observed within half an hour. In other cases four or six were seen at once. Capt. O'Leary, of the British steamer *River Avon*, on February 28th saw, in latitude 39° 30′ N. and longitude 57° 20′ W., "What he took to be a heavy squall to the south-east. Upon looking at it with his glass, he saw that it was a whirlind raising the water to a great height. It must have been *over a mile in diameter*, but he hesitates to even estimate the height to which the water was raised, or the size of the spout."

Mr. Hayden asks for sketches, or, if possible, photographs of these phenomena, together with notes of the temperature of air and water, barometric readings, direction and force of wind, and changes in each, if any, while the spout lasts.

LAND AND FRESH WATER MOLLUSCA OF LEICESTERSHIRE.—We have received from Mr. H. E. Quilter, M.C.S., a list of the mollusca of Leicestershire, indicating their habitat; the list contains sixty-three species and twenty-seven varieties.

Abstracts of Papers, Lectures, etc.

GEOLOGICAL SOCIETY OF LONDON.

AT the meeting held on June 20th, W. T. Blanford, LL.D., F.R.S., President, in the chair, the following communications were read:—

"On the Occurrence of Marine Fossils in the Coal-Measures of Fife." By James W. Kirkby, Esq. Communicated by Professor T. Rupert Jones, F.R.S., F.G.S.

This paper recorded the discovery of fossils of good marine types in the Fifeshire coal-measures. This coal-field is of limited extent, the coal-measures dipping under the sea towards the east and south. The prevailing fossils are those characteristic of the coal-measures in other districts, *Anthracosia*, *Anthracomya*, *Anthracoptera*, *Spirorbis*, many fishes, and some few Amphibian remains. Lately a sinking was commenced in the Upper Red beds, below which, and just above a thin band of poor coal, a thick bed of dark shale was passed through, which proved to be tolerably fossiliferous. *Lingula*, *Murchisonia*, and two species of *Bellerophon* occurred. This horizon was subsequently proved elsewhere in the district, and furnished the following fossils from three localities, namely, *Strephodus sauroides* (?), Ag. (teeth and scales); *Rhizodopsis*, sp. (scales); Palæoniscid scales; *Diplodus gibbosus*, Ag.; *Mesodomodus*, sp. n.; *Petalodus Hastingsiæ; Discites rotifer* (?), Salt.; *Discites*, sp. (with longitudinal ribs)· *Discites*, sp. (smooth); *Orthoceras attenuatum* (?), Flem.; *Bellerophon Urii*, Flem.; *Murchisonia* (*Aclisma*) *striatula*, De Kon.; *Sanguinolites*, sp.; *Productus semireticulatus*, var. *Martini*, Sow.; *Discina nitida*, Phill. *Lingula mytiloides*, Sow.; *Lingula squamiformis;* crinoid stems (*Actinocrinus ?*); plant-remains (obscure).

Reference was then made to the occurrence of similar fossils in the same formation elsewhere, and particularly in the West of Scotland, North of England, and Lancashire. The author concluded, from the frequency of the beds containing true marine remains, that the coal-measures were formed in low-lying areas; and that, when the land was slightly depressed, at times the waters of the sea had access to such spots, bringing back species of shells and crinoids that had existed in the carboniferous-limestone ocean of an earlier period.

In conclusion, the author observed that no marine deposits have been observed as yet in the upper red beds of the Fife or other Scotch coal-measures.

"Directions of Ice-flow in the North of Ireland, as determined by the observations of the Geological Survey." By J. R. Kilroe, Esq. Communicated by Prof. E. Hull, F.R.S., F.G.S.

While the striæ S.E. of a line drawn from Strangford Lough to Galway Bay all trend in one direction, two sets of striæ occur N.W. of that line, which are generally at right angles to each other, and are frequently seen upon the same rock-surface. The direction of these is N. by W. in Antrim and Londonderry; N.W. over the highlands of Fermanagh; and N.E., N., and N. by W. in Donegal, etc. That of the second set is W. 25° S., swinging round to W. in Donegal and S.W. towards Galway Bay, and is strikingly persistent throughout. Besides these, a very few striations occur which do not conform to these directions, and are attributable to local ice-flows.

The second set of striations was referred to the ice of the *Scottish Glacial System*, and evidence was cited from the researches of Messrs. Symes and McHenry, Dr. Geikie, and others in support of this view, which is confirmed by the relative positions of the boulders and their parent rocks. Striæ bearing westward have been observed at a height of 1,100 feet in co. Mayo.

The effects of the *Irish Glacial System* have been considered by the Rev. W. Close, Mr. G. H. Kinahan, and Prof. Hull. Striations occur up to 1,340 feet in Donegal. The ice of this system flowed in a general S.E. direction to the S. of the axis.

With regard to the relative age of the two set of striæ, it is observable that those bearing northward are by far the most numerous; so that although it is reasonable to suppose that as a considerable accumulation of snow and ice obtained in the Irish area whilst the Scotch system was gathering its maximum strength, the striations produced by this gathering would be largely effaced by the westward-flowing Scotch ice; and that, after the decline of the latter, an independent Irish *mer de glace* flowed northward and southward, finding its axis of movement in the great central snow-field.

"Evidence of Ice-Action in Carboniferous Times." By John Spencer, Esq., F.G.S.

The author combated the notion that there is any *a priori* improbability in the action of ice during the period in question. In the case under consideration, of the two agents, land-ice or floating-ice, he was inclined to adopt the latter, as having been the cause of the phenomena he described. The bed affected is the Haslingden Flag-rock, a member of the Millstone-Grit series, which is directly covered by a shale of the same series. The surface of this Flag-rock is largely striated, the striæ having a N.E. and S.W. direction, and being nearly parallel. The area exposed is 200 square feet. The Flag-rock dips to the east at an angle of 30°; but there seems no possibility of these striæ having been produced by landslips or local disturbance. A quarry on the same horizon, near Rochdale, exhibits similar phenomena. As collateral evidence of ice-action, he alluded to the boulders frequently found in the coal-seams.

In the subsequent discussion, Mr. Topley said the question of the striæ was difficult to decide; but he thought the reference to boulders in a coal-seam a thousand feet above did not help matters. He considered the appearances due most probably to movement of the nature of slickensides. It was too hazardous to put it down to ice-action.

"The Greensand bed at the base of the Thanet Sand." By Miss Margaret I. Gardiner, Bathurst Student, Newnham College, Cambridge. Communicated by J. J. H. Teal, Esq., M.A., F.G.S.

This bed may be seen between Pegwell Bay on the east, and Chiselhurst on the west, and a somewhat similar bed occurs at Sudbury, Suffolk. An examination of the Kentish layer showed it to consist of 45 per cent. of quartz, 15 per cent. of glauconite, and 40 per cent. of flint. Amongst the rarer minerals are felspar, magnetite, spinel, zircon, garnet, rutile, tourmaline, actinolite, epidote, and chalcedony; and there are a few microscopic organisms, either Radiolarians or Diatoms, and some Foraminiferal casts.

The Sudbury greensand has 75 per cent. of its grains consisting of glauconite, and of the quartz and flint-grains only 10 per cent. are flint; several of the rarer minerals found in Kent occur here also.

The large flint-percentage in the Kentish grains was alluded to in support of the existence of an unconformity at the base of the Tertiary deposits of that area; and the relatively small percentage of flint in the sands now being formed along a very similarly situated shore, was suggested to be due to the drifting of *debris* derived from the coasts composed of Tertiary and Wealden rocks, which became mixed with the material brought down by the Thames.

"On the occurrence of *Elephas meridionalis* at Dewlish, Dorset. By the Rev. O. Fisher, M.A., F.G.S.

The author's attention was first drawn to this subject on seeing two molars of an elephant in the Blackmore Museum labelled "Dewlish, Dorset." He at once attributed them to *E. meridionalis.* Subsequently he ascertained that they were part of a find made in 1813 by a Mr. Hall. Dr. Falconer, from rubbings, attributed the teeth to *E. antiquus*; and Dr. Leith-Adams would not allow that they belonged to *E. meridionalis*, because that species had never been found so far west. Last year the author and Mr. Mansel-Pleydell went to Dewlish, and the latter has since continued the workings. The remains have been found high up on the face of a steep chalk scarp facing west, ten feet below the brow and ninety feet above the existing stream, in such a position as to suggest that the deposit was the result of an undercut of the stream when it flowed at a higher level.

"On Perlitic Felsites, probably of Archæan age, from the flanks of the Herefordshire Beacon, and on the possible Origin of some Epidosites." By Frank Rutley, Esq., F.G.S.

The author has previously described a rock from this locality in which faint indications of a perlitic structure were discernible. In the present paper additional instances were enumerated and a description was given. The perlitic structure is difficult to recognise, owing to subsequent alteration of the rock.

The author suggested, from his observations, that felsites, resulting from the devitrification of obsidian, quartz-felsites, aplites, etc., may, by the decomposition of the felspathic constituents, pass in the first instance into rocks composed essentially of quartz and kaolin; and that by subsequent alteration of the kaolin by the action of water charged with bicarbonate of lime, and more or less carbonate of iron in solution, these may eventually be converted into epidosites.

He regarded it probable that the rocks are of later Archean or Cambrian age.

"The Ejected Blocks of Monte Somma. Part I. Stratified Limestones." By H. J. Johnston-Lavis, M.D. F.G.S.

Introductory.—The author referred to the Hamilton collection, now in the British Museum, and to the work of Professor Scacchi, who enumerates 52 mineral species as having been found in the ejected blocks, and indicated the importance of these from a geological and volcanological point of view. His own collection contains over 600 specimens, showing the graduation from unaltered limestones, through various stages of change into numerous varieties of "true metamorphic rocks," which, in their turn, shade into igneous rocks more and more approaching the several modifications of the normal cooled magma of the volcano. Moreover, such rocks come from depths where they have not been affected by alterations of a secondary nature.

He then gave a classification of the varieties of ejected blocks. The tertiary rocks are but slightly metamorphosed, whilst the limestones of cretaceous or earlier age afford an almost unlimited series of mineral aggregates. Physical changes have converted them into carbonaceous and saccharoidal marbles; next oxides and aluminates have separated, and silicates have been introduced. Such rocks come under the definition of *accidental* ejectamenta. They are only ejected when the apex of the crater-cavity, formed by an explosive eruption, extends below the platform of the volcano into the underlying rocks. He then traced the history of the eruptions of Somma-Vesuvius through divers phases, showing that it was only at a comparatively late period that limestone fragments were blown out, though this had taken place long before the Plinian eruption. The stratified limestones have been chosen for the first part of this paper, because their original lithological structure acts as a guide as we proceed from a normal limestone to its extreme modifications.

Part I.—The character of the limestones which underlie the platform of Vesuvius may be studied in the peninsula of Sorrento, where the mass attains a thickness of 4,700 feet. They are magnesian in varying proportions. A table was given showing twenty-seven analyses, made principally by Ricciardi, the amount of MgO ranging from 1 to 22 per cent. Silica rarely exceeds 2 or 3 per cent., whereas in the greater number of limestones it is absent. The bituminous matter, though a powerful colouring agent, usually exists in quantities too small for estimation, but sometimes reaches 3 per cent. Such are the materials out of which the extraordinary series of silicate-compounds have been developed, and as these materials of themselves could not form peridotes, micas, pyroxenes, etc., it is clear that the silica, alumina, iron, fluorine, etc., must have been introduced from without, viz., from the neighbouring igneous magma. The author then discussed the question of the probable methods, being inclined to favour the notion of vapour in combination with acid gases.

The bulk of the paper was occupied with a detailed description of the microscopic structure of these stratified limestones and their derivatives. The author remarked that the same metamorphic changes may be traced on a much grander scale amongst the ejected blocks, and hinted at the similarity of these changes to those of contact-phenomena as seen elsewhere, and even of regional metamorphism, the two main factors to be considered being the composition of the rock to be acted upon and that of the magma acting.

The changes which ensue in an impure limestone are, in the first place, the carbonisation of the bituminous contents, which are converted into graphite; and a kind of recrystallisation, approaching the saccharoidal structure, seems to have taken place, although the stratification, etc., is preserved. A few grains of peridote now begin to make their appearance, chiefly as inclusions within the calcite crystals, and thus by degrees the results already recorded are effected. In the early stages only is the metamorphism selective. The order in which the new minerals seem to develop is the following:—

(1) Peridote, Periclase, Humite.

(2) Spinel, Mica, Fluorite, Galena, Pyrites, Wollastonite.

(3) Garnet, Idocrase, Nepheline, Sodalite, Felspar.

Many of these minerals are crowded with microliths, which there is reason to believe consist of pyroxene.

MANCHESTER CRYPTOGAMIC SOCIETY.

At the meeting held on the 18th June, Dr. B. Carrington, F.R.S.E., in the chair, Mr. W. H. Pearson exhibited a collection of mosses and lichens from Jamaica, which had been fowarded by Mr. Cockshot for the Society's inspection. Amongst the lichens Mr. Bowers pointed out specimens of *Parmelia perlata* in fruit. This is a British species, but is always found barren in this country. The collection had been made by Miss Eglinton in the neighbourhood of Kingston, Jamaica. Mr. Pearson also exhibited a collection of Hepaticæ from New South Wales, collected by Mr. Thomas Whitelegge, of the Australian Museum. These had been described, and drawings made by Dr. Carrington and himself, and published by the Linnæan Society of New South Wales. The authors presented a copy to the Cryptogamic Society. Another interesting collection shown by Mr. Pearson was a series of specimens of the Hepaticæ of Queensland, sent by Mr. C. Wild, a former member of the Society. They had been identified for the most part by Herr Stephani, and two had been named by him in honour of the discoverer, Mr. C. Wild, now resident in Queensland.

Mr. F. Bowers exhibited specimens of the Hepaticæ collected by himself during the excursion of the Yorkshire naturalists in the Saddleworth district on Saturday last; and Mr. Pearson exhibited specimens of *Marsupella stableii* which he had found during Whitsun week near Cwm Idwal, North Wales, this being a new station for this rare hepatic.

Mr. William Forster showed a pan of young ferns from his fernery, which was most interesting, showing as it did the reproduction of ferns without the intervention of the developed spore (Apospory). The fern frond experimented upon was *Athyrium filix fœmina*, var. *Plumosum elegans*, which was laid flat upon the soil about three years ago, covered with a sheet of glass. The young ferns were now showing themselves, having sprung from the veins of the old frond so laid down.

Mr. Whitelegge, of Sydney, sent a specimen of a handsome moss, *Spiriden muelleri*, in fruit, which he had collected during a recent scientific expedition to Lord Howes Island. It is a large moss, growing from eighteen inches to two feet long.

EDINBURGH AND GLASGOW GEOLOGICAL SOCIETIES.

These societies had a joint excursion on Saturday to the Camps limestone quarries and the mineral oil works at Oakbank, in the vicinity of Mid-Calder. The quarries were first visited. The rock quarried forms the outcrop of a basin-shaped deposit of very finely-banded limestone, the works following the dip at a pretty sharp angle. A roof eight feet thick, forming the upper layer of the bed, and lying under a tough glacial till, has been left by the workmen, along with massive columns at intervals of about twenty feet; and on entering the cavernous penetralia one is strongly reminded of the ancient temple excavations found in Mesopotamia and Armenia. The oldest and deepest quarry could not be entered: it has been unworked for some time, and has filled with water;

but preparations are being made by Mr. Torrance, the manager, to have the water pumped out, and operations started again. The limestone is a hard, beautifully laminated rock. It was very likely deposited in a small loch into which a stream flowed whose waters were highly saturated with carbonate of lime, which had been precipitated owing to the escape of carbon dioxide and evaporation. The spring had likely been of volcanic origin. Very few fossils were found by the party. The well-known carboniferous plants are of course those that characterise the bed, and a few slabs with scales of lepidodendra and the allied genera were seen, mostly on sheets of shaly blaze that crumbled on being touched. One quarryman brought forward in triumph what he described as a fossil—a small slab studded with crystals of calcite. The party were taken to the office attached to the quarries, and were there shown a few of the fossils said to have been found in the beds. The chief specimen was a well-known brachiopod, *Producta gigantea*, a marine fossil, which, it turned out, had come from Kirkcaldy. The museum also contained lumps of dolomite, steatite, copper and iron ore—from Norway. After inspecting the quarries and these products, the company went on to the oilworks at Oakbank, and were shown over the works and initiated into all the mysteries of that complicated process of chemical decomposition by which all the various commercial products of shale are elaborated.

GEOLOGICAL CLASS, EDINBURGH UNIVERSITY.

The last excursion for this session took place under the guidance of Professor Geikie to Innerwick on Saturday. After examining the carboniferous beds at Innerwick, the class proceeded along the coast to the cove, where were seen the stacks and arches produced in the old red sandstone by marine erosion, also some fine sections showing the false bedding. They afterwards visited Siccar Point, where one of the finest examples of unconfirmity in Scotland between the old red and silurian was inspected. The crumpling and folding of the latter, and their subsequent long exposure to denudation before the deposition of the sandstone were clearly demonstrated.

BEWICKSHIRE NATURALISTS' CLUB.

The second field-meeting of this club was held at Kirknewton on the 27th ult. A visit was paid to the pele tower at Heathpool Farm; very little of the tower is left, but the remains of an old spiral staircase attracted much attention from the size and condition of the stones. A move was next made for Coupland Castle, now composed of an old pele tower and an adapted farmhouse, with a modern building intervening. A fireplace in the pele tower bears date 1619. The party then returned to Kirknewton and inspected the curious church. There is evidence of a Norman edifice having stood on the same site. During the times of Border strife that building was destroyed, and for some time the site remained unoccupied. Subsequently a pele tower was erected, and in a more peaceable period a second church was erected, the vault of the tower being used for the chancel, a feature which makes the edifice peculiarly interesting.

The Parisian Bill of Fare.—The consumption of horse-flesh in Paris for the year 1887, according to *La Nature*, exceeded eight million pounds.

THE SOCIAL CONDITION OF THE BABYLONIANS.

Abstract of a Course of Lectures delivered by Mr. G. Bertin, M.R.A.S., at the British Museum.
Fourth Lecture—Laws.

When a new nation is formed, either by conquest or by revolution, it generally adopts the laws of the preceding society. The Semites, however, when they invaded Mesopotamia found only savage populations, and they brought from their first home no codified laws, for as they were divided into small tribes or kingdoms, traditional customs and what may be called natural laws had sufficed; nor did the arrival of the Akkadians bring any change to this state of things. After the two races had amalgamated there appears to have been an attempt at a codification of the unwritten laws. Whether it was the work of a wise king or that of a philosopher, as happened in Greece, or that of a number of legislators deputed by the people, we are not able to say. The date of this codification is even uncertain, it can only be said that it was anterior to Sargon of Agade (about 3,000 B. C.), and that it was probably the work of Akkadian speaking legislators, for these laws, or rather precepts, were written in Akkadian and translated by order of Sargon.

In these precepts—for they are more precepts than laws—the legislator considers man under his three most important aspects: first as a private individual, second as an agriculturist, third as a trader. The two first treatises or tablets have come down to us nearly complete. In the first are stated the duties of man in his private life; these we have already considered. In the second are enumerated the rights and duties of the agriculturist, the methods he is to use in the cultivation of his field, and the different kinds of tenures; the tablet gives also a list of the furniture, implements, utensils, etc., which constitute the plant of a farm. The third tablet, though much mutilated, appears to be a treatise on property. It speaks of the different kinds of holdings by contract for a limited period, or for life, or by purchase without reservation; of the possession of slaves, horses, and other animals; of the power of the owner had over them, and of the way in which other people were to assist him in capturing fugitive slaves; and of the defects making a contract void. It treats also of payments, loans, and interest on money.

These three treatises were the base of the Babylonian laws; they formed the first text-book of the scribe in his early education, and were always consulted by the interpreters of the law.

With the progress of the society new wants were felt and new points were raised in the courts of laws; these were met by edicts of the king or orders of the governors of towns; but more often the new points raised in the courts of law were decided in the same way as with us; the sitting magistrate, with the assistance of some of his colleagues, after a careful examination of the case, decided according to the best of his ability and gave judgment. This decision constituted a legal precedent, which had force of law if similar cases were brought before the court. There is in the British Museum a tablet on which a scribe has inscribed a certain number of such legal precedents; one, for instance, states that if a man make a contract in the name of another, such contract shall be void unless he has a power of attorney. Another states that if a man has promised to give his daughter in marriage, and has paid part of the dowry, he is bound by this act and cannot withdraw his word. Difficult cases appear to have required the light of the highest authorities in the bar. One tablet bears the seals of seven judges and two scribes. The tablets recording the most important cases involving new points were copied, very often at the request of lawyers, for if the decision recorded was brought as argument the tablet or its copy had to be produced. After every law suit the original tablet bearing the seals of the magistrates was kept by the scribe who had drawn it, but every party concerned received a copy. This explains how we possess several copies of the same document.

The criminal and civil cases were dealt with in much the same way, but in the former the accused was generally put under arrest, and kept in prison till his case came before the court, even when the accusation emanated from a private person. The prisoners so kept in suspicion were sometimes very badly used, especially when accused of political offences. We have the letter of a magistrate who complains in a petition to the king of having been accused by his enemies, and treated most harshly when in prison. Many cases which, among us, are considered as civil were by the Babylonians regarded as criminals, such as repudiation without cause, the refusal of a child to provide for his parents, etc. The criminal court was probably held in a public building in the centre of the town. The civil courts were held at the gates of the town.

Every magistrate was accompanied by his clerk, or witness, as he was called, who answered exactly to the French *greffier*. This special scribe read all the documents, and wrote the tablets giving the decisions of the judge. As already stated, everything appears to have been transacted in writing. The plaintiff or prosecutor had to give his statement in writing, then the defendant answered in writing; the witnesses, when called to the bar might have given their statements in words, but they were always taken down by the judge's clerk, and from this, perhaps, came his name of "Witness." Every statement or affidavit had to be accompanied by all the documents referred to therein, what is called in our legal parlance "exhibits." This last point was essential. A tablet, now in the British Museum, records the case of a slave who claimed the rights of a citizen on the ground of his having been freed by his late master, but not being able to produce the tablet containing the deed of freedom, the judge declared that he could not grant his request, and that he was to remain a slave.

In civil cases the penalties were limited to fines and compensation to the injured party, the condemned was seldom sent to prison, and even this was done only in the event of his refusing, or of his inability, to pay the fine and compensation inflicted on him; for the death of a slave also—for slaves were ranked as properties—money was received for compensation. Capital punishment—mere decapitation by the means of a sword—torture, mutilation, exile and imprisonment were reserved for criminal offences, and judging from the very few number of cases which have come under our notice, the application of such penalties was of rare occurrence. The Babylonians, like the Ninevites, appear to have inflicted the most cruel forms of punishment on their political enemies.

When a criminal had been condemned he was placed in a cart and driven about the town, while a herald announced the cause of his condemnation. In some cases the criminal was even exhibited in the pillory in some public place. There is in the British Museum a small tablet which has been a puzzle to many scholars, for it contains only one sentence, apparently unfinished. This tablet merely gives the text which the herald had to read aloud: "For having killed her own child," and in connection with this custom can be easily understood.

There was no court of appeal among the Babylonians; when the prisoner was condemned his fate was generally sealed. He had, however, one resource—the right of petition to the King. The kings, as a rule, were most conscientious, and took into consideration every letter addressed to them; if a judgment was evidently unjust, there was every reason to believe that it would be reversed.

The Akkadian treatises spoken of above were considered as the base of the Babylonian law, but the laws, as amended, modified, and explained by new edicts of the kings, orders of the chief civil officers of the state, and the legal precedents, were never codified officially; if private works existed on the matter, as is likely, none have come down to us. The consequence is that to get an accurate notion of the Babylonian laws, the student has to go through an innumerable number of tablets taking note of every special case and classifying them, just as the compiler of our English laws has to do if he wishes to produce a book of references, but with this disadvantage, that many important Babylonian documents may be lost, or still buried in Mesopotamia. The labour through which we have to go may give us an idea of the important part played by the legal scribe in every law suit in Babylon.

Another point deserves a special mention, that is the influence exercised by the Babylonian laws and customs on those of other nations. The Babylonian influence on Greek art, literature, religion, and philosophy has recently been recognised, but the laws and customs are no exception. If the Greeks borrowed from Mesopotamia the custom of burning the dead, they must have adopted others also. In fact, when going through these legal tablets one cannot help being struck by the existence of laws and customs which have been continued by the Greeks and Romans. If our lawyers study the Justinian Code, why should they despise and neglect the Babylonian laws? These have, historically, perhaps even a greater importance.

What are Microaerolites?—We are fully convinced of the occurrence of the shooting stars which occasionally traverse the heavens and of the meteoric stones of different sizes which sometimes fall from the depths of space. But it is not so decided whether or not the earth receives true showers of cosmic dust. M. Démoulin has collected and examined the inorganic dust brought down by the rain at Grignon in the Côte d'Or, in France. He calls these dust grains, *microaerolites*. They seem to belong to three distinct types. One kind is globular, very black and highly magnetic, closely resembling ferruginous globules obtained by incandescence. Those of the second type are of a sponge-like structure, resembling minute corals. These also are very magnetic. The third type are small stony masses of variable colour. Among them may be distinguished small black granules which are in general but slightly magnetic.

POISONS AND POISONING.

A Lecture delivered by C. Meymott Tidy, Esq., M.B., etc., before the Royal Institution of Great Britain.

TOXICOLOGY is the science of "poisons and poisoning." How comes "toxicology" to mean "the science of poisons?" The Greek word τόξον (derived perhaps from τυγχάνω) signified primarily that specially Oriental weapon which we call "a bow." In the very earliest authors, however, it included within its meaning "the arrow shot from the bow."

In the first century, A.D., in the reign of Nero (a poisoner and a cremationist), Dioscorides, a Greek writer on Materia Medica, uses the expression τὸ τοξικόν to signify "the poison *for smearing arrows with.*" Thus, by giving an enlarged sense to the word—for words ever strive to keep pace, if possible, with a scientific progress —we get our modern and significant expression "Toxicology," the science of poisons and poisoning.

And there, in that little piece of philology (τόξον and τοξικόν—a bow and a poison), you have not only the derivation of the word, but the early history of my subject.

A certain grim historical interest gathers around the story of poisons and poisoning. It is a history worth studying, for poisons have played their part in history. The "subtil serpent" taught men the power of a poisoned fang. History presents poison in its *first* aspect in a far less repulsive form than it has assumed in latter days—for a world may grow wiser and wickeder withal. Poison was in the first instance a simple instrument of "open warfare." For this purpose our savage ancestors tipped their arrows with poison, in order that they might inflict certain death on a hostile foe. It can scarcely be questioned that the poison of the snake was the first material employed for this object. The use of vegetable extracts (such as *curarine*, the active principle of which is strychnine, and is employed at the present time by certain uncivilised communities) belongs to a later period.

And so the first use of poison was for an "open fight." It was reserved for later times to mix the cup of kinship with a treacherous, diabolical venom!

"An open fight!" Is the suggestion (think you) too wild, supposing "war chemists," with their powders, their gun-cotton, and their explosives never to have been invented, that nations would have turned for their "*instrumenta belli*" to toxicologists and their poisons. I claim, however (notwithstanding that in this we missed our chance), no more for my subject than its due, if I attempt to localise the very cradle-room of science as the laboratory of the toxicological worker.

Besides snake-poison, the use of animal fluids, either alone or mixed with snake-poison, with which to charge arrows, is pre-historic. Thus in old Greek legend we read how Hercules dipped his arrows in the gall of the Lernœan hydra to render the wounds they inflicted incurable and mortal, and how at last Hercules himself was poisoned by his wife's present, the tunic of the Centaur Nessus stained with his poisonous blood, which she vainly hoped might restore her husband's affection, but which only procured for him the frightful agonies and tortures of which he died.

The use of putrid blood as a poisonous agent, and the admixture of the snake-poison with blood, constitutes a curious history, when regarded in connection with our present views on septicæmia. The toxic activity of putrid animal fluids seems to have been recognised in very early times. And I suppose these early observations on the effects of putrid blood explain the view almost universally adopted, that blood itself was a poison. Thus the deaths of Psammenitus, King of Egypt (as recorded by Herodotus), and of Themistocles (as recorded by Plutarch), were said to have been effected by the administration of bullock's blood. Even Blumenbach, so lately as the middle of the last century, persuaded one of his class (by way of settling the question) to drink seven ounces of warm bullock's blood. The young man (good as were his intentions) did not die a martyr to science.

The history of poisons and poisoning, the contents of the first chapter of which I have thus briefly indicated (viz., the toxicity of the snake-poison and of blood), down to the final chapter, which commences with the properties and reactions of arsenic, forms a tempting subject for my lecture to-night. The histories of Circe and Medea—of Livia Drusilla and Locusta—of Tiberius and Nero—of the Borgias—of Hieronyma Spara, Tofana, Catherine de Medicis, St. Croix, and a host of other worthies, have proved charming topics for the marvel-monger. And it would not have been an unworthy subject to bare the truths underlying the stories of generations of story-tellers, obscured as they have become by the demand of ignorant sensationalism and the terrors of a mean superstition. But this is not the subject I have proposed to myself for the discourse to-night.

"What is a Poison?"

Two difficulties present themselves in answering this question:—

1. *The law has not defined a poison, notwithstanding that the law at times demands of science the definition of a poison.*

I know a case, for example, where a prisoner, indicted for the administration of a poison, escaped because the scientific witness declined to say that the drug administered by the prisoner was a poison.

2. *The popular definition of a poison is far from being a sound, much less a scientific definition.* Generally speaking, it comes to this, that "A poison is a drug that kills rapidly when administered in a small quantity."

The phrase "a small quantity" as regards weight, and the word "rapidly" as regards time, are as indefinite as the classical piece of chalk as regards size.

I define a poison as—

"Any substance which otherwise than by the agency of heat or electricity is capable of destroying life either by chemical action on the tissues of the living body, or by physiological action after absorption into the living system."

(A) It will be convenient to consider first, *What a poison is not.*

It is not an agent that destroys life by physical influences, such as heat and electricity.

It is not an agent that destroys life by any purely mechanical act (*e.g.*, pins are not poison, although fairly included in the phrase "destructive things").

It is not an agent that destroys life by the mere blocking out of that which is necessary to maintain life (*i.e.*, the action of a substance to be a poison must be more than mechanical).

This latter point requires further consideration:—

Both nitrogen and carbonic acid destroy life as certainly as they extinguish a burning taper. Yet nitrogen is not a poison, whilst carbonic acid is.

Nitrogen simply destroys life by blocking out oxygen. Given the presence of 20 per cent. of oxygen, the 80 per cent. of nitrogen possesses no toxic effect.

The carbonic acid, on the contrary, is specifically toxic. The admixture of 20 per cent. or of 80 per cent. of oxygen does not materially alter the case. Oxygen or no oxygen, CO_2 is a poison.

(B) Consider next, *What a poison is.*

It is an agent capable of destroying life.

The use of the phrase *deadly* poison is surplusage. If a body be a poison, it is deadly; if it be not deadly, it is not a poison.

My definition limits the mechanism whereby the toxic effect is induced, to *chemical* and *physiological* actions. I am conscious that this definition suggests classification. Certain it is, that Nature hates classification as truly as she declines definitions.

Let us trace some of these mechanisms of toxic activity. I select three illustrations of poisons belonging to different classes.

(1) *Sulphuric Acid.*—If a person swallows *sulphuric acid*, the tissues with which the acid comes into contact are more or less charred—"more or less," that is, according to the strength of the acid and the time of contact.

Charred.—This implies a chemical act, dependent on the power of sulphuric acid to combine with water.

The portion of the body thus charred dies. We call this *molecular* death. (This does not imply that *the person* is dead. Health is disturbed. Health is derived from the old Saxon word "Wholth," signifying *entirety.* Health implies the perfect rhythmicity of the bodily functions. It is that condition expressed with charming simplicity by Suffolk folk, who describe being "quite well" by the phrase "*they feel all over alike.*" The charring process [molecular death] has disturbed rhythmicity.) Before long all the members suffer with the charred stomach. The death, localised in the first instance, becomes general, the death of the entire body, *i.e.*, of the person, eventually taking place. We call that *somatic* death. This is poisoning by sulphuric acid. But the primary act of disturbance—the first interference with the rhythmicity of health—resulted from the chemical power of sulphuric acid to combine with water. It will be evident that the chemical action of a poison depends on the chemical relationships of that poison.

(2) *Carbonic Oxide.*—Carbonic oxide is a true poison. It is a gas that may often be seen burning with a blue flame on the top of a bright fire in the open fire-stove.

Its importance amongst poisonous bodies depends on the circumstance that it is evolved in many manufacturing operations (*e.g.*, lime and brick kilns, iron blast furnaces, copper-refining furnaces, etc.), and that it is always present in small quantity in coal-gas, constituting its true toxic constituent.

What, then, is the mechanism whereby carbonic oxide destroys life? The active agent of the blood is its red colouring matter (*Hæmoglobin*). To the chemist this substance abounds in wonder.

We have reason to believe that hæmoglobin is formed from the albumenoids, the synthesis of which albumenoids is limited to the vegetable. Essential as the albumenoids are to animal life, the animal is dependent for their formation on the synthetical processes taking place in the plant laboratory. The animal, however, can transmute one albumenoid into another (*e.g.* he can change albumen into a peptone), whilst he can also form from them bodies of less complicated constitution (*e.g.*, fat)—in other words, he can lower them in the scale. But, save with one exception, he cannot use them to effect higher synthetical formations. This single exception is hæmoglobin.

It is no matter for surprise that a body like hæmoglobin—one of the chief actors, so to speak, in the curious drama of life and living, which comes on the scene through a stage opening of which we neither know construction nor whereabouts—should possess unique chemical properties and relationships. I shall only trouble you this evening with one of these relationships.

As a general rule a substance that combines with oxygen with difficulty parts from it with ease, and *vice versa.* It is difficult to make gold combine with oxygen, but it is easy to decompose oxide of gold. Potassium easily combines with oxygen, but it required the genius of a Davy and the resources of the Royal Institution to separate potassium and oxygen.

In hæmoglobin, however, we have a substance that combines with, and delivers up, its oxygen (*i.e.*, is oxidised and reduced) with almost equal facility under similar conditions. Upon this and other chemical characteristics of hæmoglobin—as the oxygen-receiver, the oxygen-carrier, the oxygen-deliverer, the carbonic-acid receiver, carrier, and deliverer—the act of living depends. In other words, life depends on *the integrity* of the hæmoglobin—on the rhythmicity of those chemical processes in affecting which hæmoglobin is the primary worker.

With these facts before us, let us turn to the toxic action of carbonic oxide.

The hæmoglobin at once seizes upon and combines with the carbonic oxide, carbonic-oxide-hæmoglobin being formed.

Two difficulties arise:

1. The hæmoglobin, saturated with carbonic oxide, cannot combine with oxygen. Regarding hæmoglobin as a *common carrier*, the carriage is full.

2. The hæmoglobin, being saturated with carbonic oxide, cannot get rid of the carbonic oxide under the ordinary conditions of respiration and circulation. Again, regarding the hæmoglobin as a common carrier, the vehicle, full up, cannot be unloaded.

To put all this in scientific phraseology, carbonic-oxide-hæmoglobin is a comparatively stable compound, being neither decomposed by the presence of an excess of oxygen (as in the lungs) nor by carbonic acid. What must happen? The man dies because the integrity of the hæmoglobin has been disturbed—because the normal sequence of its oxidation and reduction has been interrupted by the formation of carbonic oxide hæmoglobin.

We call the result of all these chemical actions and interferences, poisoning by carbonic oxide.

3. *Strychnine* (the poison derived from St. Ignatius' Bean).

How does strychnine act? We know sadly little about it—so little that we use the phrase "physiological action" to express our want of knowledge. But we know something.

A marked chemical characteristic of strychnine is its power to combine with oxygen when the oxygen is presented to it in a nascent form.

Note then the conditions. Strychnine is in the body. There is also present in the blood hæmoglobin loosely combined with oxygen, which oxygen the hæmoglobin is always ready to give up on first demand. We are able to trace this action, and to see that the period of the primary strychnine fit coincides with the reduction of the hæmoglobin.

Why (you ask) does that kill? I cannot tell you. It is the highest form of knowledge to see the limits of positive knowledge, and to make that the starting-point for fresh inquiry.

From what I have said, it will be evident that my object has been to trace toxic energy to the chemical action of poisons on living tissues or fluids. The phrase "physiological action" must not be understood as implying any theory *re modus operandi.* There is a danger lest the phrase "physiological action" should be employed, or regarded, as explanatory. It no more explains (be it remembered) the action of certain drugs on the living body than the word catalysis explains fermentation.

(*To be continued.*)

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

EFFECT OF THE VENOM OF THE RATTLESNAKE ON ITSELF.

On page 612 of your paper it is said that "the venom of a viper or a cobra is entirely without effect when introduced into its own system or into that of another of its kind." This rule does not hold good with all snakes. A rattlesnake in the possession of Dr. Dearing is stated by Dr. W. J. Burnett, of the Boston Society of Natural History, to have "accidentally struck one of its fangs into its own body, when it soon rolled over and died." E. P. P.

THE NEW RINGS OF SATURN.

Your journal of June 29th contains an interesting description of the alleged discovery, by Dom Lamey, of several new rings exterior to those already known to gird the planet Saturn. The announcement of these new features will come as a genuine surprise to all those numerous observers who have never discerned a vestige of them, though habitually studying this interesting planet during a long series of years. I have myself obtained many hundreds of careful observations of Saturn, during the last quarter of a century, but never noticed anything of the rings supposed to have been seen by Dom Lamey. My own negative results, combined with the similar experience of hosts of other observers, lead me to the confident assumption that the new rings have no objective existence. They are either imaginative or illusory instrumental phenomena, and it is desirable, for the sake of scientific truth and the necessity of avoiding the dissemination of error, that the presumptive discoverer should critically test his instruments and his vision, and endeavour to trace out the cause of his abnormal seeings. He may depend upon it that he has been misled by non-attention to some simple source of illusion, and that the new rings have no foundation in fact. They are probably false appearances; the images of the true rings are perhaps reproduced by the bad adjustment of the lenses of the telescopes employed.

I think we may safely regard these supposed new rings of Saturn as in the same category as the satellite of Venus, the planet Vulcan, the rings of Neptune, and other chimerical discoveries which are more fanciful than real.

A Member of the Liverpool Astronomical Society.

ANSWERS TO CORRESPONDENTS.

C. W. L.—Kindly send your address. See notice at the head of this column.

RECENT INVENTIONS.

The following list has been compiled especially for the Scientific News *by Messrs.* W. P. Thompson *and* Boult, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

Removal of Old Varnish.—A Mr. Myer has just patented in Germany a composition for removing old varnish from objects. It is obtained by mixing five parts of 36 per cent. silicate of potash, one of 40 per cent. soda lye, and one of sal ammoniac (hydrochlorate of ammonia).

Music.—Mr. J. Sample has patented means for turning over leaves of music. The invention consists of a tassel attached in rotation to the edges of the leaves of music, so that the tassel on the first leaf is at the bottom, the tassel on the second an inch higher, and so on to the end. The tassels or fringe may be fastened to the leaves by gum or other fastener.

Steam Generators.—Mr. J. Smith and D. Cowan have patented a steam generator. The invention consists essentially in the combination and arrangement of tubes and flues whereby a double return of the flame and heated gases from the furnace is obtained, and the area acted upon by them considerably increased. A thorough absorption of all the gases before they reach the chimney is ensured, and thus a great saving of fuel is obtained.

Electric-energy.—Mr. J. Ross has patented means for the production of electric-energy for lighting purposes. According to the invention, two commutators are mounted on the same spindle, which is driven at a high speed by a small motor. These commutators are each placed in circuit with a dynamo electric machine. They are also each placed in circuit with the inner and outer wires respectively of an induction coil, through which alternating currents of electric-energy are made to pass. The electric-energy produced may be employed for lighting lamps or other purposes.

Targets.—Mr. W. E. Heath has patented a miniature target for rifle practice at short ranges. The target is constructed as follows:—An iron shield, with wings to prevent splashing, is provided, having in its upper portion an opening through which the target is shown representing the proportion of a target as seen from the firing point on the actual range. The bull's-eye is in all cases at about the same height. Behind the screen is placed an iron plate, forming the segment of a circle, to which are attached all the targets required in their varying sizes. This plate revolves on a centre, so that any target can be shown at the opening by revolving; provision is also made for marking.

Speaking Tube.—A speaking tube has been patented by Mr. S. Gratrix, Manchester. This invention is to avoid the necessity of speaking and hearing at the same mouthpiece. The metallic coupling to which the tube and mouthpiece are attached is provided with another opening at the side which is covered by a revolving disc, to which is connected one end of an elastic tube, having an ear-piece at the other end. The revolving plate is so constructed that when the tube is allowed to remain in its normal position it closes the side opening so that there is no communication between the speaking tube and the ear-tube, but when the latter is raised to place it to the ear it opens the communication with the speaking tube.

LIFE-SAVING JACKET.—Mr. S. y. Valdivielso has patented a life-saving jacket. This garment is formed of waterproof material in the shape of a jacket having a hood which covers the head with the exception of the mouth, nose, eyes, and ears. The jacket, hood, and sleeves are all made of double cloth hermetically joined, so that when inflated by means of tubes it forms an air bag all round the body, the jacket being attached to the waist by a belt and metal rings. The front of the garment has four waterproof receptacles to carry water, meat, a lamp, and a trumpet. The back has a waterproof receptacle for containing documents, jewellery, etc. When not in use this garment is used as a handbag, but when in use it will sustain the wearer in the water, leaving his hands and all body movements free.

SIGNALLING.—Mr. P. R. Derriman has patented a visible signalling code. According to this invention, four signal lamps or flags are employed, these being arranged so as to be raised and lowered in rapid succession, and thus be visible and invisible at the distant station. The system is arranged so that the four signals being used in succession in various preconcerted orders, will indicate the letters of the alphabet, not more than three signals being required for any one letter. Of these groups of signals representing the alphabet, about one hundred sets are set out in a key book in four sections of twenty-five each, and to each is affixed, in the key book, a number whereby the same may be referred to a code of such phrases and signals as are most commonly required for use. These code numbers are capable of being increased to several thousand if desired.

GUNS.—Mr. W. Anderson has patented an apparatus for loading guns. The apparatus is as follows. The barrow, carrying the shot, has upon it two standards, at the upper end of which are recesses in which are carried the trunnions of a tray, in which the shot is laid. The shot is held steady in the tray by a movable stop upon the handle, which is removed before the shot is elevated to the gun. This elevating apparatus consists of a curved rack held between guide rollers, so that a circular movement can be imparted to it by a pinion which gears with the rack teeth. The curved rack has at its rear end an outer cradle, which receives the shot to be elevated, and also the tray in which the shot is carried upon the barrow. As the barrow comes to its place against the lifting apparatus, the trunnions on the inner tray pass up inclines upon the sides of the outer tray and drop into recesses; then the curved rack being put in movement the shot and trays are carried up in a circular course to the position required. When on the barrow, the shot is carried with its point inclined upwards at a considerable angle, but as in elevating the movement is over a curved course, the axis of the projectile becomes nearly horizontal, and it is then properly aligned to enter the gun.

TECHNICAL EDUCATION NOTES.

NATIONAL ASSOCIATION FOR THE PROMOTION OF TECHNICAL EDUCATION.—On Saturday afternoon the second annual meeting of this Association was held at the rooms of the Society of Arts, John Street, Adelphi. Lord Hartington, who presided, in his opening address referred to the Bills dealing with technical education in the House of Commons. The Bill of last year had been supported generally by the Association as being a step in the right direction, although they had desired to press on the Government and on the House several important amendments. The Bill of the present session, while it would, he believed, remove some of the objections which they had had to the measure of last year, contained proposals which he feared would revive some of the old controversies on the subject of education generally, and especially upon the religious question and the question of denominational and voluntary schools, which he feared would endanger the passing of any measure this session, and would be prejudicial to the cause of technical education. He trusted, however, that the effect of the discussion which had taken place might be to secure the passing of some measure without much further delay. The Committee of the Association still felt that there was a wide field open to the exertions of the Society by the establishment of branches in all the commercial centres by the circulation of information, and especially by the promotion of discussion as to the scope and character of the technical education which required to be provided. There were very few open opponents to the extension of technical education. There were very few who actually disparaged or denied its necessity, but still they were very far from having obtained a proper recognition of its necessity and importance. If we could rely on the old agencies and the old methods to secure that supremacy in later times they might rest in peace, but if they were threatened by a new and a formidable competition in all parts of the world, then, if other nations have discovered by means of a better system of technical education how to make the labour of their populations more valuable, and if they had discovered methods of competing with ourselves, which were better than our own, then he thought the Association, by calling public attention to it, and by endeavouring to point out the way in which we could retrieve, if we had lost, our commercial prosperity, was one which was doing a good work, and one which deserved the support of the country.

ANNOUNCEMENTS.

AWARD TO PROFESSOR VIRCHOW.—The Scientific Society has adjudged the Boerhaave gold medal for anthropology to Professor Virchow.

BRISTOL AND GLOUCESTERSHIRE ARCHÆOLOGICAL SOCIETY.—This Society will hold its thirteenth annual meeting at Gloucester on the 16th, 17th, 18th, and 19th of this month. The opening meeting will be held on Monday morning; in the afternoon the cathedral will be visited, and in the evening papers will be read on "The Annalia Dubrensia," by Mr. F. A. Hyett; "The Masons' Square and Masons' Marks," by Mr. H. Jeffs; and on "St. Oswald's Priory," by Mr. H. Medland. On Tuesday Mr. J. Bellows will deliver an address on "Roman Gloucester," and the Rev. W. Bazeley an address on "Mediæval Gloucester." Parties will be organised to visit the Roman remains, and the churches, priories, and other mediæval remains. An expedition will also be made to Llanthony Priory and Hempstead Church. In the evening the following papers will probably be read:—"The Hospitals of St. Margaret and St. Mary Magdalene," by the Rev. S. E. Bartleet, M.A.; on "The Grey Friars, Gloucester," by Rev. W. H. Silvester Davies, M.A.; on "Scrivens' Conduit," by Mr. H. Medland; and on "Gloucester Tokens of the 17th Century," by Mr. J. P. Wilton. On Wednesday an excursion will be made to Brockthorpe, Haresfield, Standish, Hardwicke, and Elmore. In the evening there will be a *conversazione* in the temporary museum. On Thursday the final meeting will be held, and an excursion will be made to Churchdown, Badgeworth, and Prinkwash.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

SELECTED BOOKS.

Outlines of Geology. By James Geikie, L.L.D., F.R.S. An introduction to the Science for Junior Students and General Readers. With 400 illustrations. London: Edward Stanford. Price 12s.

Three Cruises of the "Blake." By Alexander Agassiz, Director of the Museum of Comparative Zoology at Cambridge, Mass. Fully illustrated. London: Sampson Low, Marston, and Co. In 2 vols., 8vo. Price 42s.

Nature's Hygiene. A Systematic Manual of Natural Hygiene. By C. T. Kingzett, T.I.C., F.C.S., Ex-Vice-President of the Society of Public Analysts. Third edition. London: Bailliere, Tindall, and Co. Price 7s. 6d.

The Physical Culture of Women: Lecture delivered at the Parkes Museum of Hygiene, March 16th, and at the Society of Arts, April 25th, 1888. By Miss Chreiman. Published by request. London: Sampson Low, Marston, and Co. Price 1s.

Forms of Animal Life. A manual of Comparative Anatomy, with Descriptions of Selected Types. By the late George Rolleston, D.M., F.R.S. Revised and enlarged by W. Hatchett Jackson, M.A. Second Edition. London, Clarendon Press. Price 36s.

A Text-Book on Steam and Steam Engines. For the Use of Students Preparing for Competitive Examinations, By A. Jamieson, C.E., F.R.S.E. Prof. of Engineering. Glasgow Technical College. With 200 illustrations and four folding Plates. Third edition. London, Charles Griffin and Co. Price 7s. 6d.

A Manual of the Mollusca. A Treatise on Recent and Fossil Shells. By Dr. S. P. Woodward, A.L.S. With Appendix by Ralph Tate, A.L.S., F.G.S. With numerous Plates and 300 Woodcuts. Fourth edition. London: Crosby, Lockwood and Sons. Price 7s. 6d.

Electro-Plating: a Practical Handbook on the Deposition of Copper, Silver, Nickel, Gold, Aluminium, Brass, Platinum, etc., with Descriptions of the Chemicals, Materials, Batteries, and Dynamo Machines used in the Art. By J. W. Urquhart, C.E. London: Crosby, Lockwood and Co. Price 5s.

An Atlas of Anatomy; or, Pictures of the Human Body. In 24 large Coloured Plates, comprising 100 separate figures, with descriptive letterpress. By Mrs. Fenwick Miller, late Member of the London School Board. Third edition. London: E. Stanford. Price 12s. 6d.

The Laboratory Guide. A Manual of Practical Chemistry for Colleges and Schools. Specially arranged for Agricultural Students. By A. H. Church, M.A., F.R.S., Professor of Chemistry in the Royal Academy of Arts. London: Gurney and Jackson, 1, Paternoster Row. Price 6s. 6d.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, July 2nd, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	48·9 degs., being 1·9 degs. below average.	5·6 ins., being 0·5 ins. above average.	472 hrs., being 37 hrs. above average.

Scientific News

FOR GENERAL READERS.

FRIDAY, JULY 20th, 1888.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

In my last I said something that may have puzzled some of my readers, viz., that the indestructibility of matter is virtually the same as the conservation or indestructibility of energy.

The following passage by an eminent writer, who has ably elucidated the subject of the conservation of energy, shows plainly enough that an explanation of my apparent heresy is demanded.

Balfour Stewart says (*Nature*, vol. ii., p. 78) that "the chemist has always taught us to regard quantity or mass of matter as unchangeable, so that, amid the many bewildering transformations of form and quality which take place in the chemical world, we can always consult our balance with a certainty that *it* will not play us false." But now the physical philosopher steps in and tells us that energy is quite as unchangeable as mass, and that the conservation of both is equally complete. There is, however, this difference between the two things—the same particle of matter will always retain the same mass, but it will not always retain the same energy."

Here is stated a broad distinction between mass and energy, although the mass is described as measured by gravitation. Mass is regarded as inherent, while energy is represented as something contingent, something supplied to matter from outside—something demanding, as Herbert Spencer says, an outside conservator to effect its conservation.

According to my view, the energy of matter is inherent, and what we call the *mass* of matter is simply a measure of its primary energy, *i.e.*, its gravitation. As Stewart says, the balance is always consistent, but what is a balance but an instrument for measuring the mass of matter in terms of its gravitating energy?

I regard that old scholastic word "*inertia*" as a most wicked word—philosophically speaking—as the source of an incalculable heap of offences against true philosophy. Matter is not inert; those who believe it to be so are scientific pagans, their paganism corresponds to that of the ancients and other savages. These people imagined an outside fetish, or spirit, or god, or demon to specially animate moving masses; there was Boreas, who set the winds a-going; there were river gods that made the river flow; there was Apollo, to give the sun a daily ride in his chariot; there was Vulcan or Thor thumping out earthquakes; there was Jupiter, with his handful of thunderbolts, transacting the business now made over to the electric fluid; and a multitude of other active movers of inert matter.

In continuation of the above-quoted passage, Stewart says, "As a whole, energy is invariable, but is always shifting about from particle to particle, and hence it is more difficult to grasp the conception of an invariability of energy than of an invariability of mass."

Energy is thus presented as an active, meddling spiritual entity—a demon or fairy always at work setting dead or inert matter in motion, and possessing that special attribute of the gods and demons and fairies, the power of assuming various forms, according to the tricks to be played or the work to be done.

Why not reject, at once and completely, all these superstitions, whether ancient or modern? Why not accept the unquestionable fact that matter is active—that all the energies or forces of the universe, so far as we know them, are simply the inherent activities or energies of matter itself? How it became endowed with such activity is a question I will not venture to approach.

We become acquainted with the existence of matter only by means of our senses—by its action upon our senses. I see an object when the object is actively engaged in emitting radiations towards my eyes. Otherwise I see it not. I smell an object if it is actively emitting odour. I taste those things which have certain chemical activities. I hear the movements of those bodies which actively transmit their tremblings to the air, and thence to my auditory apparatus. I feel those objects that resist my efforts to remove them, or that exert an energy of cohesion resisting my passage through them.

If a world as big as Jupiter, and absolutely inert, were now in front of me, touching my nose, I should be unconscious of its existence. If absolutely inert, it would have no energy of reaction wherewith to resist my slightest forward movement; I should pass through it or push it forward without sensible effort. I could not see it unless it were actively emitting light. It would not hide other objects unless its own energy were sufficient to overpower the energy of luminous radiation.

The idea of such a body is of course a paradox, but why? Simply because our natural and necessary idea of an existing thing involves fundamentally the idea of some inherent energies, *i.e.* properties, in such entity.

Long ago Torricelli said, "La materia altro non è che un vaso di Circe incantato, il quale serve per ricettacolo della forza"—"Matter is nothing more than an enchanted cup of Circe serving as the receptacle of force." He thus located force within matter itself, but I go further, and maintain that matter and force are inseparable—for aught we know, identical.

All matter is in motion or striving to move. The chair on which I sit is moving with the earth in its rotation and revolution and flight with the sun through space, and is at the same time striving to move towards the earth's centre, and would do it, but for the active resistance of the earth's cohesive energy.

If you strike a man, and he retaliates with equal force, you cannot describe him as inert. In like manner I regard Newton's axiom, that action and reaction are always equal and contrary, as a description of the universal pugnacious activity of every form of matter.

To further illustrate this, let us take an imaginary case. Let us suppose the earth to be perforated by a tubular tunnel, going through from any part of its surface to its centre of gravity and on to the antipodes. Let us suppose this tube to be a vacuum. What would happen if a ball of any material were dropped from one end of the tube in such position that it should not come in contact with the sides in the course of its falling through? It would descend with accelerated velocity until it reached the centre; the velocity there acquired would be just sufficient to throw it up to the antipodean surface on the other side of the earth. At the surface it would stop for an instant, then fall back, and go on again to its starting place. This reciprocating journey would continue eternally, and the whole motive force producing such perpetual motion being the inherent activity of the matter of the earth and that of the travelling ball, *i.e.*, their gravitating energies, the invariability and indestructibility of which is shown, as Stewart says, by "our balance with a certainty that it will not play us false."

In this case we have molar motion of enormous velocity, both created and arrested without any loss or increase of temperature whatever.

Before leaving this subject, I must correct a common error, viz., that of assuming that the doctrine of the conservation of energy is a modern innovation (see Balfour Stewart, *Nature*, vol. i., p. 647). Leibnitz, who was a contemporary of Newton, in a letter to Dr. S. Clarke, says: "*I have maintained the conservation of active forces in the world.* It was objected to this that two soft, non-elastic bodies, on meeting, lose some of their force. I answer no. It is true that the masses lose it, as to their entire movement, but their particles receive it, being internally agitated by the force of the meeting. Thus the loss is only in appearance. The forces are not lost, but only dissipated among the small particles. Now this is not to be lost, but to act as those do who change a piece of money into small coin."

No modern writer has enunciated the doctrine more concisely and clearly than this.

TENNYSON AS A NATURALIST.

TENNYSON is our English Theocritus. It would be bold to claim that he has excelled the Sicilian idyllist in charm or knowledge of his art, but it is not extravagant to thank him for giving to the grave thoughts of our reflective age that airy poetic touch with which Theocritus was able to brighten the trivial details of a simple country life. In Tennyson we have many qualities besides those that make the singer. Among the rest are learning and knowledge of Nature. Perhaps no English poet since Milton has read so widely and so profitably in the books of ancient verse; probably no poet in any past age has drawn so real an inspiration from birds, and flowers, and from the thoughts which occupy the scientific student. Sometimes Tennyson uses his knowledge of Nature as a store of graphic circumstance. Observation enables him to enrich his expression by telling epithets, without alteration or even expansion, of the thought thus decorated. When he bids the long-delaying new year

"Bring orchis, bring the foxglove spire,
The little speedwell's darling blue,
Deep tulips dashed with fiery dew,
Laburnums, dropping wells-of fire."
("In Memoriam," lxxxiii.)—

our memory gains some jewelled phrases, which, detached from all thought of sorrow for the dead, come back into our thoughts year by year, as the seasons bring the flowers of summer.

Sometimes the observation of the naturalist-poet is so penetrating as to fix our attention for all future years upon features in which no one before Tennyson saw anything worthy of remark.

"More black than ash-buds in the front of March"

is a line which stamps an emphasis never to be forgotten upon a sight which we used to pass by with listless indifference.

The stanza,

"When rosy plumelets tuft the larch,
And rarely pipes the mounted thrush,
Or underneath the barren bush
Flits by the sea-blue bird of March,"

sets the larch and the kingfisher of early spring in their corner of the canvas with the sprightliness and the sure touch of Rosa Bonheur.

Tennyson has other uses for these rapid glances into the underlying significance of Nature. Now and then the flash of unfamiliar analogy suggests a thought new to poetry. The lines,

"Wearing his wisdom lightly, like the fruit
Which in our winter woodlands looks a flower,"

are the very soul of that Dedication, which, but for the Spindle-tree, would have taken a quite different and less vivid turn.

The verses to J. S. reach their highest point when they bring in the long-lasting summer twilight of the northern shores, never turned to such poetic service before:

"His memory long will live alone
In all our hearts, as mournful light
That broods above the fallen sun,
And dwells in heaven half the night."

That Tennyson's use of natural fact depends upon real sympathy—that the sight has power in him to call up the thought—is clear to all who observe how the animals and flowers which throng his written fancies render each its due service. This is the test of reality and sincerity. Browning squeezes into his rhymes

"The bee with his comb,
The mouse at her dray"

(It should be the squirrel),

"The grub in its tomb,
Wile winter away;
But the fire-fly, and hedge-shrew, and lob-worm, I pray,
How fare they?"

The bee, and the grub, and the lob-worm do nothing for the poet at least. But what desolation is added to Aylmer's Field by the shy creatures which come back to their ancient haunts, after the wilful lord has undone the last of his race:

"The hedgehog underneath the plantain bores,
The rabbit fondles his own harmless face,
The slow-worm creeps, and the thin weasel there
Follows the mouse, and all is open field."

THE BLACKMAN AIR PROPELLER.—II.

IN our last number we described this very useful apparatus, and mentioned that, besides being suitable for ventilation, it is largely used in many industries for drying purposes. In the accompanying figures we illustrate some very successful applications of the propeller. Fig. 2 represents the rag-cutting room of a paper mill, where the dust is not only very inconvenient but injurious. By means of a propeller, which causes upward currents of air through gratings in the floor, in the direction ot the arrows, the dust is now completely removed from the cutting-room, and is all discharged into an adjoining settling room, where the bulk of it is collected.

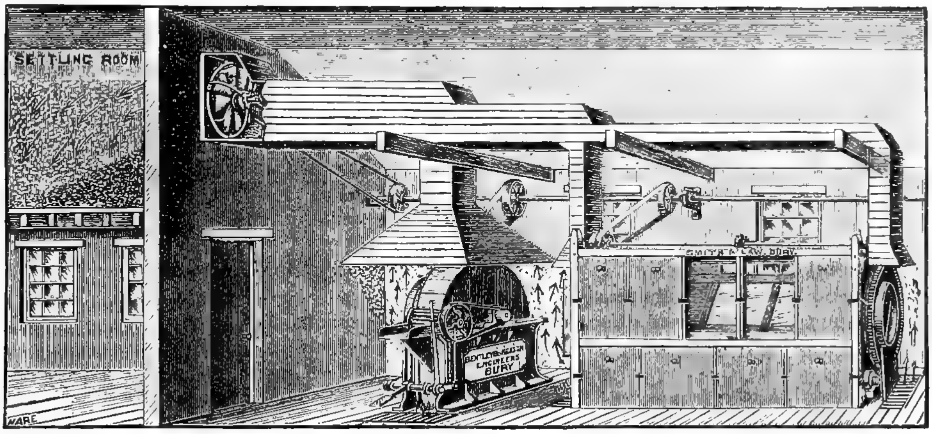

Fig. 2.—Air Propeller RemovingDust from a Rag-Cutting Room in a Paper Mill.

In Fig. 3 we give a longitudinal section of a steam laundry where one air propeller is used for three different purposes. It will be seen that the propeller is fixed between the drying room and the washing room. The air inlets are in the ironing room, and between the latter and the upper drying room, and again between the upper and lower drying rooms there are openings in which are placed coils of piping, heated by steam. The outlet is at the end of the washing room, farthest from the propeller. When the latter is in operation fresh air is drawn through the ironing room, which is agreeably

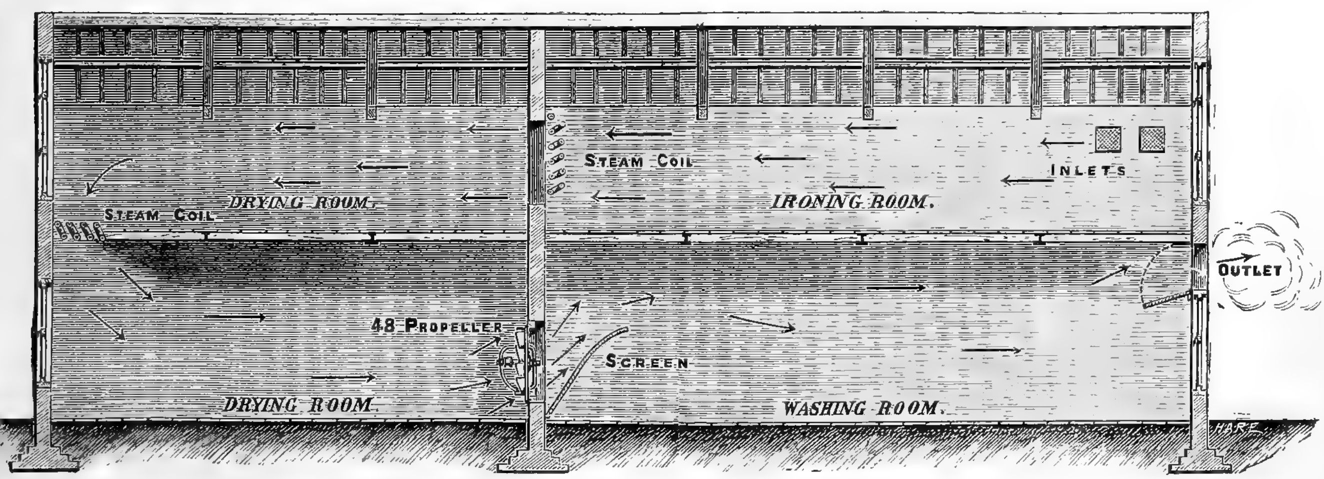

Fig. 3.—Air Propeller used for Cooling, Drying, and Ventilating in a Steam Laundry.

The Dog Nuisance in Paris.—Rabid dogs are said to be extremely prevalent at present in Paris, and the authorities are at last taking stringent measures. A medical contemporary remarks that the Pasteur Institute ought to be most abundantly supplied with cases for treatment.

cooled. The air then passes over the first steam coil, and is heated sufficiently for the upper drying room. After this it is again heated by the second steam coil, and is used for drying in the lower room. Finally it serves to remove the steam in the washing room. The whole contrivance is at once simple and effective, and is a great relief to the *employées*, who would otherwise have to do their work under the usual very unhealthy conditions.

BUDS.

(*Concluded from page* 34.)

It has been mentioned that lateral (not apical) buds arise in the axils of the leaves, which is known as *axillary* growth, and this mode of origin is characteristic of the buds of all flowering plants except the gymnosperms, or plant with naked seeds, such as the pines, which certainly produce their lateral buds in the axils of their leaves, but not in the axils of *every* leaf, as is usually the case with the other flowering plants. In the cryptogams, or so-called flowerless plants, lateral buds arise mostly near or below the leaf. But even in the flowering plants various deviations from the axillary mode occur, *e.g.*, two or three buds may be formed one above another (*Lonicera*), or the bud may advance along the stem so as to be above the axil, or the leaf may be formed late and advance upon the young shoot itself, appearing as its first leaf. In flower-buds also—to which many of the details concerning leaf-buds apply, flowers being composed of modified leaves—the *subtending* leaf or bract is frequently wanting. Still the system of axillary growth is pretty constant, and Warming looks upon the leaf and bud in flowering plants as a double organ, they being united at the base.

But this constancy of formation as buds is far from being accompanied by constancy of development into shoots, as many buds from want of sufficient nourishment do not sprout at all; some, indeed, being suppressed in a regular manner, giving a characteristic branching to the plant. This latter feature is well shown in certain members of the pink family (Caryophyllaceæ) where the leaves grow in pairs that cross each other, and only one axillary bud is developed, giving rise to a spiral arrangement. In certain plants (elm, hazel, and lilac) the bud at the end of each shoot is suppressed, the next below, which is lateral, continuing the growth. Terminal suppression tends to produce bushiness, whilst lateral suppression produces loftiness. The difference of form thus brought about may be well contrasted in the Lombardy poplar and the black poplar, the former being tall and slender through the suppression of its lateral buds, the latter short and spreading through the suppression of its terminal buds. The greatest suppression takes place in the Monocotyledons (plants with generally parallel-veined leaves), and is well seen in most palms, which produce their foliage-leaves in a cluster at the top of an unbranched stem. It frequently happens in plants, the buds of which are not suppressed upon a regular plan, but from want of nourishment, that these "dormant eyes" will sprout, an occurrence which generally takes place in consequence of the access of more light and air, or more often through some of the branches having been lopped off, as in pollards, leaving an excess of nourishment in the plant that stimulates the dormant organ to activity.

These "dormant eyes" must not be confounded with what are termined *adventitious* buds, the term *adventitious* being used in opposition to *normal*, which, when applied to buds, signifies that they are formed, as most buds are, *acropetally*, or from the base to the apex of the axis, no normal bud arising lower than one already existing, whilst buds are *adventitious* when they do so arise. They occur in many ways, and seem to be the result of an attempt on the part of the plant to get rid of excessive nourishment and vitality. On old cut stumps they appear upon the "callus," or cambium layer swollen up between the bark and the wood, and upon detached leaves and pieces of stem and root, especially when these are kept in darkness. But it is chiefly on the leaves that they are formed, as in the bulbils found in the angles of the branching of the veins of the cuckoo flower (*Cardamine pratensis*), and in the common water-cress (*Nasturtium officinale*), and most strikingly in the centre of the leaf of *Nymphœa micrantha* and in several of the Aroideæ, *e.g.*, *Atherurus ternatus*, as tubers or bulbs which separate and become independent plants. They are found on the foliage-leaves of many monocotyledons too, but remain in the bud condition so long as the mother-leaf continues vigorous. They are very common on the fronds of ferns (fig. 8) (*Ceratopteris thalictroides*, *Asplenium caudatum*, *Woodwardia radicans*, *etc.*), where, as in the cuckoo-flower, they become vigorous, many-branched shoots, which ultimately carry on an active individual growth free from the parent. The male fern (*Aspidium filix-mas*) produces no other lateral branches than those which proceed from adventitious buds situated on the basal parts of the backs of the older foliage-leaves. Not infrequently the roots of plants give origin to buds which develop into independent plants, the ordinary Acacia being a familiar example, whilst on certain of the roots given off, by the underground stem of the Bird's Nest Orchis (*Neottia nidus-avis*), a very rare mode occurs in which the root-cap is torn off and the growing-point of the root becomes a shoot. The origin of adventitious buds has been usually considered to be what is termed *endogenous*, that is to say, they arise from the internal layers of the tissue of the axis producing them, which on stems would be from under the bark or from its inner layers, whereas normal buds arise *exogenously*, or from the outer layers of the bark. But recent researches have thrown some doubt upon the theory of the endogenous origin of adventitious buds which Hoffmeister taught. Particularly pertinent are the experiments of Hanstein on the cuckoo-flower and the water-cress, in which he shows that in the epidermis, and subjacent tissue of fully-developed leaves, certain changes occur, which transform permanent tissue into embryonic, by which a conical growing-point is produced, from which arise roots and leaves. With regard to the adventitious buds formed on cut stumps, these must be endogenous, as they spring from the cambium layer, which is situated in the middle of the fibro-vasular tissue of a plant. Indeed, until very lately, it was thought that the normal buds of horsetails (*Equisetums*) were an exception, and arose endogenously; but it has been found that at the growing point their origin is exogenous, and they become enveloped by the tissue of the mother-shoot by subsequent changes. (Fig. 9.) Hansen has further shown that in *Gleditschia* the embryonic tissue near the axil persists for a long time becoming overgrown by the cortex of the current year's growth, and that upon sprouting in the following spring the bud appears to break through it, it being one of the ways in which growing points are protected for future growth.

The matter in general, however, requires further investigation.

Connected with this subject of adventitious buds is a number of facts which go to demonstrate what may be termed the independent vitality of buds. Gardeners have long made use of this property of adventitious budding as a means of propagation. *Anemone japonica*, for example, is generally propagated by cuttings of the root. The artificial production of adventitious buds on the scales of bulbs and on leaves and fragments of leaves of *Bryophyllum*, *Echeveria*, *Gloxinia*, etc., is generally effected by subjecting them to heat and moisture, as by laying them on moist earth or sand. For scientific experiments, it is better to suspend them in moist air to obtain an "equable environment." When pieces of stems are so suspended, roots arise from their bases and buds from their apexes, the reverse being the the case in pieces of root. But this power of independent growth is far from being confined to adventitious buds; in fact, it is a rule that every leaf-bud may be removed, and with proper treatment turned into a new plant—a fact that, both naturally and horticulturally, is of

FIG. 8.—(After Sachs.) *Asplenium decussatum*; central part of the mature leaf; its mid-rib *st* bears the pinnae *ll*; at the base of one of these is formed the bud, *k*, which has commenced to grow.

great importance. In Nature this occurs by axillary buds in *Lilium bulbiferum*, bulbiferous bitter-cress, or coralroot (*Dentaria bulbifera*), and in the inflorescences of flowers, as in species of *Allium*, and that interesting example, the viviparous polygonum (*Polygonum viviparum*), where either all the flowers or the lower ones are changed into little red bulbs. The "eyes" of the potato, also, may be separated and caused to produce an independent plant, as is also the case with the "cloves" or small bulbs formed in the axils of parent bulbs. Bulbs, it may be said, are analogous to buds, the great difference being that the fleshy leaves of the former act as reservoirs of plant-food, whereas those of the latter are, of course, the great centres of its manufacture. The operations of grafting, "budding," etc., depend upon this property of independent development, and in such operations one important precaution has to be taken, viz., the bringing of the cambium regions (layers of embryonic tissue running through the plant which maintain and renew their annual growth) of both "scion" and "stock" into contact. As an illustration, the following account of the operation of "budding," abstracted from Beeton's "Garden Management," may not be out of place :—"The bud is cut from the parent plant with about $\frac{1}{4}$ in. of bark attached above and below, forming what is called a 'shield,' and from this the wood must be removed without injuring the inner bark. The buds or 'eyes' in the axils should be well developed, or they must be made so by pinching the growing point and causing a reflux of sap to the base, and in twelve days the axillary buds will be sufficiently developed, the bud then being separated. Should any leaves be expanded they must be detached, the stalks being left. A T-shaped cleft is then cut in the 'stock,' which should be from one to five years old, and in full growth (May to September), allowing of ready removal of the outer bark from the 'liber' or inner bark. The bark of the bud is then inserted under the bark of the 'stock,' and the whole is then bandaged up, contact between the liber of

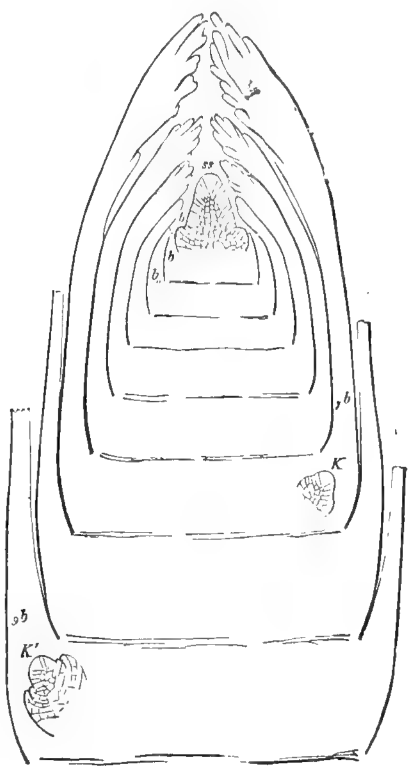

FIG. 9.—(After Sachs.) *Equisetum arvense*; longitudinal section through an underground bud in March; *ss*, the apical cells of the stem; *b*-9*b*, its leaves; *KK'* two endogenous lateral buds exposed by the section × 50.

both being ensured. The head of the 'stock' is then cut down in order to reserve an ample supply of nourishment for the 'scion,' which rapidly shows vigorous growth. Grafts may be made on roots in the same way, which, when separated with the bud in the following spring, forms new individuals."

Among the many interesting facts connected with the physiology of buds, those connected with *respiration* and the circumstances which determine the time of sprouting may be mentioned here. With regard to respiration, Garreau is responsible for the following particulars :—"12 buds of the lilac, weighing 2 grams (about 1-16th of troy oz.), at 112° Fahr. exhaled 70 c.cm. (about $4\frac{1}{2}$ cubic inches) of carbonic acid gas in 24 hours, the leaves having expanded. Five buds of *Æsculus macrostachya*, a kind of horse-chestnut, weighing 85 grams (about 2½ troy ozs.), gave off 45 c.cm. (about 3 cubic inches) of carbonic gas in 24 hours, the leaves having expanded." And in regard to bursting flower-buds, it has been noted that an orobanche in full bloom used up its own volume of oxygen in 36 hours, or 4·2 c.cm. per grain of substance, corresponding to a loss of 2·26 milligrams of carbon. All this chemical action is concerned in the production of energy required to do the work of expansion, and is accompanied by the production of heat that becomes particularly evident in opening flower-buds, which are often quite warm to the touch. Plants like the arum are good examples, because of the crowded flowers and the retention of the heat by the enveloping spathe, a rise of from 4° to 10° above the temperature of the surrounding air having been registered, whilst a flowering palm has been known to cause a rise of 68° to 92° Fahr.

With regard to the season of sprouting, it is a most remarkable thing that, as has been shown, although "winter buds" to all appearances are as developed in autumn as in early spring, it is impossible to get them to sprout in autumn or at the beginning of winter. Professor Sachs performed many interesting experiments in this direction, but the earliest he could get them to develop was January or February, by allowing the branches to stand in water in an ordinarily warm room. This was likewise the case with bulbs and potatoes, which he could by no means get to grow before February. Such an inability to grow before a certain time can, he points out, be due only to internal changes, as there are no evident external ones; but as yet no change has been observed between the composition of potato tubers in autumn and in early spring, nor in the reserve food materials of the "resting-spores" of such algæ and fungi as are subject to the same conditions. Sach's hypothesis is a very probable explanation, and is to the effect that this dormancy is due to a slow production of ferments which are necessary to the vigorous chemical changes consequent on germination or sprouting, and that this formation is favoured by cold or dryness, whilst, where germination and activity in spores and buds take place immediately, it is because these ferments are taken up from the mother-plant. As the production of ferments is now receiving considerable attention, this hypothesis will have a chance of being confirmed or rejected. Whatever be the reason, the provision is an extremely valuable one to plant life, for were trees in the habit of budding in winter, the sap would be frequently frozen in the buds, causing death, an event which often happens when in early spring a few warm days cause certain of the buds to open, only to be killed by a return of the cold. A remarkable instance of premature budding is that given by Gilpin, in his "Forest Scenery," of a famous tree known as the Cadenham Oak, growing near the village of Cadenham, in the New Forest. Some opening buds were sent to him on January 15th, 1782, the leaves being about one inch long, two being expanded from some buds and one from others. The people in the neighbourhood believed that the tree would bud only on old Christmas Day, an idea which is entertained also of the Glastonbury Thorn. The buds soon shrink and die with the frost, and no more leaves are produced until the return of vegetation. Mr. F. G. Heath confirms Gilpin's statement, and mentions that he found the Cadenham Oak still living in 1879, though possessing only half its trunk, which had a girth of about 8½ feet. The same property has been attributed also to other trees.

In conclusion, as a slight contribution to the evolutionary side of the subject, a few words concerning what is termed "bud-variation" may not be out of place. Sometimes certain buds will develop in a manner different from that of others on the same plant. It occurs in two different ways, each of which has a different import. In one case the abnormal shoot produced by a variety reverts to the original form; *e.g.*, in the Botanic Garden of Munich there is a beech with divided leaves. This is a backward step. In the other case, new features appear on certain shoots of a plant, as in the myrtle, where single shoots produce their leaves in alternating whorls, instead of in the customary alternate pairs, whilst the branches produced from the axils of these leaves exhibit the ordinary form. This variation must not be confused with such irregularities as differences in the same plant between the sizes and numbers of leaves, flowers, and fruits, which are the result of excessive or deficient nutrition, of a full or an insufficient exposure to air and light. These changes are not hereditary, and do not occur in the descendants of such plants when subject to normal conditions.

Asbestos to Promote Filtration.—Viscid liquids, such as are obtained in processes of artificial digestion, may be filtered, according to W. Fresenius (*Ztsch f. Anal. Chem.*), by the aid of finely picked asbestos fibre. Not only is the filtration of such fluids exceedingly slow, but the filtrate often passes turbid, even through paper of the closest texture. To filter such a fluid, Fresenius advises to dilute with water, add some recently ignited asbestos, and shake the mixture vigorously. After about twelve hours the suspended matters will have subsided, leaving the supernatant liquid perfectly clear. This is to be syphoned off, and the residue to be washed once or twice by decantation, and then passed through a glass funnel, the neck of which contains a pellet of asbestos. If the first part of the filtrate runs off cloudy, it is returned to the funnel until it passes clear.

The Smith Observatory, Geneva, N.Y.—By the liberality of Mr. William Smith, of Geneva, a first-class astronomical observatory has been established at that place, fully equipped with instruments of the highest standard, to be known as the Smith Observatory. Professor Wm. R. Brooks, who is well known for his contributions to astronomical science from the Red House Observatory at Phelps, N.Y., has removed to Geneva, N.Y., where he will in future carry on his astronomical work, under more favourable auspices, as director of the new Smith Observatory. The many valuable discoveries in astronomy heretofore made by Prof. Phelps not only attest his competency and indefatigability, but afford the best promise of success in his new location.

Influence of Forests in Australia.—According to Dr. K. V. Lendenfield (*Petermann's Mittheilungen*), the influence of forests upon the climate of Australia is the reverse of that which they are supposed to exert in Europe. While European trees retain much of the water among their roots, the trees of the Australian wastes send their roots to great depths in search of water, and open their stomata only at night.

General Notes.

PROFESSOR CHEVREUL.—The health of the veteran *savant* is beginning to occasion some anxiety to his friends. He still eats and sleeps well, but he is rather feeble, and has difficulty in ascending stairs.

SUBSIDENCE IN WORCESTERSHIRE.—Owing, it is said, to the insufficiency of props in the underground workings of a colliery some 600 feet below the surface, a subsidence has taken place in the neighbourhood of Cradley. The area affected is about one hundred yards square, and unfortunately it is covered with houses.

UNITED STATES COAST AND GEODETIC SURVEY.—The following publications have recently issued from the offices the Coast and Geodetic Survey, Washington :—"Tide Tables for the Atlantic Coast of the United States for the Year 1889," "Catalogue of Charts and other Publications during 1887," and "The Atlantic Local Coast Pilot, Subdivision 21."

HOUSE-BOATS ON THE THAMES.—The house-boats on the Thames have increased to such an extent that the excrementitious matter and other refuse discharged from them into the river has become a serious item of pollution. The evil is the more serious because the "putrescent and putrescible matters" thus emitted can undergo no kind of purification. The attention of the Thames Conservancy Board has been at last attracted to the nuisance, and measures are being taken for its repression.

THE MOUND-BUILDERS' UNITS OF MEASURE.—According to Mr. R. P. Gregg, quoted in the *Popular Science Monthly*, the ancient Peruvians, the Aztecs, Toltecs, and Central Americans employed a foot equal to $11\frac{3}{4}$ inches English. This foot was divided into twelve equal parts. The mound-builders of Ohio, according to Dr. Abbott, used a foot equal to 10 English inches, also divided into twelve equal parts. Seven of the Ohio inches were thus equal to six Peruvian inches.

REFRIGERATING MIXTURES WITH SOLID CARBONIC ACID.—According to MM. Cailletet and Colardeau, flocculent carbonic acid is capable of cooling bodies down to -60° Centigrade at the ordinary pressure of the atmosphere, and down to -76° in a vacuum. If the solid carbonic acid is mixed with ether the temperatures are -77° and -103°. If chloride of methyl is used instead, of ether there is obtained a temperature of -82° at the pressure of the atmosphere, and of -106° C. in a vacuum which is equal to 190° below freezing or 158° below zero on Fahrenheit's scale.

DETECTION OF GAS-LEAKAGE.—The use of matches or other lights to detect an escape of gas is not free from danger. A test-paper for detecting such leakage has been devised by Dr. Bunte, improved by Herr Schauffers, and is published in *Invention*. The paper is steeped in alcohol, containing to every three parts chloride of palladium one part chloride of gold. One pint costs 9s., and will steep filter paper enough for 10,000 tests. The observer may be misled if there is present tobacco smoke, a smoky chimney, fusel oil, the smell of onions, sulphuretted hydrogen, or the vapour of mercury.

ABSORPTION OF GASES BY CARBON.—From analogy we should expect that chemical action within carbon filaments is very possible, since, however carefully they have been prepared, a greal volume of gases must be condensed in their texture. Smith and Reichardt report that the gas which these carbons give off is carbonic acid, the more abundant the moister is the air. Baker has since established that in perfectly dry air carbonic oxide only is evolved. In any case a combination of carbon and oxygen takes place, which accounts for the gradual deterioration of the filaments in incandescence lamps.

EXPLORATION IN MOROCCO.—The following message sent to the coast by special courier, by Messrs. Joseph Thomson and Harold Crichton-Browne, and forwarded from Tangier by the Eastern Telegraph Company's cable, has been transmitted by Sir James Anderson to the Royal Geographical Society :—"Left Demnat June 5th, followed the glen of the Wad Gadat to the Tilnet, which we crossed at a height of 8,000 ft. Reached the house of the Governor of Ghaoria on the 8th; magnificent reception; all goes well; prospects good; remain here for a few days.

FLIES AS COMMUNICATORS OF DISEASE.—Dr. Hoffmann, of Dresden, confirms the statement that the common house-fly distributes the bacillus of tubercle. In a ward occupied by phthisical patients, four out of six flies caught were found to contain the bacillus in their intestines. The insects collect the microbia from the expectorated matter, and discharge them again unhurt. The *Medical Press* appends to this paragraph the following curious moral: "Abstain from eating flies or their excreta, and bottle up all phthisical sputa." Would it not be better to say treat all such sputa with corrosive sublimate or strong sulphuric acid?

HYPNOTISM AS AN AMUSEMENT.—By way of emphasizing the caution which we gave (vol. i., p. 621), we quote from the *Monthly Magazine of Pharmacy* the following paragraph :—"A well-connected young man, who lives with his mother in a fashionable part of Paris, recently attended what is called a *soirée d'hypnotisme* at a friend's house. He went to sleep, and a stuffed mannikin was placed by his side, which he was told was a man, whom he must murder. The youth did as he was told, and when a knife was put into his hand he ripped the dummy figure open with the exultation of a man who was wreaking a long-cherished revenge on an enemy. After that he awoke, but ever since he has been labouring under the delusion that he murdered his mother. He ran away from his home, and sat weeping on a bench in the Champs Elysées, when two policemen, whose curiosity had been excited, came up to him. On seeing the agents of the law the poor fellow took to his heels, and was, of course, pursued and arrested. It was only when he was brought face to face with his mother that he regained his senses."

PURCHASED RESEARCH.—"We regret," says the *American Naturalist*, "to read in our esteemed contemporary, the American *Geologist*, an editorial apology for a practice which scientific men condemn. We refer to the purchase of the scientific work of a man, and the publication of it by the purchaser as though it was his own production. While this kind of contract is perhaps legal, it is disreputable to the purchaser. A man under necessity for the means of a livelihood may make such a sale of himself without blame, but the man who buys cannot in any way get a sound scientific reputation. But, whatever the law may be, the moral obliquity and intellectual poverty that such a transaction implies on the part of the purchaser are too plain for dispute. We must here draw a distinction. If, as it sometimes happens, a man of science comes upon certain ideas and hands them over to an assistant to work out, giving him instructions how this is to be done, we must hold that the originator retains by right the credit of the work. The relation of the two is like that of the architect and the mason. But if a man buys, as our worthy contemporary intimates, what he has neither conceived nor executed, and publishes it as his own, he is simply an impostor."

The Longitude of Paris.—We understand that the details of arrangement for redetermining the difference of longitude between Paris and Greenwich have been settled between the Astronomer Royal and Mr. Lœwy, of the Bureau des Longitudes and Paris Observatory. It has been decided to use the geodetic station at Montsouris, which has already been connected with several important points in Europe, as the French station and the Royal Observatory as the British. Two English and two French observers will take part in the operations, which will probably commence in September next. In 1854 the work was done by one observer from each observatory, the observations being made by the observer noting the time and estimating the fractions of seconds at which the stars used passed over the wires of the transit instruments, and galvanometer needles were deflected. On the present occasion the transits and times of deflection will be registered on chronographs. This work is looked upon as most important by astronomers and geodesists, as it will connect Greenwich with the continental surveys which have of recent years been made with a very high degree of accuracy.

Archæological Find in a Peat Moss.—On Thursday, June 28th, the workmen employed by Mr. Gordon, of Fowlisters, in cutting peat in the moss, "Hen Heads," on the westmost shoulder of the Hill of Aultmore, dug out from the moss a large kit of fatty matter, which had certainly been placed there by some of the inhabitants of that district a very long time ago, as about fifteen feet of moss had grown on the top of the place where it was found. This fatty matter was encased in a jar made of tree bark and surrounded with a basket of wicker work, some of the wattles of which were nicely plaited together. The matter, which is quite hard round the outer edge, is somewhat in the form of a miniature corn rick, tapered to the point from the rim of the jar. The thick part of the body, which, from the impression of the bark jar, resembles in appearance part of the trunk of a tree, measures in circumference 5ft. 6in. and in height about 3ft. 5in., and weighs nearly 2cwt. Unfortunately one of the workmen, actuated no doubt by a desire to see if there was anything worth looking after inside, cut off the top, which act has marred the original form considerably. Nothing, however, was found inside. The whole contents seems to have been a solid mass of prepared fat, which time has turned into what is known now as adipocere. The whole find has been carefully deposited in the Keith Museum.

Sophisticated Wine.—The death of eleven persons in the South of France, traceable to arsenic in the wine sold by a local merchant, has directed attention to a new process of sophisticating wine. *Mouillage* has long been a custom in the trade. It consists in multiplying the quantity of a good wine in the following manner: A quantity of good wine is purchased, and to it is added an equal quantity of a much cheaper sort. Sometimes water is also added. This is the *mouillage.* The process does not, however, end here, for the eye and the palate of a fairly good judge, to say nothing of the analyst, would easily detect the fraud. The doctored wine is flat to the taste, and spoiled in colour. The palate of the taster and the skill of the analyst have now to be cheated. This is effected by adding alcohol. Sometimes the alcohol is added pure; sometimes it is introduced in the form of glucose from which alcohol is derived by fermentation. There remains the colour. Those who have travelled much in France may have noticed acres of tall flowers called hollyhocks, and wondered for what purpose they were grown. The petals of these flowers afford a decoction which is capable of restoring the colour to the wine without revealing its presence to the chemical analyst. This was the old and harmless method; but it appears that we have grown less scrupulous and less careful, for in the case of the wine which occasioned the deaths alluded to, it was found that coal tar colours had been substituted for the hollyhock petals. The matter is yet under investigation; but it is said that some arsenic was contained in the colouring agent.—*Industries.*

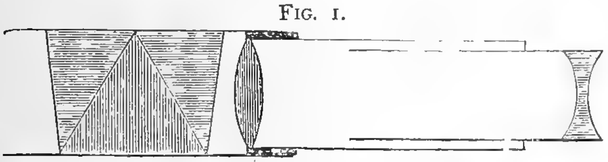
The Public Health.—The Registrar-General's return for the week ending July 7th shows that the deaths registered last week in 28 great towns of England and Wales correspond to an annual rate of 15·0 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Brighton, Nottingham, Leicester, Birkenhead, Huddersfield, and Halifax. In London 2,348 births and 1,211 deaths were registered. Allowance made for increase of population, the births were 332, and the deaths 372, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 14·5 and 15·1 in the preceding two weeks, declined again last week to 14·8. During the 13 weeks of last quarter the death-rate averaged 16·9 per 1,000, which was 3·0 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,211 deaths included 23 from measles, ten from scarlet fever, 29 from diphtheria, 31 from whooping-cough, 7 from enteric fever, 2 from ill-defined forms of continued fever, 51 from diarrhœa and dysentery, 3 from cholera and choleraic diarrhœa, and not one from small-pox or from typhus; thus, 156 deaths were referred to these diseases, being 175 below the corrected average weekly number. In Greater London, 3,130 births and 1,502 deaths were registered, corresponding to annual rates of 29·5 and 14·2 per 1,000 of the population. In the Outer Ring six deaths from diphtheria and six from whooping-cough were registered. The fatal cases of diphtheria included two in Tottenham and two in Walthamstow sub-districts.

SPECTRO-TELEGRAPHY.

SPECTRO-TELEGRAPHY is the name of a new invention by Paul la Cour, the inventor of the phonic wheel, and its synchronism for multiplex telegraphy. The instruments are shown at work at the present moment in the Copenhagen Industrial Exhibition, and the invention, which is patented, is based upon quite a new principle. It may be used for several purposes, but I shall here confine myself to pointing out and describing in detail the application of the system to nautical use as a simple means of communication from lighthouse to ship, and *vice versa*, and between ships themselves.

It is well known that such a signal system exists, but it is only available in the daytime. The first idea was originated in England, in 1857, it was taken up by France, and afterwards by nearly all maritime nations, and is known as the international flag system. Generally speaking, the signals are not meant to express words and sentences by spelling, but only to give a limited, though very large number of sentences, which are arranged in a signal book (international code of signals). It has the advantage, however, that each vessel can carry

FIG. 1.



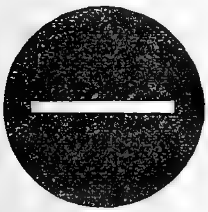


FIG. 2.

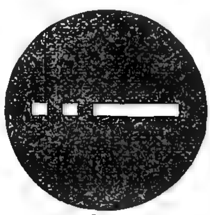

FIG. 3.

a signal-book in its own language, and two ships of different nationalities are thus enabled to correspond without understanding each other's language.

The signalling is accomplished by means of 18 flags and pennants, each of which indicates one of the letters, B, C, D, F, G, H, J, K, L, M, N, P, Q, R, S, T, V, W. Of these are then formed two, three, or four-flags signals, respectively, in the number of 306, 4,896, and 73,440. All the two and three-flags signals and the first 18,960 of the four flags are intended for the different communications, queries, and answers. The others are reserved as "distinguishing signals" for ships, 1,440 for men-of-war, and 53,040 for trading vessels.

The large extension which this system has attained in a comparatively short period is a proof of its practical arrangement; still it has one disadvantage, namely, it is useless at night, and yet ships sail as much then as in the day. The value of this mode of correspondence is thus reduced one-half, and an owner wishing to give final instructions to his captain by this means, hesitates in doing so, as he is not certain that his ship may pass the lighthouse in the day.

La Cour's system is not intended to supersede the present flag system, but to supplement it in the night. This invention enables us to utilise a corresponding *modus operandi* at night by means of the same signal-book, and in such a way that the night duty becomes as simple as the day duty, and even possesses certain advantages over the latter.

When we observe a distant white light, a star, or the light from a lighthouse through a prism with vertical edge, then such a light, as is well known, appears as a horizontal luminous line, consisting of red, orange, yellow, green, blue, indigo, and violet-coloured rays. Sir Isaac Newton discovered that this was owing to the fact that the white light in reality is a combination of all these colours, with their infinitely many shades, and that they are refracted differently in the prism and thus separated, whilst they can again be combined and reproduce the white light.

Instead of a simple, a compound prism may be used. The latter separates the colour rays, but does not, on the whole, deflect them much from their original direction, and such a prism fixed on a telescope (fig. 1) is specially adapted to dissolve the in-going light. When a distant *white* spot of light is observed through this, a luminous line (fig. 2) is seen in the field of the telsecope, *coloured from red to violet.*

If now the person *who is sending* the light signal is able to arrange, in a simple manner, that all the

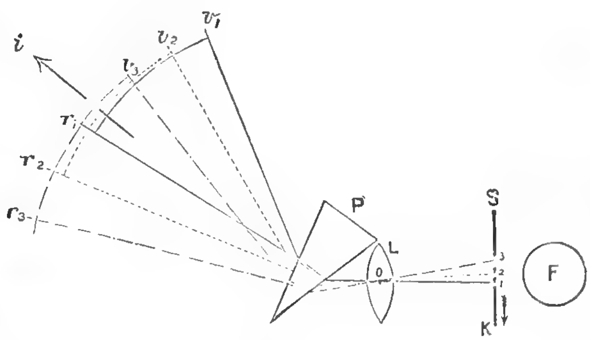

FIG. 4.

colour rays are not emitted, but only some, while others are entirely removed, it can be so managed that the remaining part of the spectrum appears as a distinct signal, for instance the Morse signal - - —— (fig. 3.) This is exceedingly easy to decipher, and does not even require colour sense, for although it is differently coloured, yet it is only the shape which is of importance (the colours are the only means of providing the conventional shape), and the signal can be read by any one, even the colour blind.

The sending instrument is represented diagramatically in fig. 4, which shows a horizontal section of the instrument (it is about 1 foot high and long, and 8 inches wide), together with the rays of light on their road to the horizon. F is the lamp, S, K is the screen, in which openings are cut corresponding to the signals to be sent, for instance, two small openings (1 and 2) and one wide (3), corresponding to the signal - - ——. L is a lens, the distance of which from S, K is equal to its focal length. Therefore all the rays of light which, passing through the opening I, strike the lens L, will, after travelling through it, become parallel with the line, 1—o, from the opening, 1, to the optical centre of the lens (o). The other rays of light are therefore not shown, for they have the same direction as 1—o. This ray of light will then strike the prism P, and be refracted and spread, so that it forms the coloured, fan-shaped rays of light r_1, v_1, containing all the colours. In the direction of the distant observer, *i*, a distinct colour only will be emitted from the opening 1, say *orange;* from the opening 2, there will also be rays emitted, which are first made parallel by the lens, and afterwards spread by the prism in the fan-shape r_2, v_2, of which a single colour only strikes *i*, say *yellow*. In the same way the opening, 3, produces the fan-shape r_3, v_3, but this opening being wider, *i* will receive several kinds of *green* and *blue* rays.

To the naked eye, or with an ordinary telescope, the light which issues in the direction *i*, will give shapes of colour corresponding to a mixture of the respective colours; but if the spectro-telegraphic telescope is used, the signal appears as in fig. 3.

When the sender moves the screen S, K, in the direction indicated by the arrow, opening 3 will take opening 2's place, opening 2 takes 1's place, and in the field of the telescope the receiver will also see the line of light 3, slide smoothly into 2's place, etc., etc., so that the signals are seen to glide through the field, in at one side and out at the other.

To perfect the present system of signalling, and use La Cour's signals at night, a sending instrument, with the eighteen perforated metal pieces, together with the receiving telescope is only required. Instead of hoisting the four flags in the daytime, signifying, for instance, C, F, G, L, the four corresponding pieces of metal need only be inserted in the sending lantern, and made to move backwards and forwards several times, so that the receiver has time to read them.

These night signals are in some respects superior to the day signals. They are, for example, not diminished by distance, as their size only depends upon the receiving telescope, so that however far they are sent they keep the same dimensions. They are also independent of the direction of the wind, which often disturbs the flag signals by making them turn edgeways to the observer so that he cannot see them.

This same system has been tried for ordinary telegraphy by passing a perforated slip (as in the Wheatstone's transmitter) through the sending instrument, and a telegraphist can read these marks so easily, that the telegraphing can be performed with the same speed as with an ordinary Morse instrument.

It is well known that a hazy atmosphere first obliterates the violet and blue rays of light; it has therefore been supposed by some that spectro-telegraphy would fail under these circumstances. This is, however, not so, for as the signals seem to glide through the whole spectrum, they can always be read in the red, yellow, and green, even if they are lost in the violet and blue.

This principle also appears to be applicable in several different ways. If a lighthouse be supplied with a sending instrument, in which the first letter or letters of the light's name are placed, the mariner will always be able to see in the spectro-telegraphic telescope what light it is, and thus mistakes and loss may often be prevented.

Further, an entrance to a harbour does not need to be indicated by *two* lights, which direct the course, but by *one* only of La Cour's system, with a fixed signal or letter, which is only seen in the middle of one's telescope, if one is exactly on the right track. By steering a little to the one side or the other, the letter or signal will appear to glide in the telescope to either of the two sides and if the ship passes entirely out of the proper course the signal disappears from the field of the telescope. Another advantage in this method is, that the light from the harbour lantern is very easily distinguished from all other lights, for these latter appear in the telescope as a continuous light from red to violet, whereas the former gives its own peculiar signal, for example - —— - ——.

Finally, ships might be supplied with a fixed lantern of this kind, which throws light forward, and obliquely to the sides. Two ships going in opposite directions will thus in their telescopes immediately see whether their course lies to the starboard or port of each other, and also whether they are in the act of altering their helms, for the letters in the telescope will then appear to glide to one side or the other.—*Electrical Review.*

THE ELASTIC LIMIT OF IRON AND STEEL.—An interesting series of experiments on the alteration of the elastic limit of iron and steel, which have now extended over several years, have been made by Professor Bauschinger at the laboratory of the Technical High School at Munich, and some very interesting and important results have been obtained. Most of the experiments were made on one of Werder's testing machines, the deformation being read by Professor Bauschinger's mirror apparatus, but for the experiments on the endurance of bars a Woehler machine has been employed. In the course of these experiments it was discovered that the break-down point of a bar had no connection with the elastic limit: thus, when a series of gradually-increasing stresses, exceeding that corresponding to the original break-down point of the material were applied to the bar, this point rose with the stress, and this rise was continued for weeks and months, and possibly years, if the bar was left at rest under the greatest of these loads. On the other hand, when a bar was subjected to an increasing stress, greater than that corresponding to the elastic limit of the material, but less than the stress at the breaking-down point, the elastic limit and elastic modulus both increased, but reached a maximum as the breaking-down point was approached, and then rapidly decreased, the former at times even reaching the value of zero. If, however, the bar is left at rest under a stress exceeding that of the primitive breaking-down point, the elastic limit and elastic modulus increase again, and the former may attain a point far above its original value. Moreover, the limit in elastic tension is, in general, very different from that of the material when subjected to compression, and artificially raising the elastic limit in tension, as described above, causes the limit in compression to be decreased, and this may even pass through the point of zero stress. In other words, a bar of steel or iron has two elastic limits, and whatever position these occupy on the scale of loads, the range between them is nearly a constant quantity. By alternately stressing a bar in tension and compression just beyond the elastic limits, these, after a certain number of repetitions, occupied positions equally distinct from the point of zero load, and the limits thus obtained are called by Bauschinger the natural elastic limits of the bar. It was then noted that the stress corresponding to these limits sensibly coincided with that found by Woehler as the limiting stress to which a bar could be subjected to alternate tension and compression. It would thus appear that a bar would bear an indefinite number of repetitions of stress, provided the range of stress does not exceed the elastic range mentioned above.—*Glasgow Engineer.*

HAWICK SCIENTIFIC AND PHILOSOPHICAL SOCIETY.—At the annual general meeting the following gentlemen were elected officers and council of the society:—President, Mr. John Berry, Stewartfield; Vice-President, Mr. James Gowans, jun.; extra Vice-Presidents, Mr. W. S. Irving and Mr. John N. Lamb; Secretary, Mr. John N. Lamb; Assistant Secretary, Mr. David Miles; Treasurer, Mr. W. C. Goodfellow; Council, Messrs. A. Blackwood, A. Huggan, W. S. Irving, W. Sinclair, R. Watson, and Jas. Young.

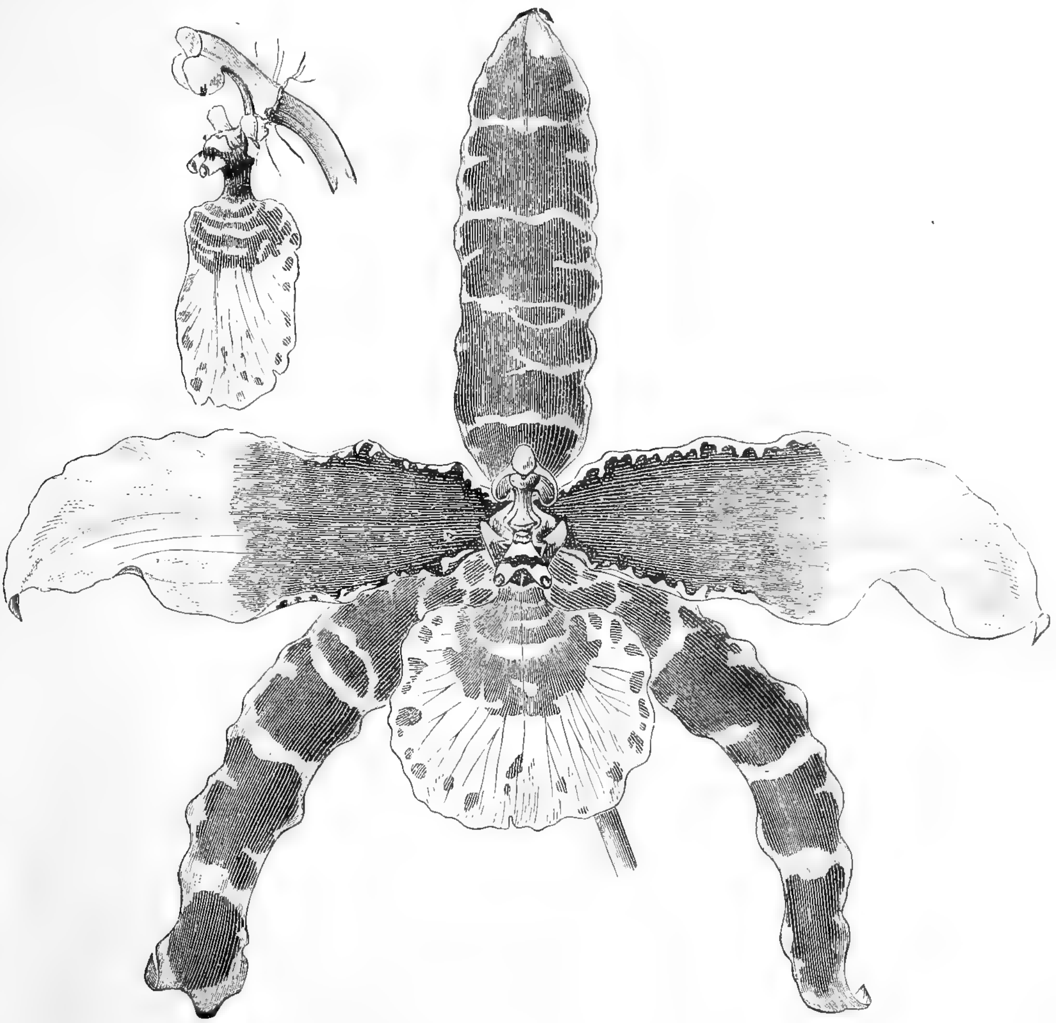
Natural History.

THE ORCHIDS: WHAT ARE THEY?

(Continued from p. 36.)

AMONG the cultivators of orchids these plants are commonly divided into a "cool" and a "hot" group, a classification based, not upon any structural distinction, but upon the temperature which they require. The "cool" orchids are almost exclusively natives of the western hemisphere, where they extend from lat. 20° N. to 30° S. In South and Central America, high temperatures of course prevail in the plains, but the bulk of the "cool" orchidaceous plants which we encounter in European conservatories are natives of the mountains, some of them extending to the altitude of 9,000 feet above the sea-level, whilst some of the small-flowering species which grow not on the trunks of trees, but upon rocks, or even in the ground, like the orchids of Europe, may be found at heights even of 11,000 or 12,000 feet.

Of the "cool" orchids the most noteworthy genera are Odontoglossum, Cattleya, and Laelia. The first-mentioned genus includes some of the most popular species of the entire family. Some idea of its general structure may be formed from our figure on p. 35, though even carefully coloured illustrations can convey but an imperfect conception of the beauty of most of the plants. The technical characteristics of Odontoglossum are: *sepals* spreading and free, the lateral ones rarely united at their bases; *petals* generally of the same size as the sepals, though sometimes broader; *lip*, parallel with the column at the base; the intermediate lobe or limb, either spreading or deflexed, and furnished with a fleshy crest near the base. *Column*, club-shaped, often elongate, usually narrow at base, sometimes expanded into a membranous wing on each side, or into auricles at base, or wingless. *Pollinia*, two, pear-shaped or ovoid, united by a linear or flattened caudicle to an oval viscid disc or gland. *Capsule* variable in form, but usually ovoid or oblong, and often rostrate.



ODONTOGLOSSUM GRANDE. (After Veitch.)

As regards their colouration, we may say that *Od. blandum*, the species which we figured in our last number, has its sepals and petals white, spotted with reddish purple, whilst the white lip displays bright yellow streaks.

The *Odontoglossum grande*, an illustration of which we are enabled to give through the courtesy of Messrs. Veitch, is the largest flowered of all the known Odontoglots. It was found in 1839 by Mr. G. Ure Skinner, in dark ravines near the city of Guatemala, in situations where it was secure of moisture and constant shade. The flowers are from 5 to 6 inches across, the sepals are bright yellow, barred with cinnamon-brown; the basal half of the petals is cinnamon-brown, bordered with yellow, the other half bright yellow; the lip is pale yellow, and the fleshy crest an orange yellow.

The species of *Odontoglossum* form an indefinite number of hybrid forms, which require much further study before we can hope to reach any general law concerning their production. Mr. Veitch remarks that "notwithstanding the investigations of Darwin, Müller, and others had resulted in a very considerable modification of the belief in the fixity of species, the first appearance of these hybrid odontoglots was to many orchidologists a surprise and a puzzle." Further:—"From the first it has been observed of these natural hybrids that it is an extremely rare occurrence for any two appearing in different importations to be identical, although apparently derived from the same two species, and sometimes even sufficiently like each other to come under the same name. Nor ought this to be wondered at; the agency by which these hybrids and polymorphisms have been produced has been in operation for ages past, and it cannot but have happened that a large number of these forms, both of those that are known and of those hereafter to be brought to light, are not the immediate offspring of two recognised species or more primitive types, but are descended from their mixed progeny, further complicated by an occasional cross with one or other of themselves. Hence we already possess a number of forms that are 'confluent in series,' of which the extremes are too widely separated for the interval to be covered by one, two, or even more intermediate forms."

The headquarters of the great genus *Odontoglossum* are in the more eastern portion of New Granada, stretching from Bogota towards Ocaña, the valleys of the Cauca and the Magdalena being especially rich.

(*To be continued.*)

Aquatic Caterpillars.—A number of instances are on record of catterpillars that normally descend beneath the surface of the water to feed upon submerged plants. One of the best known is an Argama, which feeds on the leaf-stalks of water-lilies, and which was observed by Prof. Comstock several years back. Though these insects spend a large part of their time under water, they are obliged to come up to the surface at intervals for a supply of fresh air. Some caterpillars, however, are more truly aquatic. One of these, *Paraponyx stratiotalis*, was described by De Geer more than a century ago. Another from Brazil, *Cataclysta pyropalis*, which, like the former, belongs to the family *Pyralidæ*, was described, in 1884, by W. Muller, of Blumenau. In a recent number of the *American Naturalist* is an account of a third species, described by Prof. Wood-Mason in a pamphlet, entitled *Report on Paraponyx oryzalis, an Insect-pest of the Rice-plant in Burma.*

A Cow with only one Kidney.—Dr. H. Shimer (*American Naturalist*) lately saw killed a healthy cow which had only one kidney—the right one. It was double the usual size and weight, being 11 inches in length and $2\frac{1}{4}$ lbs. in weight.

Mineral Matters Consumed by Animals.—It is commonly said that animals, unlike plants, are not able to assimilate inorganic matter. Experiments at Rothamsted show that pigs fed on corn-meal alone did not do well until a mixture of coal-ashes, salt, and superphosphate of lime was given them, which gave the most satisfactory results, both as to the health of the animals and their progress in feeding.

Gigantic Sponge.—It is announced that a spherical sponge, $10\frac{1}{2}$ feet in circumference, has been fished up in the Mediterranean and brought to London.

A Redeeming Feature of the "Blizzard."—According to Mr. E. Ingersoll (*Field*), the fearful blizzard which visited New York in March has destroyed many of the European sparrows which had been so foolishly introduced into America, and are there proving so severe a nuisance.

The Pyralidæ of Japan.—The magnificent collection of Japanese *Pyralidæ* formed by the late Henry Pryer, and containing 4,000 specimens and more than 375 species, many of them probably new to science, has been purchased by Dr. W. J. Holland, of the American Eclipse Expedition. It is to be regretted that this collection did not find its way to the British Museum.

The Golden Oriole in Britain.—Mr. Kerr records in the *Newcastle Weekly Chronicle* that the golden oriole has been seen—and of course massacred—in several parts of England. The great obstacle to the re-establishment of this beautiful bird among us is the "British mania." Egg collectors are found willing to give from 20s. to 25s. for an egg of this species, if only they are told that it has been laid in Britain. A bird "in the flesh" fetches still more. No similar folly prevails in any other country, and until it can be exorcised, the preservation of rare birds and insects will be found impossible.

THE NATURALIST AT THE SEA-SIDE.

II.—The Marine Dredge.

Years ago the writer's enthusiasm for dredging was kindled by Edward Forbes' charming descriptions. It is truly a delightful occupation, and, after years of occasional practice, the old excitement comes back again and again. The lap of the waves against the side of the boat, the rush of sparkling water, and the eager expectancy with which the hauling in is done, beat all the pleasures of the angler. The marine dredge need not be described, for it is figured in many common books, and it is a well-known article in the market. Any boat will do that is big enough. A large coble, or a small steamboat, are what the naturalist commonly employs. Lucky, indeed, are they who have a steam-winch for winding up the dredge!

The western shores of our islands are by far the best for the purpose, and the west coast of Scotland is the paradise of the dredger. A likely spot is found by consulting the Admiralty chart. Sand is avoided as barren. A rocky bottom is dangerous to the dredge, and special precautions must be taken here, such as tying one handle with string instead of rope, so as to give the dredge an extra chance of freeing itself. The boat is kept just moving, and, when all is ready, over goes the dredge, a few feet of chain being commonly fastened to the rope, not far from the handles, to keep the iron jaws well down upon the bottom. We flop about for half an hour or so in a manner very unpleasant to those who are liable to sea-sickness, or who don't care about the work in hand. Now and then it is well to pull the rope, and feel whether all is right. The grating of the dredge on the bottom is quite perceptible to an experienced hand. At length the word is given to haul in. All hands are called to pull, and slowly, foot by foot, the wet rope climbs to the top. One big heave at the last, and the dredge lies on deck. Often it is absolutely empty; often it is choked with tangle or dead shells, or useless shingle. But the lucky casts make amends for many a failure. The most promising indications are a good number of Echinoderms (starfishes and echini) or broken fragments of pink nullipore. Then the contents are spread out, and the collectors, kneeling on the sloppy deck, rummage for treasures. Pails of salt water, glass plum-jars, tubes of all sizes, and watch-glasses are at hand. Big things are piled up in the pails, delicate creatures which can hardly bear the lightest touch are carefully placed in separate tubes. Meanwhile some thoughtful soul takes compass-bearings of two conspicuous points, so that another trial may be made in the same place. If the weather is tolerable, and the fishing profitable, hour after hour slips by unnoticed. There are fifty things to do, and every moment is precious. At last everybody's strength is worn out. The back refuses to stoop any longer, the knees are bruised, the fingers benumbed. A sailor's meal of boiling-hot tea and biscuits is served out, pipes are lit, and the sense of having enriched one's collections, and laid up happy employment for many a coming winter evening, is a fit reward for all toil and anxiety.

Like all work that is done at sea, dredging is full of uncertainties. Make no promise as to the hour of return. If you come back empty-handed that is nothing; but if you have a touch of enthusiasm, and are fond of hard work—if you like a life in which no day is like any other—and if a new animal sends a thrill of delight through your frame, set up a dredge and go to sea as often as you can.

THE EDISON AND SWAN ELECTRIC LIGHT COMPANY *v.* HOLLAND.

AFTER occupying no less than twenty-two days of the Court of Chancery, and affording opportunity for the display of the talents of some of the leading members of the bar, a most important patent suit, and one which will be of historical importance, has been decided by Mr. Justice Kay. A case in which the Attorney-General (Sir Richard Webster, Q.C., M.P.), Mr. Aston, Q.C., Mr. Moulton, Q.C., appeared for the plaintiffs, and secured among their witnesses and experts Sir Frederick Bramwell, Dr. J. Hopkinson, Mr. I. Imray, and Professor Dewar, and in which the defendants were represented by Sir Horace Davey, Q.C., Mr. Finlay, Q.C., M.P., with the assistance of Professor Crookes, Professor Frankland, Dr. Meymott Tidy, Professor Silvanus P. Thompson, Professor Perry, besides junior counsel and many other well-known electrical engineers, naturally attracted considerable attention both from other barristers and persons interested in the case.

The Edison and Swan United Electric Light Company sued Mr. W. Holland, the Manager of the Alexandra Palace, for using electric glow lamps which were alleged to be infringements of Edison's patent, No. 4,576, of 1879, and of a patent of Sawyer and Mann, taken out in the name of Cheeseborough, a patent agent. Mr. Holland was guaranteed against liability by the Jablochkoff Company, who had supplied him with the lamps, and they in turn were guaranteed by the Anglo-American Brush Company, by whom they were manufactured. The Brush Company were, therefore, practically the defendants.

The Edison specification describes the manufacture of filaments for glow lamps from paper, vegetable fibre, splints of wood, or from a thread rolled from a mixture of lampblack moistened with tar, and "kneaded till it assumes the consistency of thick putty." It is directed that the filaments are to be "carbonised in a closed chamber by subjecting it to a high heat." The claims are: "Firstly, an electric lamp for giving light by incandescence, consisting of a filament of carbon of high resistance, made as described, and secured to metallic wires as set forth. Secondly, the combination of a carbon filament within a receiver made entirely of glass, through which the leading wires pass, and from which the air is exhausted, for the purposes set forth. Thirdly, a coiled carbon filament or strip arranged in such a manner that only a portion of the surface of such a carbon conductor shall radiate light, as set forth. Fourthly, the method herein described of securing the platina contact wires to the carbon filament, and carbonising of the whole in a closed chamber, substantially as set forth."

In defence it was sought to prove that the patent was anticipated by Mr. Swan, of Newcastle. This gentleman had begun to experiment with carbonised paper strips for the purpose of producing light by incandescence as early as the year 1845. With a better air pump he repeated his experiments, and in the autumn of 1877 he met Mr. Stearn, who was very skilful in the use of the Sprengel air pump, by which an extremely perfect vacuum can be produced. At a lecture in February, 1879, Mr. Swan exhibited a lamp which was produced in court, and which is well described by the first and second claims of Edison's patent. Edison was at this time creating a scare with a worthless lamp consisting of a platinum wire, and succeeded in producing a panic in gas shares; he evidently did not know what Swan and Lane-Fox were doing in this country, and he soon found that a filament of platinum was useless, and turned his attention to carbon. The two English inventors were now on the right track, but had not succeeded in producing a really satisfactory lamp. Swan, though he exhibited very interesting lamps at several lectures, did not appear to think that the combination of a carbon conductor in a vessel wholly of glass, from which the air was exhausted, was sufficiently novel for a patent. In a letter to Mr. Stearn, he said that he had heard that Edison was experimenting with carbon, and he feared that he would forestall him. Invention followed invention so fast, that one method was superseded by another before it could be brought before the public. It is certain that the first Edison lamps that were seen in Europe were at the Paris Electrical Exhibition in 1881. These, however, had fine strips of bamboo, and were made under a subsequent patent. No lamps made according to the patent in question, ever appear to have been sold, or indeed were ever made in this country *except for the purpose of evidence in litigation.* To make them was no easy task. Professor Crookes, whose skill in delicate manipulations is as great as his reputation as a chemist, was no more successful in his attempts than were Professor Silvanus P. Thompson, Dr. Tidy, and others. Filaments were reduced to ashes, putty of tar and lamp-black refused to be rolled out to a thinner thread than one twenty-fifth of an inch, and lamps which with the greatest difficulty were at length made and tried, broke down after a minute or two. Mr. Gimingham, for the plaintiffs, however, seemed to have little difficulty in making any number of the lamps. Professor Dewar rolled out a fine filament in the witness-box from a "tar putty" which he brought with him. With such conflicting evidence, the judge ordered that the experiments should be repeated by two experts from each side, in the presence of counsel and of an independent "moderator." Professor Stokes was selected for this office, and he sent an extremely interesting report to the judge. It turned out that this "putty" must be kneaded and worked with a considerable expenditure of force for about an hour and a half. It then assumes the consistency of gutta-percha, and can be rolled out. But of one hundred lamps made of this substance some broke down as soon as the electric current was turned on. Eleven lasted less than twenty hours, eighteen could not stand forty hours' run, and after sixty hours only four survived.

In a most masterly judgment, in which Justice Kay showed that he had made himself thoroughly conversant both with the theory of the subject and with the most minute details, he decided that Edison's patent was void for six reasons. First, that the claims were too wide. Second, that it does not describe a lamp which has met with a commercial success. Third, that there is an insufficient description of the processes of manufacture. Fourth, that in one of the processes described, by which volatile substances, such as camphor, are mixed with the "tar putty," the presence of such substances would be injurious. Fifth, that the use of certain "nonconducting noncarbonisable substances," which it was said might be used as a coating to the filaments, were of no utility. And sixthly, that the coiling of the filaments as described by Edison, was also of no utility. Judgment was therefore given for the defendants with costs.

The invention of Sawyer and Mann is for a most ingenious and beautiful process of depositing carbon upon a filament of an electric lamp. The bulb is filled with a hydrocarbon gas or liquid; coal gas is often used, and the filament is "flashed" by passing a current through it. If one part be thinner than another, this will offer more resistance to the passage of the current than will the thicker parts. The temperature will therefore be greater, and the heat will decompose the hydrocarbon, the carbon of which is deposited on the heated part. It is clear that this process is perfectly automatic, and the result is a great uniformity throughout the filament, each part glowing with the same brilliancy. The defendants say that their filaments are so regular that it is very rarely that they could be improved as far as uniformity is concerned, but that they use this process to deposit a coat of carbon on the filaments in order that their resistance may be made the same, so that a number of lamps will give the same light. They admitted that if there were by accident any flaw in a filament, this "flashing" would remedy it. They endeavoured to show that the invention had been anticipated by the French chemist Depretz, who, in trying to fuse carbon by the passage of a strong current of electricity, surrounded it with a hydrocarbon gas, and found that it increased in size. Not only was this discovery of no apparent use, but it interfered with Depretz's experiment. The patent was therefore upheld, and an injunction was given restraining the defendants from using the process, and they were ordered to pay the proportion of costs.

This case, which has excited a considerable amount of interest, thus throws open the manufacture of incandescent lamps, as far as the elementary use of a high resistance carbon filament in a vacuum is concerned, but there are a considerable number of patents for such details as the "flashing" process, which will probably render it improbable that the fancy price of 5s. each will be at once reduced to a more reasonable sum.

At an early stage of the case, Mr. Percy Sellon gave a full account of the process of manufacture of the lamps as made by the Anglo-American Brush Company. The material from which the filament is prepared is cellulose in an extremely pure condition. It is formed by dissolving ordinary cotton wool (which consists almost entirely of cellulose), in a solution of chloride of zinc. By the application of heat this produces a viscous semi-liquid mass, the fibres and cellular structure being destroyed, as in the materials called "vulcanised fibre" and "Willesden paper." The material, which is then not unlike a strong solution of gum arabic, is then forced through a small hole or die by the pressure of a column of mercury. It is received as it issues from the hole in alcohol, which both stiffens or congeals the thread, and removes any chloride of zinc that may be present. It is then left to soak in another jar of alcohol, and is allowed to dry. It has the appearance of fine gut as used for fishing. It is wound on wooden drums covered with velvet, which yields to the thread as it contracts while drying. It is then wound on a block of plumbago, provided with a piece of cardboard at one end, and the whole is placed in a plumbago crucible, and is packed with powdered plumbago, a little paraffin wax being placed at the bottom of the crucible. It is then closed and placed in a furnace, and gradually raised to a white heat, which is attained after about six hours. The paraffin vaporises and drives off the air contained between the interstices of the plumbago, and the piece of cardboard consumes, and allows the filaments to contract. The temperature is raised to a fierce heat for some hours, the total period in the furnace being about eleven to fourteen hours.

The crucible with its contents are allowed to cool, and the filaments are taken out and separated. They are "flashed" as has been described, the resistance being measured between the flashings, which are repeated until the right standard is attained. They are then permanently mounted on the platinum wires, which are coiled at one end into a spiral, into which the carbon filament is pushed. A local flashing is then applied, the current being diverted from the filament itself by a bridge of wire. The junction alone, which offers some little resistance, becomes heated, and the deposit of carbon takes place, sealing the filament to the wire. The wires are then sealed into the glass bulb, and the air is exhausted, the lamp being subjected to a current during the latter part of the operation, thus driving off any gas which is "occluded" by the carbon or the platinum.

THE VAGUE CRY FOR TECHNICAL EDUCATION.

UNDER this heading Lord Armstrong contributes a short article in the July number of the *Nineteenth Century*, which is well worthy of attention. It will be remembered that not long ago Professor Huxley wrote an able article in that magazine on "Technical Instruction," and the one now before us comes as a useful supplement on this very important subject. Lord Armstrong speaks with authority as one of the largest employers of skilled labour in this country, and as one who has established successfully immense works, whose reputation is second to none in dealing with the practical application of science to the requirements of modern warfare. We have therefore the views of a writer well able to judge of the need for technical instruction. Let us see what he has to say on the subject.

In the first place Lord Armstrong complains that at the present time there is a general outcry for technical education, although few people have any distinct idea of what they mean when they use that term, or any definite opinion either as to the class of persons who will be chiefly benefited by it, or as to the time of life at which it ought to be acquired. We cannot help feeling that there is much truth in these remarks, and we go further and say that the vague and indefinite speeches often made in public on technical education do more harm than good. They show to manufacturers and others who have the responsible conduct of works where technical skill is required, that the speakers are often mere *dilettanti*, having but very slight knowledge, if any, of the true bearings of the subject they profess to understand. To put it plainly, this rather disgusts the well informed, and if it does not lead them to pooh-pooh all that is said, it at least begets a feeling of distrust, and they often stand aloof. The practical result is that discussions usually are too diffuse and wanting in thoroughness. It is all very well to give expression to admirable generalities, but to be useful they must be accompanied by definite conclusions in detail, based on actual knowledge. Before dealing with technical instruction, Lord Armstrong comments on the present system of primary or elementary education, and he gives it as his opinion that it has the radical defect of aiming at instruction in knowledge rather than the training of the faculties. It will be remembered that Professor Huxley also thinks the present system of elementary education too bookish, and the opinion that this is so is becoming more general. Far be it from us to depreciate the value of knowledge —knowledge is power—but it must be limited, and of a suitable kind for the young mind, and have some relation to the work by which the student must afterwards earn his or her living. Lord Armstrong rightly points out that a man's success in life depends much more upon his capacities for useful action than upon his acquirements in knowledge, and he objects to the memory of a child being burdened with facts, rules and information which for the most part are of little use for developing the intellect, or preparing it for the ordinary vocation of life. He adds that not only should the mind be trained in habits of thought, and in quickness and accuracy of perception, but that the hand, the eye, and the ear should all participate in training exercises. He recommends the teaching of drawing, as well as exercises for cultivating the mobility of the hand, with precision and delicacy of touch. If in so doing the ability to use simple tools were acquired, it would be advantageous in any line of life that might be ultimately adopted. Every man and woman would be the better for pre-acquired manual dexterity, but to attempt to teach children special trades and processes of manufacture would, he conceives, be a mistake, and in this we entirely agree. It would involve great expense, would be a misapplication of time, and would only forestall the more effectual teaching, which at a more suitable age may be obtained by actual practice in factories and workshops. He aptly remarks that if a juvenile pickpocket can be trained to use his hands with exquisite adroitness in the practice of his nefarious occupations, why should not the hands of a schoolboy acquire by proper training similar mobility and delicacy of touch, to be used for honest purposes? The cultivation of the power of observation he also considers of great importance, and he reminds us that Houdin, the celebrated conjuror, and his son practised the receptive power of their eyes by walking quickly past shop-windows, and then recounting all the objects which in the moment of time had been presented to their view. Coming more closely to the subject of this article, Lord Armstrong says that most people have the mistaken notion that technical education is especially required for the working classes. He is of the opposite opinion, and points out that in the numerous class of labourers figuratively styled hewers of wood and drawers of water, no man would be rendered more efficient by the possession of any kind of technical knowledge, although the value of his labour would undoubtedly be enhanced by his having been, as a boy, trained in the exercise of his hands and limbs. In a higher scale of labour he takes the case of artificers, such as joiners, carpenters, fitters, and all others who work in wood and iron for constructive purposes. Here again he finds that manual skill, intelligently used, is the chief criterion of the value of their labour. These men, in general, work under direction, and so long as they do so it is their manual skill, and not their knowledge, that comes into play. He concludes, therefore, that knowledge, distinct from manual skill, does not add to the value of their labour. In the case of foremen, and others who emerge from the class of manual workers, he thinks that a certain amount of technical knowledge is useful, but considers that all the formation they require, can be found in a condensed and tabulated form in handbooks applicable to all kinds of constructive art. He then considers the class of managers and designers, who require technical education in a higher degree; but even here he thinks it is only in rare instances that high attainments in science are essential to practical results. Without doubt there is much truth in these statements, but we cannot help feeling that they need some qualification. We think Lord Armstrong is right in saying that technical instruction will not improve the work of labourers. At the last meeting of the British Association it was urged seriously that farm labourers would be better able to do their work if they learnt the science of successful husbandry; but such an idea is Utopian. By all means let the children of the working classes seek the best instruction obtainable, but do not let any one of them be misled by supposing that he has mastered the science of his calling, when in truth he can have but a parrot-like acquaintance with it. Lord Armstrong may also be right in supposing that joiners and mechanics will not be benefited by technical instruction, but we cannot agree with him that there is little or no need of it on the part of those who superintend the work of labourers and artificers. The need for this will vary somewhat in different trades, but in all we think it most desirable that the masters, the managers, and the leading foremen should have a technical training, which will not only fit them to direct and improve the work done under them, but enable them to understand and appreciate new or improved methods of attaining the ends required which may be brought to their notice. As we once before took occasion to remark, this is the crux of the whole question, and it is because our managers and superintendents have so neglected this part of their training, that the better trained foreigners have in many instances overtaken them. If the foremen, or heads of departments, are to be merely improved or extra-skilled labourers, or artificers, as Lord Armstrong leads us to suppose, it cannot be expected that they will benefit much from technical education. We trust, however, that the time will come when it will be necessary for those who are to take charge of workshops and factories to have learnt the science of their work, *i.e.* (to borrow Mr. G. J. H. Lewes's admirable definition) the systematic classification of experience, as well as the mere manupulative skill. At the present time, in Germany, superintendents often know more of the theory than of the practice of their work, but this, of course, is going to the other extreme. We only ask for a fair proportion of both theory and practice. Lord Armstrong has no faith in saving our commerce from the effects of foreign competition by a wide diffusion of technical knowledge. He thinks that cheapness of production and superiority of quality will decide the victory in the race of competition. This we think also, and we also agree with him that we shall improve our chance of maintaining a foremost place by the development of the mental and bodily faculties of our workpeople. At the same time we must remember that cheapness of production and superiority of quality will largely depend on the supervision of the works being in charge of persons who have received a good theoretical and practical training.

Reviews.

The Book of Bee-keeping; a Practical and Complete Manual on the Proper Management of Bees. By W. B. Webster, First-class Expert, B.B.K.A. London: L. Upcott Gill.

We well remember inspecting with no small pleasure the exhibits of the British Bee Keepers' Association at the "Healtheries." We were then strongly impressed with the conviction that bee-keeping, or, as it is now more learnedly called, "apiculture," might be carried on to a much greater extent in this country than it has yet ever been. In all rural, and even surburban districts, there must be multitudes of flowers which are never made to yield their tribute of nectar to any hive. We are, therefore, much pleased at the appearance of the volume before us, written specially, as the preface tells us, for amateurs, beginners, cottagers, and others who are desirous of keeping two or three hives of bees. Mr. Webster writes so simply and plainly, and from so evidently practical a point of view, as to be intelligible to all.

The profits of bee-keeping, when conducted in an intelligent manner, are shown to be much greater than an unobservant person would imagine. The author mentions two cases of working men who in this way cleared £29 and £25 in one season. We are glad to learn that, in addition to the supply of honey and wax, the value of bees is beginning to be recognised by gardeners and fruit-growers as promoting the fecundation of blossoms, and consequently increasing the crop. Says the author: "A widow woman in Hertfordshire, who depended in a great measure upon her cherry orchard for a subsistence, was obliged to obtain a fresh supply of bees after she had sold her original hives, as her orchard was not nearly so productive; this quickly righted itself after the introduction of the bees. Such facts speak for themselves." Most lovers of nature, though they may never have had any experience in apiculture, regard the mellow hum of bees over the garden beds as quite one of the enjoyable features of a summer day. The fear of being stung is very needless, unless we go out of our way to disturb a hive. It must, however, be remarked that some persons give off a specific odour imperceptible to our duller senses, which the bees recognise and resent. The nicety of smell and taste in bees is remarkable. Eminent chemists—the wish being, perhaps, father to the thought—tell us that beet-sugar and cane-sugar are the same thing. The little bee knows better. She will not touch the beet-product if any of the genuine tropical article be within reach. It is much to be regretted that tons of spurious honey, consisting of glucose, manufactured by the action of sulphuric acid upon potatoes or maize, have long been imported into England, and have done no little towards bringing honey into disrepute.

Of the different varieties of bees the author recommends the Ligurian strain. In productiveness they beat the common black bee by quite 25 per cent., and in addition they beat off robber insects in a more systematic manner. The Cyprian is said to be an excellent honey gatherer, but extremely irritable.

Beginners are advised to read some plain modern treatise on bee-keeping, and inspect some of the exhibits of bees to be seen at horticultural shows. The hive purchased should be one with the standard Association frames, which are all easily interchangeable. The stock purchased should be pure Ligurians.

In describing the method of hiving a swarm, the author declares that the old style of beating a "tom-tom" on pots, frying pans, and kettles, may amuse the beaters—it is a duty for which boys always readily volunteer—but it has no effect upon the bees.

The reader will find, in short, that every point in the practice of bee-keeping is very clearly explained. We may recommend this little manual to all intending bee-keepers, and we hope it may induce many persons who live in suitable places to try what they can do in apiculture.

The Land of the Broads. A Practical and Illustrated Guide to the Extensive but Little-known District of the Broads of Norfolk and Suffolk. By Ernest R. Suffling. London: L. Upcott Gill.

A pleasant, open-air book, fraught with the imageries of woodland and stream and open fields and skies innocent of smoke! It would, of course, have been more to our taste had the author been a naturalist, able to tell us something more about the fauna and flora of the district. He writes, indeed: "To the entomologist, ornithologist, and botanist I would say, By all means take your holiday here, for you may bring back with you specimens wherewith to beguile many a long winter's evening with your favourite pursuit. For butterflies, birds, and plants, this is a perfect El Dorado."

The book is rich in scraps of archæology, architecture and folklore, notes on the architecture prevailing in the region, and specimens of the curious local dialect. That he has a keen eye for the picturesque and an appreciation at once of the beautiful and the humorous, the reader will soon recognise. It is painful, however, to find that Mr. Suffling has to put in his protest against the practice of setting up empty bottles in the fields as "cockshies," and leaving the broken glass scattered about, to the danger of cattle and horses.

The author mentions the Norfolk coasts as localities where the palæontologist sometimes finds treasures, especially after a strong north-westerly gale.

Due mention is made of the museum at Norwich, eminently rich in raptorial birds and in fossil bones. Incidentally the author speaks of the "Madder Market." This makes us wish that he, as a native of Norfolk and evidently well acquainted with the history and traditions of his native county, had told us whether madder was formerly cultivated on an industrial scale in the eastern counties.

The changes which the River Yare has undergone since the days of King Canute are duly chronicled. It seems strange, though established beyond doubt, that Norwich was once a fishing-town. But other East Anglian rivers have fared like the Yare. It is said that all the stone for building the Abbey of St. Edmund's was brought by sea from Caen, and conveyed up the Orwell and the Gipping, past Stowmarket, and to within a few miles of its destination. Now the tide does not ascend beyond Ipswich.

The account of the kingfisher—a bird doomed, we fear, to early extirpation—is open to misunderstanding. The author doubtless knows that not merely one species of this bird, but many are found in tropical and subtropical countries, though none surpass the native kingfisher in beauty.

The author is perfectly correct in affirming that herons are capable of swimming and diving, and we should scarcely have thought that the contrary opinion was still held by any naturalist. Waterton maintains that these dignified birds neither swim nor dive, but his friend and biographer, Norman Moore, has seen them doing both in the lake at Walton Hall.

We find here a notice of some curious superstitions. The writer, however, does not mention two of the most curious which exist in Suffolk, and doubtless extend into the sister county. One of these is the notion that stones—paving-stones, mile-stones, boulders, etc.—grow if left lying on the ground. The other is the faith in the practice of hoplochrysm. If a labourer cuts himself with sickle, bill-hook, or knife, he simply binds up the wound and applies some medicament to the tool or implement which has caused the injury. This is a venerable superstition, and was in former ages recommended by Helmont and practised by the most eminent surgeons. That such delusions will sooner or later fade away is very probable, but it is to be feared that their place in the popular brain may be taken by follies as illogical and more dangerous. Mr. Suffling's book may be safely adopted as a guide by pleasure-seekers bound for the "Broads," and we believe that in seeking a place for their holiday excursions they might go further and fare much worse. We must not overlook one pleasant feature of the work before us—the author is not troubled with "views," or, if he is, he does not feel bound to obtrude them upon his readers.

Henslow's Botany for Beginners. A short course of elementary instruction in practical botany for junior classes and children. By the Rev. Professor G. Henslow, M.A., F.L.S., F.G.S. Fourth edition. London: E. Stanford.

We are not in the least surprised to find that a fourth edition of this excellent little manual has been required. In our judgment it is a model of a scientific treatise for beginners. The course of instruction from the very first is practical, not wordy, but *thingy*, if we may so call it. If this book is used according to the principles laid down in the preface, the pupil will be gradually trained to observe closely and correctly. This, we submit, much more than the mere facts recognised, is the true point to be aimed at in teaching any of the natural and physical sciences.

The author takes up in succession a number of common British wild plants—easily procurable in most country places—and by their means expounds the leading principles of botany. By the time a boy or girl of ten to twelve years of age has worked through this series, he or she, except of unusually narrow capacity, will have "eyes" in place of the "no eyes," now so alarmingly common. At the same time the pupil obtains a living, a hand-to-hand familiarity with the technical language of botany, and can henceforth read botanical works with understanding and profit.

We notice with pleasure that the author gives instances of fruitful hybrids, thus fortifying the pupil against one of the favourite fallacies of the opponents of evolution.

A Catalogue of the Moths of India. Compiled by E. C. Cotes, First Assistant to the Superintendent, Indian Museum, and Colonel C. Swinhoe, F.L.S., F.E.S., F.Z.S., etc. Part II. *Bombyces.* Calcutta: Trustees of the Indian Museum.

This division of the author's work comprises no fewer than 1,623 species, including, of course, the important silk-yielding genera *Bombyx*, *Attacus*, *Saturnia*, and *Antheræa.*

The *Bombyces* are here divided into the families *Aegeriidæ*, *Zygænidæ*, *Agaristidæ*, *Chalcosiidæ*, *Nyctemeridæ*, *Lithosiidæ*, *Arctiidæ*, *Liparidæ*, *Bombycidæ*, *Notodontidæ*, *Drepanulidæ*, *Limacodidæ*, *Lasiocampidæ*, *Phaleridæ*, *Sa urnidæ*, *Cossidæ*, and *Hepialidæ.*

As in Part I. of the "Catalogue," the synonymy of each species, if needful, is given, and there is reference to collections where the type is to be seen.

The *Bombyces*, owing to their comparatively feeble powers of flight, show a much less tendency to become cosmopolitan than do the *Sphinges.* Families and genera are often common to India and to Europe, but we do not recognise a single species except it has been artificially acclimatised. Not a few of the species here described were ranked by Linnæus, Cramer, etc., among the *Sphinges.*

Archæological Discovery at Chester.—A curious line of massive blocks of sandstone have been recently unearthed in Foregate-street, extending for nearly one hundred yards in a line with the present street, and four feet in depth. No definite conclusion has been arrived at respecting the stones or their age.

Abstracts of Papers, Lectures, etc.

MINERALOGICAL SOCIETY OF GREAT BRITAIN.

A GENERAL meeting of this Society was held on June 28th, at the Museum of Science and Art, Edinburgh. Professor Geikie occupied the chair. "The Distribution and Origin of the Mineral Albertite in Ross-shire" formed the subject of the paper by Mr. Hugh Miller, F.R.S.E., H.M. Geological Survey. The conclusions he arrived at were that the primary source of the albertite in the Strathpeffer district was the bituminous shales of the old red sandstone; that the mineral, although it occurred in gneiss, in sandstone, in conglomerate, and in the bituminous shales themselves, was found mainly in the vicinity of faults, where the strata had been subjected to great pressure; that the veins are, in some cases at least, injection veins, having some of the characters when studied in detail of intrusive dykes; that the veins, having very seldom the same direction as the lines of fault or the fault-joints parallel with these, probably were injected into lines along which there was relaxation of pressure; and that the mineral, in those instances which can best be studied, entered the veins in a fluid and penetrating form, probably in the form of some kind of petroleum. A paper, accompanied by a series of tables, was next submitted by Messrs. Alexander Johnstone, F.G.S., and A. B. Griffiths, Ph.D., F.R.S.E., on "The Rock-forming Feldspars and their Determination." Papers were also submitted by Professor Albert H. Chester, Hamilton College, U.S.A.; the Rev. W. W. Peyton, William Morrison, M.A., Dingwall; and Professor M. F. Heddle. A series of hydro-carbons were exhibited by Professor W. Ivison Macadam, and an analysis given of the albertite beds; some fine crystals were shown by Mr. S. Peyton and Dr. T. A. G. Balfour; a series of minerals from Iona and Tiree were sent for exhibition by the Duke of Argyll.

ROYAL HORTICULTURAL SOCIETY.

AT the meeting of the Scientific Committee, on June 26th, Professor Church contributed a summary of his highly interesting and important researches upon the presence of aluminium in the ashes of plants. This substance, instead of being peculiar to the species of Lycopodium, as once supposed, is found in minute traces in the ashes of very many others, a circumstance not to be wondered at, considering the abundant distribution of the element in many soils. It occurs in all the species of Lycopodium examined, except those which are of epiphytic habit, and which, consequently, do not directly derive their food from the soil. It does not occur in the allied genus Selaginella. It occurs in the ashes of some tree ferns in large proportions, sometimes forming as much as 20 per cent. of the ash, as in *Alsophila australis*, *Cyathea medullaris*; while from others it is all but absent. In the British species of ferns little or no alumina has been found.

Mr. McLachlan showed specimens sent from Trinidad of beetles injurious to tobacco and egg plants in that island, and which he found to be a species of Epitrix, allied to that which feeds on *Atropa belladonna* in this country.

Mr. McLachlan called attention to the notion that cold winters are injurious to insects—a notion he stated to be erroneous, although, no doubt, severe alternations of cold, heat, drought, or moisture, were prejudicial to insect life. During the present season it was noticed generally that great destruction of foliage occurred from caterpillars, which destroyed the succulent portions of the leaf and tied the frame-work and fragments together by a web of fine threads comparable with spiders' webs. These caterpillars were different in different cases. In the oak they were species of Tortrix; in the apple the winter moth was destructive; while in other cases the larva of the Ermine moth was exceedingly hurtful to leaves.

Mr. Plowright, in a note, stated that the Æcidium on pea and on the bean was produced on both plants by infecting them with the same infecting material, viz., *Uromyces fabæ*. The Æcidium on the pea differs in appearance from that on the bean, the pseudoperidia in the former being few, and scattered over pale yellowish spots, while on the bean they are crowded in thickened white spots.

THE SANITARY INSTITUTE.

AT the twelfth annual meeting of the members of this Institute, held on July 12th, in the Lecture Hall of the Royal Institution, Mr. E. Chadwick, C.B., in the chair, Mr. B. W. Richardson, M.D., read a paper on "Storage of Life as a Sanitary Study." After referring to instances of long life in lower animals and in man, he said these animals and these persons by some peculiar process as yet but little investigated held life as a long possession, and to this faculty he applied the term "storage of life." The conditions which favoured such storage he held to be (1) hereditary qualification, (2) the virtue of continency, (3) maintenance of balance of bodily functions, (4) perfect temperance, (5) purity from implanted or acquired diseases. Speaking first on the influence of heredity, he remarked that if the ages at death from natural causes were obtainable of the parents of a man or woman through three generations, the sum total of them divided by six might be accepted as the commercial value of the last life. Bilious and sanguine temperaments were the best for a long life, and the nervous and the lymphatic the worst. Treating on the virtue of continency, he maintained that under a proper sanitary and healthy régime there would be no danger of, nor trouble from, over-population. In the third division of his discourse he held that a body comparatively weak, but with all the organic structures of good balance, was calculated to live longer than a finer body with one of its organs enfeebled or diseased. Coming next to temperance, he maintained that all luxuries are bad for long life, that stimulants of every kind are detrimental, and alcoholic stimulants the most so. The prevention of disease was the last topic dealt with, and here it was, he said, that the art of sanitation came into most effective play.

LIVERPOOL ASTRONOMICAL SOCIETY.

THE annual meeting was held at Liverpool on Monday July 9th, when the report of the Council was read. The Society appears to have made very satisfactory progress during the year. The number of members has been increased by more than 200, and the balance-sheet shows that, in a pecuniary sense, the Society occupies a favourable position. Considerable additions have been made to the library during the past year, and the work of the different sections has been of a very varied and extensive character.

Mr. T. G. E. Elger, who is well known in connection with selenographical work, was elected President for the ensuing year, in succession to Mr. W. F. Denning, of Bristol, whose valuable labours in meteoric and planetary astronomy have long been recognised. The report of the Council included a reference to the resignation of the Hon. Sec., Mr. W. H. Davies, and expressed a gratifying tribute to his zeal and assiduity in performing the arduous duties of his office for such a long period. His energy and capacity for management has contributed, more than any other cause, to the rapid development of the Society, and to the high position which it has attained amid kindred associations. Mr. Davies is succeeded by Mr. W. E. Rowlands, and there is every prospect that the future of the Society will be conducted on an equally satisfactory base as in the past. There can be no doubt that it is accomplishing a most useful purpose in banding together and utilising the work of our astronomical amateurs. The *Journal*, which is published monthly during the sessional meetings from October to May, is widely read, and contains papers on various branches of the science by writers who are entitled to speak with authority. The possessors of telescopes, and all those who may either feel interested in astronomical theories or in practical work, must naturally regard this Society with sympathy and accord it their support, as especially calculated to encourage and stimulate their efforts in learning something more of the wonders of the heavens.

Manchester Scientific Students' Association.—On June 16th the members of this Association made an excursion to Chelford for Capesthorn, under the leadership of Mr. J. Hetherington. Owing to an unfortunate delay, Mr. Hyde's botanical lecture on "Umbelliferæ" had to be delivered in the train. On June 30th a visit was paid to the Manchester Ship Canal's Works at Eastham, and the newly-discovered old footpath or road inspected.

Barrow Naturalists' Field Club.—The first excursion of the season was made on June 30th to Ravenglass, where the ruins of Wall's Castle were inspected. A visit was then paid to Ross Camp, on Muncaster Fell.

Ludlow Natural History Society.—The annual report of this Society has just been issued, and we regret to find that the Society has been compelled to draw upon its reserve fund. We trust the appeal to the residents will be successful.

Manchester Microscopical Society.—At the concluding meeting, for the present session, of the mounting section, the chairman, Mr. E. P. Quinn, in the course of a description of nearly 100 slides exhibited by him, said that they had been specially mounted to use that evening to illustrate the micro-chemistry and physics of the vegetable cell. As he desired to show them the cells in a condition as nearly as possible like that of the fresh tissues, he had mounted the specimens mostly in fluid media and principally in a 0·4 per cent. solution of sodium fluo-silicate, which, whilst having the preservative effects of solutions of corrosive sublimate or carbolic acid, did not, like them, tend to take away the green colour which was in many cases so desirable to preserve. Another advantage in using it is that it causes but little alteration in the shape of the cells, owing to its slight solubility (four parts in one hundred) in water. It is sold as a disinfectant under the name of Salufer.

POISONS AND POISONING.

A Lecture delivered by C. Meymott Tidy, Esq., M.B., etc., before the Royal Institution of Great Britain.

(*Concluded from p. 46.*)

THERE naturally follows on what I have said respecting this chemical action of poisons, the following important question :—

Given knowledge of certain properties of the elements, such as their atomic weights, their relative position according to the periodic law, their spectroscopic characters, etc. ;—or given knowledge of the chemical composition, the molecular constitution, together with the general chemical and physical properties of compounds, in other words, given such knowledge of the element or compound as may be learnt in a laboratory—does such knowledge afford any clue whereby we may predicate the probable action of the element or of the compound respectively, on the living body ?

1st. Let us limit our attention to the *elements*.

The starting-point of this inquiry was the toxic properties of the metals. The work of Blake (1841) in this direction was afterwards extended by Rabuteau (1867). Their observations led them to the general conclusion that "the physiological activity of the metals increased with their atomic weight." This broad general statement was modified at a later period by noting that the reverse was the case with certain groups of metals. Thus potassium (39) is more poisonous than sodium (23), and barium (137 more poisonous than calcium (41). These facts led Rabuteau to the conclusion that any comparisons of toxicity must be limited to the metals belonging to the same group. Husemann and Richet, however, pointed out that even this rule did not hold good, seeing that lithium having an atomic weight of 7, was far more poisonous than either sodium or potassium.

Experiments on the metals were further conducted by Richet with the metallic chlorides. Grain by grain, at intervals of forty-eight hours, he added the chlorides to water in which he kept fish of a given kind. He then recorded the maximum strength of the solution of the metallic chloride in which these said fish would live for forty-eight hours. The conclusion at which he arrived was that the limits of the toxicity of a metal bore no relationship either to its atomic weight, or to any other chemical or physical characteristic of the metal.

Bouchardat and Stewart Cooper, in a similar manner, experimented with the non-metals. Selecting the haloid group of elements, they noted that their toxicity was inversely to their atomic weight, flourine (19) being the most poisonous, and iodine (127) the least poisonous of the group, chlorine (35.5) and bromine (80) occupying their proper intermediate positions. But here again the group theory was inevitable. What was true of monad elements was not true of the elements of higher atomicity, the toxicity of selenium (79) being far greater than that of sulphur (32).

With these facts before us there arises this question, Was a relationship to be expected between physiological action and atomic weight ? One poison acts on muscles, a second on nerves and nerve-centres, a third on the blood :—Is it likely, even supposing a relationship to exist between a certain group of elements and a given organ or a given structure, that the relationship would be the same in the case of all organs and all structures ? These researches (the outline of which I have briefly indicated) suggest this much to future observers, viz.: First of all group your poisons according to their methods of operation, and then see how far the degree of toxicity of the terms of any one group show relationship to the atomic weights of such group.

But the difficulties of comparison thicken when we consider the physiological action of certain allotropic modifications of the elements.

Thus compare *yellow* phosphorus, a body readily inflammable, soluble in bisulphide of carbon, firing by contact with iodine, with *red* phosphorus, a body at variance with the yellow variety in the three respects named. Nor is this all. For *yellow* phosphorus is an active poison, two grains being a certainly toxic dose, whilst *red* phosphorus is an absolutely inert body.

Take a second illustration. In its ordinary form oxygen plays the part of a life sustainer. But oxygen is only a life sustainer in its common form and at ordinary pressure.

On this latter point I have no time to dwell, save to mention that if an animal be exposed to oxygen at three pressures, the resulting symptoms are not unlike those induced by strychnine.

There is, however, an allotropic form of oxygen called *ozone*. The physiological action of ozone was the subject of a communication to the Royal Society of Edinburgh by Dewar and McKendrick (1873). Their experiments were made on both cold and warm-blooded animals, including amongst the latter themselves and their assistants.

The results are remarkable, more particularly when we remember that the air with which they operated, at most only contained 10 per cent. of ozone.

Placing a large frog in a jar of air, and then ozonising the air, the frog in about half a minute closed its eyes, the respirations fell from 96 to 8 per minute, and the body temperature was lowered 4° or 5° C. The animal recovered in about 8 minutes, when pure air was admitted into the receiver. Death resulted if the animal was exposed for any lengthened period to the action of the ozonised air.

As regards the action of ozone on warm-blooded animals, Dewar records certain personal experiences, chief amongst which were a tendency to breathe slowly, an enfeebled pulse, and fits of sneezing.

But now comes the curious part of the story, viz. that at the *post-mortem* on the animals that died under the influence of ozone, the blood was found to be *venous*. (The results were similar when pure ozonised oxygen was employed.) It is most remarkable that the *post-mortem* appearances of death from an intensified oxygen should resemble those of death from carbonic acid.

I give these illustrations to show why there should be reason to doubt whether the physical or chemical properties of an element can ever suggest either toxic activity or physiological action.

2nd. *Compounds*.

Is there any relationship between the chemical composition or constitution of a compound body and its physiological action?

The first series of researches on this question was directed to determining whether, in the case of a salt, the acid or the base was, physiologically, the most important ingredient (Blake 1841).

No doubt most often the active agent of a salt is the base, but this is by no means uniformly the case. Probably the solubility of a compound and the different proportions of acid to base in the salt (*i.e.* whether the compound in question be an acid or a basic salt) are agencies which also help to determine the toxicity of the body and its physiological action.

A second series of experiments was made by Blake for the purpose of showing that, given a series of isomorphic salts, the intensity of physiological action increased with the molecular weight. He further contended that salts crystallising in different forms had different physiological actions. On this basis he constructed a series of nine groups of salts, each group being characterised by special physiological actions, insisting with much reason that we possess in living matter a reagent (so to speak) capable of aiding us in our investigations into the molecular properties of chemical compounds. If from molecular constitution you can determine physiological action, probably from physiological action conversely you may determine molecular constitution.

Another series of experiments in a similar direction were made by Schoff on the Continent, and by Fraser and Crum Brown in this country.

Of these experiments the most important are those indicating how from bodies of vastly different physiological action you may obtain derivatives having similar properties.

For example, the physiological action of *strychnine* is primarily exerted on the spinal cord. As a result, convulsions occur as a prominent symptom. But if we introduce into the strychnine molecule a methyl group (forming methyl-strychnine), the action of the drug is altered—methyl-strychnine paralysing (strychnine stimulating) the motor nerves.

But here comes a curious fact. If we take morphine, or nicotine, or atropine, or quinine, or veratrine (none of which bodies are comparable in their physiological action to strychnine), and convert them into their methyl-derivatives, the methyl compounds formed (viz. methyl-morphine, methyl-nicotine, etc.) are comparable in their physiological action to methyl-strychnine.

We must admit these experiments to be striking. One treasures any experiment suggestive of the chemical constitution of a body indicating physiological action.

But again :—The true physiological action of a drug is not so much its general as its selective action, this selective action being largely dependent on the *dose* administered and the mode of administration.

For example: Inject into the circulation of a frog a *small* dose of *veratrine*, great muscular stiffness results, a *large* dose similarly administered not producing this effect. And now change the method of administration: Apply the *small* dose directly to the muscle, you get no symptom; but apply the *large* dose directly, and great muscular stiffness results. Here see the modifying influence of dose and of the mode of administration.

Again, the difficulty of "allotropism" in the case of elements, finds its counterpart in "isomerism" in the case of compounds. Thus cyanogen and paracyanogen are bodies of identical *percentage* composition, and yet cyanogen is one of the most poisonous of gases, whilst paracyanogen is one of the most inert of solids.

Or, again, take *piperin* and *morphine*. These bodies are of identical percentage and molecular composition. They agree (it is true) in being poisons. But how vastly different their physiological action!—the one an extreme irritant, the other a powerful narcotic.

I fear we must admit that, as no *a priori* reasoning could predict that by combining copper and sulphuric acid a blue salt would be formed, so no *a priori* reasoning, no knowledge of chemical constitution, can predicate what will be the special organ on which any given poison will act, nor, even supposing that the organ upon which the chemical activity of the drug will be exerted be known, what will be the nature of such chemical action. The science of drugs, like the science of chemistry, is, and must ever remain, an experimental science.

And, be it remembered, the poisons of the toxicologist are the medicines of the physician. Physiological action is a subject-matter for experiment. Let the guard be jealously set and as rigidly maintained to prevent cruelty to animals; but ask yourselves, whether to rob the higher creation of life and health rather than that one of the lower creation should suffer, be not a refinement of cruelty—the cruelty of cruelties?

Two general observations are suggested. And this first: The later age history of poisoning is the history of a profession. This profession we find closely associated, not only with the profession of medicine (the art of healing), but with witchcraft, incantation, and charms. The threefold arts of poisoning, witchcraft, and medicine, moreover, become so closely allied to religion, as to claim, each and all, the shield of a sacred sanction and the protection of a Divine voice. Even that very word *φάρμακις*, the Greek for '*a dispenser of medicines*,' is the same word used to imply '*a witch*' and '*a poisoner*.' The modern scientist has once and for ever shattered the bond that united science with superstition. It was a special ministry of science to teach men that in the preparation of medicines the pharmacist required no stuffed crocodile to preside over the mysteries of his laboratory, nor incantation to give virtue to his drugs.

And this secondly: The villanies of the early poisoners can never again be practised in the light of the science of the nineteenth century. Science can and has done what legislation could never do. I claim that a science which, like a blood-hound, can track with cunning scent the minutest atom of a poison in the body, *is* helping forward the day when poison shall cease to be the instrument of a secret treachery, because there are eyes it cannot hope to evade, and a science whose investigations it will not dare to defy.

Insect Powders.—These powders, according to a communication from M. de Tartaglia to the *Echo Universel*, are made from the pyrethrum of the Caucasus, which grows spontaneously in Dalmatia and Albania, and is now the subject of an extensive and lucrative commerce. The plant loves light, calcareous soils, free from damp. The planting is effected in spring and autumn, preserving a distance of two feet between the plants, and carefully removing weeds. The produce for the first year is insignificant; the second year it repays all expenses, and the third year the plants are covered with flowers. The crop from $2\frac{1}{2}$ acres of ground is 10 cwt., and is worth at present about £200 per cwt. Why is its cultivation not attempted in Australia or at the Cape?

Sulphonal, the new Soporific.—This newly-discovered compound, though itself free from smell or taste, is manufactured from mercaptan, one of the most malodorous products known. According to the *Medical Press*, the manufacturers of sulphonal have, in consequence, some difficulty in finding a place where they may carry on their business without the risk of proceedings for creating a nuisance.

THE GROWTH OF CHILDREN.

Until recently it was supposed that the growth of children, and in an analogous manner, of other young mammalian animals was a perfectly continuous process. Accurate measurements and weighings have shown, however, that such is by no means the case, and that, on the contrary, human growth takes place in certain periods, with intervening times of cessation.

Some interesting data have been recently collected by Malling-Hansen, Principal of and Chaplain to the Royal Institution for Deaf-Mutes at Copenhagen, and have been communicated to *Humboldt* by Prof. Gadd.

In this establishment, 130 children—boys and girls—have been daily weighed and measured since the beginning of the year 1884.

In the weights three main yearly periods of increase may be distinguished—a maximum, a mean, and a minimum. The maximum period begins in August and ends in the middle of December, lasting four and a-half months. The mean period lasts from the middle of December to the end of April, four and a-half months. The minimum period extends from the end of April to the end of July, three months. During the maximum period, the daily increase of weight is three times as great as in the mean period, and almost all that is gained in this mean period is lost again in the minimum period.

The increase in height likewise exhibits three main periods, a minimum, a mean, and a maximum. The minimum period begins at Copenhagen in August, and lasts until about the end of November, about three and a-half months. The mean period extends about four months, from the end of November to the end of March. The maximum period lasts from the end of March to the middle of August, four and a-half months.

In the mean period the daily increase in height is twice as great, and that in the maximum period two and a-half times as much as in the minimum.

The true period of growth, if we take both height and weight into account, extends from the end of March into December, and may be divided into two parts; firstly, the maximum increase of height, and then the maximum growth in weight.

During the latter period, the growth in height is so trifling that it may be regarded as a pause in growth.

The mean periods of increase both in height and weight coincide for the greater part of their duration, but the growth in height is during this period relatively more considerable than the gain in weight.

In like manner the minimum period for weight and the maximum for stature are chiefly coincident. The maximum period of growth is the pause of gain in weight, and is even attended with a loss in this respect.

The periods of height begin and close about a fortnight earlier than the weight-periods.

The periods of stature follow in an inverse order from the weight-period. The development of stature rises gradually from the minimum through the mean to the maximum, and sinks then suddenly to the minimum. The increase of weight rises at once from the minimum to the maximum, and sinks them slowly through the mean period down to the minimum.

The fluctuations of the periods of weight are much more considerable than those of the height periods.

One centimetre (3-8th inch) in height corresponds in the maximum weight period to an increase of 6 lbs. 3 ozs. (?) in the mean period to 16 ozs., and in the minimum period to 17 ozs.

It has doubtless not escaped the observation of attentive parents, that the growth of their children in height appeared to be approximately in an inverse proportion to their increase in weight. But the precise observations of Malling-Hansen have not merely established this point, but have brought it into relation with the seasons of the year.

But it is obvious that very much remains to be done in this by-way of biology. Malling-Hansen's observations were made upon children of both sexes between the ages of nine and fifteen. It is now necessary to inquire whether the same periods of increase in height and weight can be traced from the fifteenth year to the attainment of full maturity. Another point is the extension of the observations to children of other races and in other climates. Malling-Hansen has already surmised a connection between the intensity of growth of children—and of course of all organisms—and the variations in the heat radiated by the sun upon the earth. He does not suspect that the fluctuations in the totality of heat derived from the sun are the direct, immediate cause of the variations in the increase of weight, but he, with Boys-Ballot, thinks it probable that an unknown agent proceeds from the sun in periods corresponding to the solar rotation of twenty-seven days. This unknown agent he supposes to arrive unconnected with meteorological conditions. Its sphere of action, he thinks, includes all organisms which, according to the time of the year, are differently susceptible to the stimulus of this "growth-energy."

In the meantime he points out in particular one among the many practical conclusions to which his observations may lead. As much as possible of the two periods of maximum growth—*i e.*, in height and weight—should be passed in the summer holidays. In this respect the Swedes and the South Germans have, by instinct or accident, outstripped the North Germans and the Danes. The former give their children two entire months of holiday in the summer; in some parts even more. Some schools in the west of Germany, we must remark, give no holidays at all.

The summer holidays should begin at the end of June and extend to the beginning of September, thus allowing full play for the maximum periods of growth.

Besides the above-mentioned three annual phases, Malling-Hansen has recognised periods of 25 and of 75 days within which the conditions of growth undergo cyclical variations.

As regards the daily fluctuations, he finds that on the average of the three months, December 1883, and January and February 1884, every boy in the institution lost about ½oz. in weight between the conclusion of dinner, at two p.m. to nine p.m., and in the course of the night, from nine p.m. to six a.m., a further amount of about 2ozs. From six a.m. to one p.m., just before dinner, each boy regained nearly ½oz. Whilst the dinner effected in each an average increase of 2⅜oz.

The following changes of height were observed in 22 boys, varying from 13 to 16 years, during five weeks. From 6 to 8 a.m. there was a loss of 4 millimetres; during lessons, 8 to 9 a.m., a gain of 3 millimetres; from 9 to 10 a loss of 1 millimetre. From 10 to 11 (play-time), a further loss of 1 millimetre. Between 11 and 12 a.m. (lessons), a gain of 2 millimetres; from 12 to 1 p.m., a loss of 4 millimetres; and from 1 to 5 p.m., of 3 millimetres. Thus from 6 a.m. to 5 p.m. there was a nett loss of 9 millimetres in height (nearly two-thirds of an inch). From 5 to 9 p.m. the changes were trifling, and from 9 p.m. to 6 a.m. there was a gain of 9 millimetres.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

A CIRCLE PROBLEM.

Your correspondent, "A. P. T.," has again omitted to show the principle upon which his facts are based. *The circumference of a circle = diameter* $\times \pi$ ($\pi = 3{\cdot}1416$), and if, therefore, we have two circles, A and B—A with diameter 8 ft. and B with diameter 12 ft.—then the difference of the circumferences of A and B $= \{(12 \times \pi) - (8 \times \pi)\}$ ft. $= (4 \times \pi)$ ft. If A and B had diameters of 10 and 15 ft., the difference of the circumferences would be $\{(15 \times \pi) - (10 \times \pi)\}$ ft. $= 5 \times \pi$ ft. Thus we see that the difference of the circumferences of two circles is always *the difference of the diameters* $\times \pi$; and hence, when the difference of the diameters is always the same, the difference of the circumferences is always the same, no matter how small or how great the circles may be. This, as might be expected, is not the case with the difference of the areas of the circles, that difference being proportional to the difference of the *squares* of the diameters or radii.

Your correspondent also, in quoting from "Whitaker's Almanack," has given us *the diameter of Venus instead of the diameter of the Earth*, which is 7,926 miles ("Whitaker's Almanack," 1888, page 78). One error, however, is a great improvement on four, and seems to show that "A. P. T.'s" type-writer is not quite as incorrigible as he would have us believe.

KUKLOS.

COSMICAL ORIGIN OF HAILSTONES.

Ordinary meteors fall on our earth in their own time and without waiting for any special terrestrial weather. Hailstones, on the other hand, choose suitable conditions and appropriate weather. If Schwedoff's theory (mentioned by Mr. Williams in "Table Talk," No. 26 and following pages, be correct, we ought to hear of an occasional hailstone or shower of hailstones at times when terrestrial conditions are diametrically opposed to their production. Is there record of any such occurrence? If not, this seems to show a weak point in the theory.

F. M.

THE COLDNESS OF JULY 11 AND 12.

As a rule, the hottest day in the year in London is July 16th. We are therefore within a week of that date, and yet for two days I have been luxuriating in the warmth of an ever-ready gas fire.

It would not be at all difficult to find two days in January warmer than these two in July; but as it would be rather confusing to compare with two, I take only one—the first that comes to hand:—

	Minimum. Deg.	9 a.m. Deg.	Maximum. Deg.
1877—January 1st	49·3	50·0	54·0
1888—July 11th	42·8	45·4	55·7
1888—July 12th	45·4	49·9	54·2

These two days have therefore been colder than the 1st of January—July 11th by 5·1 deg. and July 12th by 3·2 deg. Memory is not a safe guide, but I remember no parallel in July.

Some years back Mr. Glaisher, F.R.S., worked up the daily temperature at Greenwich from 1814 to 1873, and in that long period I can trace no days in July at all comparable with these, except two, one in 1836 and one in 1856. The precise figures are as follows:—

Mean Temperature at Greenwich.	Deg.	Mean Temperature at Camden Sq.	Deg.
1836—July 20 ..	47·7	1888—July 11 ..	46·2
1856—July 8 ..	48·0	1888—July 12 ..	48·1

Wednesday, July 11th, is therefore absolutely without precedent, and to-day is very nearly so.

G. J. SYMONS, F.R.S.

62, Camden Square, N.W., July 12.

FECUNDITY OF SPARROWS.

Your correspondent, Mr. J. P. Nunn, states in his letter (Scientific News, II. p. 21) some very interesting facts concerning sparrows, but, unless these birds are remarkably prolific, I should like to know why they so far outnumber all our other species of land-birds. Sigma.

RECENT INVENTIONS.

The following list has been compiled especially for the Scientific News *by Messrs.* W. P. Thompson *and* Boult, *Patent Agents, of 323, High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

Producing Currents of Air.—A fanning apparatus has been patented by Mr. A. J. Boult, on behalf of F. Bisson. The apparatus consists of a rotary fan mounted in bearings; on the axis of the fan a small pinion wheel gears with a wheel of larger dimensions, and has a rotary motion imparted to it in each direction alternately; the motion in one direction being produced through a cord mechanism by the person using it, and in the other by a suitable weight or spring.

Milk-pan.—A milk-pan has been patented by Mr. J. Llewellin. The pan is constructed of a shallow receptacle, having hollow walls in two parts, the bottom of which are dish-shaped. The space between the two parts receives hot or cold water, to regulate the temperature of the milk, which is placed in the inner portion, thereby causing the cream to rise. The water is introduced through an opening having a cover, and the pan has a tap in the middle of the bottom to allow the water to be drawn off.

Anemometers.—An anemometer has been patented by Mr. J. Hicks. The object is to substitute metal pressure chambers in place of those usually used. A disc of metal is mounted on a suitably shaped chuck, and has spun upon it a number of concentric annular corrugations, the centre of the disc being formed with a tubular neck on one side, and its edge with a rim on the other side. Two of these discs are placed face to face, with the rim of the one within the rim of the other, and are soldered thus air-tight, thereby forming one section of the pressure chamber; any suitable number of these sections are connected together by the necks, which are placed one within the other, and spun over one another, and soldered air-tight. When required to indicate vacuum, the corrugated discs are made with convex outer faces and when for pressure they are made with concave outer faces. The interiors are protected by coating with india-rubber varnish and the exteriors with stove jet.

Transforming Electric Currents.—Mr. A. J. Boult has patented on behalf of S. Doubrava an apparatus for transforming electric currents. The invention is composed of a commutator consisting of a metal disc, revolving round a shaft. To the periphery of the disc are fastened insulating strips, and two contact brushes are so arranged that when one touches an insulating strip, the other touches the conducting part of the periphery. This commutator charges a condenser and discharges it afterwards into the circuit through a larger condenser. When the disc revolves, the second coating of the smaller condenser is connected with the generator by means of one of the brushes, the disc, and a sliding contact, and this coating is charged to the potential of the generator; by a further movement of the disc, this connection is broken, and the large condenser is connected by means of the other brush. By this means the smaller condenser is discharged into the larger one, through this into the circuit, and by the combination of these two condensers the potential will be lowered. By the combination of the condensers the high tension of the generator is changed into a lower one in proportion to the relative surfaces of the condensers.

Compass.—Mr. A. Gross has patented a compass for indicating when a vessel leaves its course. A hollow axle is fixed in the centre of the compass glass, and a forked piece of brass acting as a course setter is fitted thereon on the outside of the glass, with its ends resting on the rim of the compass. The axle is carried below the glass to within an inch of the compass card, and on its lower end is fitted another transmission fork. The ends of this fork are made of fine gold wires, fixed to have an outward spring and to reach the periphery of the card. The wires pass through the grooves of a slide and the perimeter ends are brought together or set apart by means of the slide operated by a pinion gear passing through the hollow axle, and having a racket adjustment fixed to it parallel with the glass. A piece of platinum wire is fixed at the north point of the compass connected with the magnetised bar of the card; this wire is bent to give spring power with the end pointing to the glass. The cap of the card is made of tempered silver steel. The wires of a battery are so connected with the compass bowl and alarm, that when either of the wires of the lower fork comes in contact with the platinum wire at the north point the circuit is complete. The wires of the lower fork limit the extent of deviation, so that when such deviation occurs the wires come into contact, and sound the alarm.

Switch.—A "bell pull" electric-light switch has been patented by Mr. A. P. Lundberg. The object is to produce a switch which will make good contact, and quickly "make" or "break" contact, and which, with every fresh pull, will make and break contact alternately. A disc is mounted on a base of any insulating material, so as to be free to rotate on a centre. Two metallic terminals, also on the base and rubbing against the circumference of the disc, are so arranged that every alternate quarter of a revolution of the disc causes metallic contact to be made or broken. The revolving disc has on its underside four pins fixed equi-distant from one another in a circle. Attached to the bases under the disc and pins is a bar, free to move vertically, having on its upper side a spring catch passing freely with the bar in a downward direction without disturbing the disc, but which engages with one of the four pins, when moving upwards, thus carrying the disc round a quarter of a revolution. The movement of the bar downwards and upwards will again move the disc through another quarter of a revolution by means of the spring catch engaging with the next of the four pins, and so, by continually rotating the disc, alternately making and breaking the contact. The bar has attached to it a spring which, left to itself, holds the bar in a fixed position, so that after being pulled down it returns to that position.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Wanted, by two experienced Mechanics, Model Work to do at home (Mechanical or Electrical). Specialities and ideas worked out to drawings, scale, or size. Good workmanship guaranteed. Moderate terms.—P. R., 40, Westbury Street, S.W.

Practical Hints on Electro-Plating, etc. One stamp.—Address, HENRIC, 234, Great Colmore Street, Birmingham.

Amalgamating Brushes, Scratch-brushes, Polishing Sand, Calico Mops, Rouge and Crocus Compositions, Nickel Salts and Anodes.—HENRIC, 234, Great Colmore Street, Birmingham.

Fretwork, Carving, Turning, Woods, Tools, and all requisites. Catalogue with 700 illustrations, 6 stamps.—HARGER, BROS., Settle.

Microscope Slides. In great variety. From 5s. dozen; lists; approval.—MICROSCOPIST, 344, Caledonian Road, London.

British Flowering Plants. Weekly supplies required for practical study.—Address, stating terms, B., 22, Osborne Terraec Clapham Road, S.W.

Do your own Electro Plating and Gilding. System inexpensive. Particulars one stamp.—PERKS, 47, Alexandra Road, Richmond, Surrey.

Steel Name Stamps, 3d. per letter. Figures (set), 2s. 4d. Post free.—F. BALDWIN, Tuffley, Gloucester.

Meerschaum and Briar Pipes Repaired, Mounted, or Cased, ambers fitted.—W. GEORGE, 324, Essex Road, Islington, London.

"Precautions on Introducing Electric Light," by Killingworth Hedges. Cheap edition. 1s. 2d., post free.—GLOBE ELECTRICAL COMPANY, 7, Carteret Street, S.W.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Splendid Solar Microscope, in case, by Nairne, six powers. Exchange photographic apparatus.—RIDOUT, Sunbury Common.

100 Geological Specimens, named. Exchange, 10s. Approval.—HOLDEN, Hoyland Nether, Barnsley.

SELECTED BOOKS.

Nature's Hygiene. A Systematic Manual of Natural Hygiene. By C. T. Kingzett, T.I.C., F.C.S., Ex-Vice-President of the Society of Public Analysts. Third edition. London: Bailliere, Tindall, and Cox. Price 7s. 6d.

A Text-Book on Steam and Steam Engines. For the Use of Students Preparing for Competitive Examinations, By A. Jamieson, C.E., F.R.S.E. Prof. of Engineering. Glasgow Technical College. With 200 illustrations and four folding Plates. Third edition. London, Charles Griffin and Co. Price 7s. 6d.

A Manual of the Mollusca. A Treatise on Recent and Fossil Shells. By Dr. S. P. Woodward, A.L.S. With Appendix by Ralph Tate, A.L.S., F.G.S. With numerous Plates and 300 Woodcuts. Fourth edition. London: Crosby, Lockwood and Son. Price 7s. 6d.

A Text-Book of Biology. Comprising Vegetable and Animal Morphology and Physiology. By J. R. A. Davis, B.A.; Lecturer on Biology, University College, Aberystwith. London: Charles Griffin and Co. Price 12s. 6d.

The Geological Evidences of Evolution. By Angelo Heilprin, Professor of Invertebrate Paleontology at, and Curator in Charge of, the Academy of Natural Sciences of Philadelphia. London: Trubner and Co. Price 5s.

Handbook of the Amaryllideæ. Including the Alstrœmerieæ and Agaveæ. By J. G. Baker, F.R.S., F.L.S., First Assistant in the Herbarium of the Royal Gardens, Kew. London: Bell and Co. Price 5s.

Electro-Plating. A Practical Handbook on the Deposition of Copper, Silver, Nickel, Gold, Aluminium, Brass, Platinum, etc., with descriptions of the Chemicals, Materials, Batteries, and Dynamo Machines used in the Art. By J. W. Urquhart, C.E. Second Edition. London: Crosby, Lockwood and Son. Price 5s.

Annals of Botany. Vol. ii., No. v. Edited by Professors Balfour, Vines, and Farlow, containing papers (illustrated by many plates). By A. Lister, G. Massee, J. R. Vaizey, F. W. Oliver, and other botanists. Notes and Reviews. London: Clarendon Press. Price 10s. 6d.

Water Engineering. A Practical Treatise on the Measurement, Storage, Conveyance, and Utilisation of Water for the Supply of Towns, for Mill Power and for other purposes. By Charles Slagg, A.M.I.C.E., author of "Sanitary Work in the Smaller Towns," etc. London: Crosby, Lockwood and Son. Price 7s. 6d.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, July 9th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	49·5 degs., being 2·5 degs. below average.	5·9 ins., being 0·7 ins. above average.	449 hrs., being 20 hrs. above average.
England, N.E.	50·6 " " 3·0 " " "	4·1 " " 0·7 " below "	476 " " 55 " below "
England, East	53·6 " " 2·3 " " "	4·7 " " 0·0 " average	402 " " 104 " " "
Midlands ...	53·2 " " 2·3 " " "	5·3 " " 0·1 " above "	380 " " 63 " " "
England, South	53·2 " " 1·9 " " "	5·8 " " 1·3 " " "	395 " " 77 " " "
Scotland, West	51·7 " " 0·8 " " "	9·1 " " 2·5 " " "	444 " " 9 " " "
England, N.W.	52·5 " " 2·3 " " "	5·3 " " 1·0 " below "	391 " " 63 " " "
England, S.W.	53·6 " " 1·9 " " "	6·8 " " 0·6 " above "	435 " " 49 " " "
Ireland, North	52·1 " " 1·9 " " "	8·3 " " 2·5 " " "	413 " " 39 " above "
Ireland, South	54·2 " " 0·9 " " "	9·0 " " 3·0 " " "	434 " " 0 " average
The Kingdom...	52·4 " " 2·0 " " "	6·4 " " 0·9 " " "	422 " " 36 " below "

Rainfall at the close of the period had risen to nearly an inch above the average for the kingdom, its distribution continuing unequal. Temperature and sunshine below the normal.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

The mysterious behaviour of the satellites of Jupiter during transit (*i.e.* when travelling between us and the planet, and consequently appearing to cross his disc) has been observed and studied during the last 200 years. The phenomena in question are most decidedly displayed by the fourth satellite, which performs as follows:—On approaching the planet it becomes rapidly and increasingly fainter, until it touches the edge of the visible disc (the "*limb*," as it is technically called). When actually seen upon the limb it shines with moderated brilliancy for about ten or fifteen minutes; then it suddenly disappears, and remains invisible, in spite of using more powerful telescopes; after about ten or fifteen minutes more it reappears, but no longer as a bright moon. It has now become a dark spot, faintly grey at first, but gradually growing darker and darker, until it equals the blackness of its own shadow on the planet.

As a matter of course these curious changes have suggested many speculations, mostly unsatisfactory, until Mr. Edmund J. Spitta took up the subject, and by investigating it experimentally has at last solved the mystery.

His first series of experiments were conducted by cutting out a disc of cardboard, 3¾ inches diameter, to represent the planet, and other little discs of paper to represent the satellites, the proportions of their dimensions corresponding to those of the objects they represented. In the course of the experiments they were tinted with various shades, from white to dark grey, illuminated strongly by means of a condensing magic-lantern. These were placed about sixty yards distant from a telescope, and the results of placing the mock satellites in front of the mock planet were carefully observed.

The "albedo" or intrinsic reflected brightness of each of the differently shaded moons, and also that of the planet disc, were determined by means of Pritchard's wedge photometer, and it was found that when a moon of equal albedo to that of the planet was held by its fine wire stalk in front of the planet it became invisible, with smaller albedo than the planet it appeared dark, with greater it formed a bright spot, the differences varying with the gradations of tint. This is simply what anybody would expect *à priori*, but it was clearly desirable to establish it positively under the conditions of the experiment.

The next series of experiments were made to determine the effect of proximity of the planet to the satellite without actual superposition. These proved that as the larger and brighter disc approached the smaller and less brilliant the latter appeared less and less bright, the phenomena of the approach of the satellites to their primary being closely imitated.

Still, the mysterious changes, the extinction of the bright moon, and its reappearance as a dark spot remained unexplained, but so far the imitation of planet and moons was imperfect; the mock Jupiter was a flat disc, not a sphere.

Another series of experiments followed those above described; in these the disc of cardboard was replaced by a sphere of plaster of Paris 3¾ ins. diameter, the other conditions of these experiments being similar to the preceding.

The result is thus described by Mr. Spitta:—"It was found that the moons with the same albedo appeared black and grey as before, but what was far more surprising, that *all the phenomena of the dark transit could be completely reproduced.* I have witnessed the real phenomena very repeatedly, but I did not contemplate a reproduction from the employment of such simple means." He proceeds to describe this as follows: —"Whilst the dark moon having an albedo of 0·13 was advancing towards the artificial planet its light became fainter and fainter, but still of sufficient brilliancy to remain a bright spot when on the limb. Still continuing its journey across the artificial planet, and having arrived at an angle of about 65 degs. measured from the centre, it became lost to sight, reappearing on arriving at an angle of about 55 degs. to 60 degs. as a dark spot, which in a short time occupied in further progress became as black as its shadow. The effect was not a little surprising, seeing that it was totally unexpected."

Mr. Spitta's expression of angles in the above require explanation, his zero being the centre of the circular image of the sphere as seen in the telescope, and his 90° being the circumference or limb; the intermediate angles of course in accordance with this.

It was evident from the results of the previous experiments that these changes were due to differences of albedo in different parts of the sphere, as the flat disc of the moons could not thus vary, and, therefore, a positive determination of such variations became a work of considerable interest.

Mr. Spitta accordingly proceeded with this investigation, using the wedge photometer, which is a long wedge of glass originally used by its inventor, Prof. Pritchard, of Oxford ("the heavenly body," as the naughty boys there call him), for determining the so-called "magnitude" of stars by first inserting the thin end of the wedge between the observer and the star, proceeding until the light of the star is extinguished, and then noting the thickness of glass which produces this effect. This instrument was applied by Mr. Spitta (with precautions and modifications that space will not permit me to describe), to determine the albedo of his model planet, which he found to vary as follows.

Over a circle extending from centrality or 0° of Mr. Spitta's measure to 30° in all directions the albedo was not perceptibly altered. It was that of the material, and is represented by the figure.. .. .. 0·735

At 40° it was reduced to	0·500
" 50° " "	0·367
" 60 " "	0·323
" 65 " "	0·261
" 70 " "	0·172
" 75 " "	0·133
" 80 " "	0·080
" 83 " "	0·049
" 86·30′ " "	0·027

The decrease with obliquity is thus seen to accelerate rapidly, the loss approaching approximately to the tangent of the angle.

Here we have a curious physical fact, a strange optical illusion. If we look at a sphere such as a planet reflecting the sun's light, or a plaster-of-Paris ball reflecting a strong artificial light and placed at a considerable distance, we see a small disc which appears to be about equally luminous all over, but it is not so, nor nearly so. We are violently deceived either, by irradiation or some other optical proceeding not at present understood.

Adaptation of Structure to Habits.—Says Mr. F. P. Pascoe, F.L.S., in an interesting work on "Natural Selection": "We admire the structure of the forelimbs (so well adapted for burrowing) of the mole; but the rabbit, an unsurpassed burrower, is no more adapted for burrowing than its congener the hare, which never burrows. The common snake (*Tropidonotus natrix*), without fins like the viper, is a rapid and graceful swimmer, while the latter rarely goes near the water.'

THE NATURALIST AT THE SEA-SIDE.

III.—Shore Collecting.

The most discouraging circumstance about sitting down to write a short article on shore-collecting is that the thing has been done very well already. Lewes, Gosse, and Kingsley have all put on paper their own experiences, and being practised writers as well as keen observers, they were able to write lively and profitable sketches. However, their books are not in every house, and some of our readers, looking forward to seaside rambles, may be glad to be told how to set about shore-collecting.

Our first remark will be disappointing to some. There are many seaside places of popular resort likely to be fixed upon for a summer holiday where little can be done in the way of collecting plants or animals. A sandy shore is unpromising; so is the neigbourhood of a big, muddy river. It is true that even in such places as these the trained eye will find something of interest, but to the beginner they are barren. The good collecting grounds are rocky coasts, with deep, clear water, and shady pools overhung by boulders. As to time, the spring-tides (new and full moon) are much the best. For tackle, a shallow basket of no great size, jars of various kinds, and a hand net of strong muslin will be found indispensable. A small crow-bar and a stout hammer are desirable. It is hard to carry about all the implements which are likely to be wanted, and for this and other reasons a small party will usually fare better than the solitary rambler. Let us visit in the first place a rock-pool at low water. Hydroid zoophytes, polyzoa, anemones, ascidian colonies, and small fishes may be met with in such haunts. Lively little crustaceans will give employment to the net. Medusoids, left by the tide, may be seen pulsating in the clear waters. Another productive ground is to be met with around big blocks of stone. Turn over such as are not often shifted by the waves, and you will often find curious marine worms, some of monstrous size. To make the most of a good bit of shore the collector must not be afraid of wading out at low tide. He should leave his stockings at home, and walk out in strong shoes only.

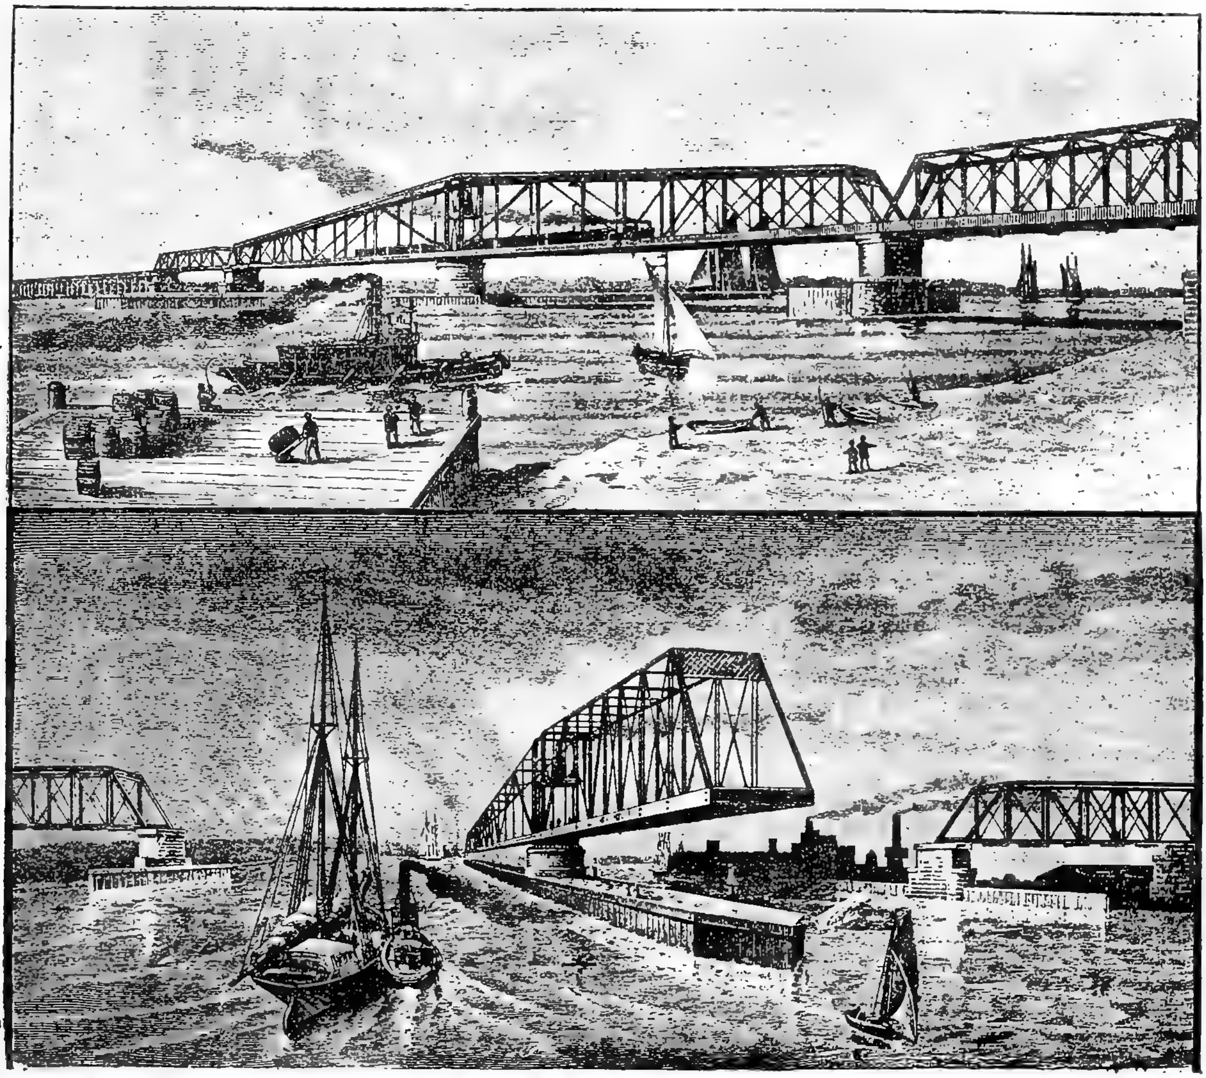
We advise those who mean serious work to bring back as much live stock as possible. Things that have dried in the sun, or have been shaken up with stones and sand, are seldom fit for real study. But many treasures of the deep, brought home in salt water, will live long in an extemporised aquarium, and may be anatomised or microscopised at leisure. Let the reader avoid the common delusion that to glue dried organisms upon white cards is useful work in natural history. A certain amount of thought must be put into every occupation if it is to turn out really productive. You cannot go far wrong if you set yourself steadily to make out points of structure, or to observe the mode of life of anything that crawls or swims. Have a note-book always at hand, and make endless drawings.

A very serious difficulty which besets the beginner is to make out what he has got hold of. Even the practised zoologist often needs a whole library of books to name his specimens. But if the determination of species be left to experts, a mere novice may hope with a little time and patience to find out what *kind* of animal he has before him. A living teacher is best by far, and a course of practical zoology gone through in advance will save much labour. So will a few visits to any tolerable museums of natural history. When actually on the coast, the collector must rely mainly upon one good, modern text-book of systematic zoology, which he will do well to have studied beforehand.

In a recent article (Scientific News, vol. ii., p. 30) we mentioned some preservatives which will be helpful. We may also refer to another article on the marine dredge (Scientific News, vol. ii., p. 60). The naturalist who wishes to make the most of his holiday should practise not only shore-collecting and surface-netting, but also dredging. If equipped with the modest provision required by these three modes of capture, he will have abundant occupation in fair weather, and a moderate amount of skill and good luck will bring him so much material that even a few wet days will be no hardship. The writer recollects with high satisfaction one stormy day in seaside lodgings, when a good fire was welcome, though the month was July. Torrents of rain dashed against the window, and there was no venturing out of doors till the cold and angry sunset came on. But hour after hour passed only too quickly, as fresh animals were placed under the microscope or in the dissecting trough. The notes and drawings made that day still bring back something of the delight which never fails to wait upon any step forward in the knowledge of nature.

THE LOW LEVEL BRIDGE ACROSS THE ARTHUR KILL.

OUR illustration, borrowed from the *Scientific American*, gives a view of the great swing-bridge spanning the Arthur Kill and connecting Staten Island, New York, with the opposite shores of New Jersey, thus opening up five or ten miles of additional water front to New York harbour.



Swing Bridge connecting the State of New York with the State of New Jersey.

The structure was erected by the Staten Island Rapid Transit Company. Its erection was authorised by an Act of Congress on June 16th, 1886, and two years were allotted for its completion. The plans and site were subject to the approval of the United States Secretary of

War, but he passed them without modification, after considering them for nine months. Work was at once commenced, but an injunction was obtained against the Company, which delayed progress for another six months. In spite of these difficulties, however, on June 13th, the swing-bridge was swung round from the open to the closed position, thus completing the bridge three days in advance of the stipulated time.

The trusses and swing-bridge are carried upon five piers of masonry, but much trouble was experienced in obtaining a solid foundation.

The entire length of the bridge proper, exclusive of approaches, is 800 feet. It comprises two shore spans, each 150 feet long, covered by fixed trusses, and two draw spans, closed by the great draw-bridge. The draw-bridge is said to be the largest now in existence, its total length is 500 feet. When open there is a clear water-way 208 feet wide on each side of the central pier.

The draw span was put together in four weeks, and the machinery was installed in another fortnight. The draw contains 656 tons, and each of the approaches 85 tons of metal. The approaches have yet to be made, but it is anticipated that by the end of August trains will be running across the bridge.

POISONS IN THE WORKSHOP.

(*Continued from page 14.*)

Of all the dangerous materials employed in the arts and manufactures, perhaps the one most to be dreaded is lead. This we say not by reason of the violence of the symptoms which it produces if introduced into the human body, but on account of the insidious nature of its attacks, and of the great number of manufacturing operations in which it plays a part.

We are not aware that the lead-miner is liable to diseases more and other than those which in general befall persons employed underground. Nor are the men employed in smelting and refining lead, in the manufacture of sheet-lead and leaden piping, of shot, and of the chief commercial alloys of this metal, such as plumbers' solder and type-metal, very frequent sufferers from lead-poisoning. The reason for their comparative immunity is that they have to deal with the noxious substance in a solid, insoluble, and non-volatile state. Their work, too, is very generally performed in the open-air or in open sheds. But it is when lead is made the subject of chemical operations that its hurtful character is most felt.

Foremost among the dangerous preparations of lead stands the well-known paint white lead, a carbonate, or rather a mixed carbonate and hydrate of lead. Into the manufacture of this pigment there is no occasion for us to enter. But it is produced and consumed in vast quantities, and often occasions in the workmen who make or who use it the most characteristic and distressing symptoms of lead-poisoning. The victim experiences severe cholic, "wrist-drop" sets in—that is, the hands hang down uselessly at the wrist or can be raised only with great difficulty—a general tremor is experienced in all the limbs, and sometimes complete paralysis comes on. The cause of the mischief is revealed by a blue-black line in the gums below the roots of the teeth.

Much of the ill-effects of the white lead manufacture may be avoided by due care on the part of the men. The chief precautions are strict attention to personal cleanliness, so that none of the dust of the white lead may remain on the skin. No food or drink should ever be partaken of or be allowed to remain in any of the work-rooms, and "sulphuric acid lemonade" — that is, sweetened water with a few drops of *pure* sulphuric acid to the glass, enough to communicate a pleasant tartness without setting the teeth on an edge—should be used as the ordinary drink. It is not pleasant having to admit that in some cases where white lead manufacturers have provided protective appliances, such as hot baths, a room where such of the men as live at a distance may take their meals away from the poisonous substance, all such precautions are neglected, if not positively refused. But the habitual use of white lead is as dangerous as its manufacture. The house-painter is constantly using white lead, not merely alone, but as an ingredient in most compound colours. The turpentine with which so many oil colours are mixed is highly volatile, and carries particles of white lead, too minute to be visible, into the mouth and lungs. Hence the painter—it is a painful deficiency that in the English language one and the same term is applicable to the artist and to the man who coats window-frames, doors, and walls with colours—is open to cholic and paralysis just like those employed in white lead works.

In the hopes of escaping this evil, a variety of substances have been proposed as substitutes for white lead, but none of them appear to suit the demands of the trade to an equal extent. Zinc white has, indeed, been used in practice to a very considerable extent, and possesses the great advantage of not becoming discoloured if exposed to sulphuretted hydrogen, coal-gas, etc. Another fraudulent use of white lead has been an unsuspected cause of poisoning. Everyone in these days knows what is meant by "weighting" or "loading" silks—a variety of practices by which a pound of genuine silk is converted into from 18 to perhaps 40 ozs. of a something which can, at any rate, be sold as silk. Now, in the case of white sewing silk this loading is chiefly effected by means of white lead, which is deposited on or attached to the fibre. Hence sempstresses, or ladies who often make use of white sewing silk, especially if they have the bad habit of biting off the ends of the thread, or trimming it with the lips before threading the needle, have been known to suffer from lead-poisoning.

Girls employed in artificial flower-making, especially in the case of wax flowers, are often similarly attacked, as very many of the pigments used contain white lead, alone or in admixture.

The manufacture of rubber articles is also not unattended with danger, as compounds of lead are not unfrequently employed for giving weight. Lead meets us further in the paper-hanging trade. Perhaps it may have been somewhat overlooked because the attention of physicians, analysts, and of the general public has been mainly turned to the arsenical compounds still, unfortunately, in so common use. But the lead is also there, and does its share of mischief.

Red lead is much less poisonous than white lead. It is less soluble in the secretions of the body, much denser, and hence less liable to form dust, and its use is much less general.

Chrome-yellow, the chromates of lead of various shades, will be discussed among the compounds of chromium, of which we shall speak below.

Tin and zinc are both more evidently poisonous than lead. Yet their employment in the arts presents little danger. We have, in former years, superintended the conversion of tons of tin into mordants, and their employment in dyeing, tissue-printing, and colour-making, but we never witnessed any injurious effects from close and frequent contact with the solution of this metal. Indeed, in the manufacturing districts we have heard the saying that a dead dyer is as great a rarity as a dead donkey. (*To be continued.*)

WHIRLWINDS AND WATERSPOUTS.—I.

ALTHOUGH we have on two or three occasions referred to these strange incidents, we do not believe that our readers will object to a further notice of this momentous subject. Momentous, we may venture to call it, since from the trifling eddy of dust which we see before us on the highway, up to the waterspout which may overwhelm a vessel or ravage a plot of land, the revolving sand-pillars in the desert which have been known to bury a passing caravan, and even to the tornado and the hurricane, there is evidently one continuous chain of phenomena, differing in magnitude, but essentially alike in their laws and their causes.

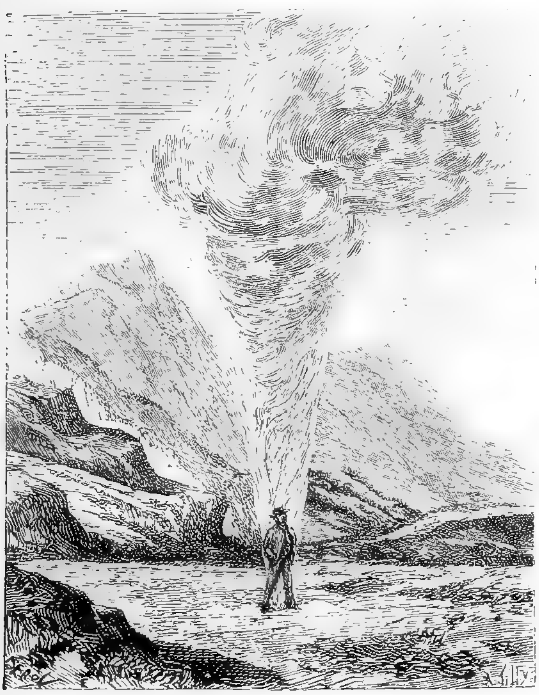


FIG. 1.—OBSERVER WITHIN A WHIRLWIND, EXPERIENCING THE SENSATION OF A VERTICAL MOVEMENT.

It is doubtless too much to hope that mankind will ever be able to prevent these catastrophes, but very much would be gained if we could obtain a few days' warning of their approaching outbreak. The aborigines of the West Indies, whom the earliest European settlers extirpated are said to have been able to foretell the advent of a hurricane for a week or more. That we, with our instruments of precision, cannot do as much is not to our credit.

We here reproduce from *La Nature* representations of whirlwinds or dust-storms witnessed by M. H. Duhamel, of Gieres, Vice-President of the Isere section of the French Alpine Club. This gentleman, referring to the phenomena, described and depicted (SCIENTIFIC NEWS, p. 561) writes :—"I have been present at the formation, the transference, and the ultimate disappearance of at least fifteen whirlwinds or spouts of dust and of snow exactly resembling in height and shape that at Vincennes described by M. Gibert, but I have never seen the bodies raised collect in an opaque globular cloud as in the whirlwind observed on May 13th last. In my observations the top always lost itself, forming a sort of streamer. All the whirlwinds which I have seen showed a movement of translation more or less regular, but the rotatory movement has always seemed to me to be from the right to the left. I have placed myself inside (fig. 1) whirlwinds of different sizes, and have always felt very distinctly both at the margin and in the middle an unquestionable sensation of upward motion. I am certain that the matters carried up are distributed through the entire mass of the whirlwind. This I have not seen, but smelt in case of dust, and in case of snow or storm I have felt its contact with my person.

FIG. 2.—TRICYCLIST RIDING THROUGH A WHIRLWIND WITHOUT STOPPING ITS FORMATION.

Another point to be noted is that on placing myself in the centre of a whirlwind it has never vanished. Its action has not been in any way disturbed by my presence. On three or four occasions I have amused myself, among other places, on a road crossing the plain of Graisivaudan between Gieres and Grenoble, by passing at a great speed through a whirlwind (exactly of the shape and size of that at Vincennes), but in spite of the current of air caused by my transit upon a broad and high tricycle (fig. 2) the little whirlwind was not in the least disturbed by this trial.

I must add that during the fifteen years for which I have been in the habit of travelling on this road I have always seen the whirlwinds formed at the same spot, within, say 150 yards. But this place, situated in the midst of the plain, seems exposed (at least in the upper layers of the superincumbent atmosphere) to an enormous current of air from the north-east, coming through a pass in the mountain chain of the *Chartreuse*, opening upon the valley of the Isere at an altitude of about 2,600 feet above the latter.

I cannot too strongly insist upon the absolute agreement of M. Glbert's observation with all mine. The aspect of the furrow traced *through* or *in*, not *over* the dusty soil is scrupulously accurate. This furrow records in a manner the oscillations of the base of the whirlwind in its twofold movement of translation and rotation.

(To be continued.)

THE STABILITY OF THE FAUNA.

IS the proportion of the several animal species in any country fluctuating or permanent? In spite of the occurrence of such well-known facts as the decline and ultimate disappearance of certain living forms within historical ages, Professor K. Fuchs, of Pressburg *(Humboldt)*, argues with great ability that, disregarding trifling changes, these proportions may remain unaltered for thousands of years, if only the climate and the vegetation do not vary. He, of course, excepts the direct or indirect agency of man, which makes itself widely felt as a disturbing factor, and that very frequently to his own injury. The Professor shows that the animal world is self-regulating: any increase or decrease in the numbers of some given species involving at once a corresponding—and sometimes more than proportionate—decrease or increase in some one or more other species. This fact, apparently very simple, involves a number of reciprocal bearings not unworthy of a passing notice.

We may first glance at the mean duration of the life of animals. It may be readily shown that the mean life of an animal is inversely as its reproductive power, *i.e.*, the more fertile any species the shorter is the life of the individual, whilst animals which multiply slowly necessarily reach a high age. Let us assume, to prove this point, that the reproduction of the hare is 2 per cent. or one-fiftieth daily, that is, among 100 hares two are born daily (a quite arbitrary figure). In this case the number of hares can be permanent only on condition that their daily mortality is also 2 per cent. or one-fiftieth out of every 100 hares, two dying on the average daily. In other words, the death-rate must balance the birth-rate. Great fertility is, therefore, for the individual a mournful gift of Nature. We find, in fact, that small creatures which multiply very rapidly, are correspondingly short-lived. The small mean duration of life is generally effected amongst animals by a numerous destruction of the eggs and the young brood, and it does not, theoretically speaking, prevent individuals from attaining a high age.

What is the practical value for an animal of endurance, the power of prolonging its life under unfavourable circumstances, such as poor food, deficient shelter, a bad climate, in short, conditions which make existence a burden? Animals which, like most beasts of prey, rarely meet with a violent end will generally increase until, by dint of deficient food, etc., the death-rate equals the birth-rate. In enduring animals, especially if they have the misfortune to increase rapidly, so that great mortality is needed to effect an equilibrium, as among the dog tribe, this condition is reached only when the general want has become very urgent. They are thus, so to speak, predestinated to distress, and their characteristic attributes, such as outrageous voracity, restless prowling and searching, have been evolved in consequence. Unenduring animals, *i.e.*, such as quickly perish under unfavourable circumstances, and which, in addition, increase slowly, so that a balance is reached even with a low death-rate, are destined for a lordly existence. As soon as want sets in their mortality rises, their numbers fall, and single individuals obtain scope, in consequence of decreasing competition, to find better food and shelter.

Endurance, combined with rapid increase, presents advantages where times of scarcity and times of plenty alternate, say in the succession of summer and winter, or of dry and wet seasons. The numbers which such species may reach at the end of the good season render it probable that few places of shelter will remain undiscovered and unutilised, whilst the power of endurance will minimise the number of individuals which perish in the bad season. Hence we may expect to find enduring and fruitful animals in extreme climates, and non-enduring and slowly-multiplying species in equable climates.

We shall find much instruction from the theoretical case of a country inhabited only by a single food-animal, say the hare, which can find food without limit, and which encounters only one devourer, say the fox. It will be seen at once that in such a case the foxes, faring abundantly upon the plentiful hares, will increase, and in virtue of their growing numbers will extirpate the hares daily more and more until the number of the latter is so far reduced that the foxes cannot catch a sufficiency, and begin to die out from want until they can catch no more hares than are born in the meantime. We then find an equilibrium. The hares can be considered as rendered stable when so many foxes are present as to devour the daily increase of the hares, so that the number of hares remains unaltered. On the other hand the number of foxes may be called stable when hares have become so few that, in spite of all exertion, as many foxes die from famine as are born in the meantime.

As soon as any species increases above the equilibrium, it digs its own grave: the fox, in the case we have been supposing, by eradicating the hares, and the hares by facilitating the increase of the foxes. Inversely each species improves its condition by falling below the normal number: the fox, by rendering an increase of the hares possible, and the hares by contributing to the dying out of the foxes.

A very interesting and seemingly paradoxical result is that as both the devourer and the devoured reach higher numbers the more difficult it becomes for the robber to seize his prey, the harder the booty is to catch. In proportion as the conditions of the chase become less easy, the numbers of the food-animal increase, since the devourer meets with his minimum supply only when the food-animal is numerous. But—and this is the peculiar point—the devourers will increase because, from the great numbers of their prey, more of the former can exist than previously. Nature, therefore would do the beasts of prey an ill service if she made the chase easier, either by giving them greater resources, or by placing at their disposal more helpless and unprotected food-animals. They would soon devour down their prey to such a low number that few devourers could exist.

(To be continued.)

General Notes.

THE FRENCH ACADEMY OF SCIENCES.—Professor Langley, of the Allegheny Observatory, has been elected, by a large majority, a corresponding member of the Academy for the astronomical section.

THE ADULTERATION OF "SPANISH JUICE."—According to Mr. B. Dyer, F.C.S., the substance sold as Spanish juice is largely adulterated with starch and glucose. The worst samples are those of French origin.

ANTI-RABIC HOSPITALS.—According to *Cosmos* there now exist in the world twenty-three establishments for the preventive treatment of hydrophobia on the principle of Pasteur, and all conducted by his pupils.

THE UNITED STATES SIGNAL SERVICE.—It appears probable that this department, which has rendered such signal services in meteorology, will be administered in future by civilians instead of, as heretofore, by military men.

EXPEDITION TO LAPLAND.—A Russian expedition, under the direction of M. Bashlund, an eminent astronomer, will be despatched to Lapland in August or September. M. Latkin, a St. Petersburg merchant, is providing the necessary funds.

SMALL-POX IN MARTINIQUE.—In this island, containing a population of only 170,000 persons, there have been already, according to a communication of Dr. Talairach to the Academy of Medicine, 2,300 deaths from this disease. The epidemic still continues.

JOINT ACTION OF AIR AND LIGHT UPON METAL PLATES.—MM. Bichat and Blondlot communicate to the *Academy of Sciences* that if the rays of an arc-light are thrown upon a sheet of brass, and a current of air is directed against it at the same moment, a well marked electric action is set up.

CARBO-DYNAMITE.—In this explosive, patented by Messrs. W. Borland and W. Reid, the nitro-glycerine is combined with carbon instead of kieselguhr. Its explosive force is greater than ordinary dynamite, owing, it is said, to the carbon absorbing a greater quantity of nitroglycerine than the kieselguhr.

DISCOVERY OF AN OLD ROAD.—In making the Manchester Ship Canal an old footpath or road has been discovered near Netherpool, about a mile and a-half from Eastham. The road is fifteen feet below the surface; it is paved in the centre with pebbles or boulders from the shore, and the curbs are built of blocks of red sandstone.

BRANDY FROM SAWDUST.—A certain Herr Zeterlund, by boiling sawdust with hydrochloric acid under pressure, is said to have converted a part of it into glucose, from which alcohol was then obtained by the ordinary process. He calculates that each hundred-weight of air-dried sawdust might be made to yield at least 27 quarts of a 50 per cent. brandy.

THE EFFECTS OF EMANCIPATION ON THE AMERICAN NEGRO.—A medical contemporary states that the deterioration of the race, physically and socially, is unquestionable. Before the secession tuberculosis was almost unknown upon full-bred negroes; to-day their death-rate from this disease is twice that of the whites. Insanity, also, is becoming fearfully prevalent among them.

ARSENICAL GLUCOSE.—According to the *Journal des Brasseurs* arsenical glucose, *i.e.*, containing arsenic derived from the sulphuric acid used in its production, is met with in commerce, and may be used in brewing and in the preparation of articles of food. The *Société d'Encouragement pour l'Industrie Nationale* offers a prize of 2,000 francs for the production from pyrites of sulphuric acid free from arsenic.

SILPHA OPACA.—We have already referred to the fact that this beetle has developed a taste for beet, and is giving French farmers a good deal of trouble. According to Miss Ormerod, this carrion beetle has also developed a taste for mangolds, and she has just issued a caution to farmers, but unfortunately no remedy is known which will check the depredations of the insects if they appear in sufficient numbers.

THE HITTITES.—It seems probable (*American Naturalist*) that the renowned Hittite city, Carchemish, is to be sought at the site of Jerablus, from which the British Museum obtained, a few years ago, most of the Hittite monuments in its collection. The heads sculptured in these monuments are in many cases adorned with a pig-tail, similar in shape and position to that worn by the Chinese. The wearers of the pig-tail have Mongolian countenances, and it seems that a Mongolian race had obtained supremacy in some of the Hittite cities.

GRASSES.—Mr. W. Wilson, jun., of Alford, N.B., has made some interesting observations on the growth of grasses. He found the first to appear above ground is the vernal grass, and is of opinion that it would make an excellent early fodder if introduced into sheep pastures. The crested dog's tail persistently throws up leaves throughout the year, and Mr. Wilson thinks that in many situations a liberal introduction of it would afford succulent food for the whole season. Red, hard, and sheeps' fescue were the latest grasses to start into activity.

A NEW THERMOMETER.—A new thermometer for measuring the temperature of the air has been constructed by R. Assmann. In order to protect it from influences of radiation and other sources of heat, he inserts the bulb of the thermometer in a metal tube which is open at its lower end. An aspirator is fastened to the tube near the bulb, and a continuous current of air of about seven feet velocity passes the latter. Thus it assumes the true temperature of the air. The tube is made of highly-polished nickel-plated brass, in order to protect it from radiation. Experiments show that this thermometer gives entire satisfaction.

INFLUENCE OF THE MOON.—A recent writer upon the subject mentions that at the Cape and in India woodcutters insist that at full moon timber is full of sap and unfit for cutting. At the Cape, nuts and other provisions are said to spoil rapidly if exposed to moonlight, though this may be due to the fact that the light serves as a guide to the insects. The editor of the *Journal of Microscopy* adds, in comment, that from many years residence in Essex he is well acquainted with the fact that no farmer's wife (of the old school) will pickle hams in a waning moon. The days between new and full moon are chosen by the farmer to kill swine for home consumption, because, they say, the meat will swell with the moon, but in a waning moon it will decrease.

Detection of Cotton-seed Oil in Olive Oil.—Ernest Milliau has, says the New York *Jewellers' Weekly*, recently discovered a new, simple, and effective means of testing the purity of olive oil, which by many watchmakers is considered the best lubricant. This oil is frequently adulterated by the addition of cotton-seed oil, and M. Milliau has ascertained that nitrate of silver causes the two oils to separate. In order to test the oil it must be mixed with three times its volume of methylated spirits. The nitrate of silver is then diluted in water and poured into the mixture. If there be any cotton-seed oil it will rise to the surface in the form of a black paste. By this means the presence of even so small a quantity of cotton-seed oil as 1 per cent. can be discovered.

Miklucho Maclay.—We regret having to put on record the death of Dr. Miklucho Maclay, at the early age of forty-two. Having studied medicine and the natural sciences at Petersburg and Leyden, he visited Madeira in 1866, in company with Prof. Haeckel, of Jena, and afterwards Morocco and the Canaries. In 1871 and 1872 he explored the north-western and south-western coasts of New Guinea, and visited Farther India, Malacca, and the Malay Islands. In 1876-78 he explored the northern coast of New Guinea. He revisited this island in 1879, and finally returned to Russia in 1882. He had resided for some time at Sydney, where he founded a marine biological station. The greater honour belongs to Dr. Miklucho Maclay because, unlike another eminent Russian traveller, he could not be suspected of being a political or military spy.

Deposits of Lignite in Italy.—The rapid rise of Italy as a nation has naturally increased her desire to be self-supplying in coal for her war-ships, as well as for commercial purposes. Many attempts have been made to find this all-important mineral, but hitherto without success. Lignite, however, exists in large beds, and has been successfully used in the great iron and steel works at Terni. A new and apparently very extensive deposit of lignite has been found on the estate of Monteguidi, midway between Siena and Volterra, and in the vicinity of the boracic acid works, formerly worked by Count Larderello. The estate having been recently purchased by an Englishman, some specimens of the lignite have been brought to England for examination, and it seems that its heating power is 80 per cent. of Newcastle Hartley coal. This would therefore seem to be the nearest approach to a coal-find in Italy.

Application of Carnot's Principle to Endothermic Reactions.—M. Pellat, in a communication to the Academy of Sciences, shows the impossibility of effecting endothermic reactions in opaque vessels at low temperatures. But this impossibility no longer exists if we allow a source of intense heat to act by radiation, a fact which is commonly expressed by saying that light effects the reaction. Thus the carbonic acid of the air is decomposed at ordinary temperatures by the green parts of plants, and the carbon combines with the elements of water. This is a decidely endothermic reaction, and it is therefore possible only by the radiation of an intensely heated body, the sun. The chlorophyll reaction can take place only under the influence of a radiant body of a higher temperature than that at which vegetable products become ignited. The higher the temperature of a radiant body the more its spectrum extends towards the ultra-violet. This explains the efficacy of the most refrangible radiations in setting up chemical reactions.

Ascent of Mount Kenia.—According to the *Times* a despatch just received from Zanzibar states that the Hungarian Count Teleki, who has been travelling for some time in the interior, was, in December last, on Lake Barengo. The Count had had numerous fights with the natives, but had always been victorious and had his caravan well in hand. He had ascended Mount Kenia, the lofty peak which lies far to the north of Kilima-Njaro. This mountain had never been ascended before, and Count Teleki states that it is higher than Kilima-Njaro, which is 18,700 ft. high; but, unfortunately, the Count does not give any figures. He proposed to go to the Samburu country and visit the lakes Basso Ebor and Basso Erok, as he calls them. His companion (a lieutenant in the Austrian Army) and himself were both in good health, and he proposed to return to the coast in November next. In this connexion we may state that Dr. Hans Meyer now admits that his original estimate of the height of Kilima-Njaro was incorrect; and that the old estimate of 18,700 ft. is more likely to be right. Dr. Meyer has just published in book form at Leipsic a narrative of his ascent of the mountain under the title of "Zum Schneedomdes Kilimaudscharo."

Image of the Moon.—The following account of a curious meteorological phenomenon is given by Herr Kammermann in the *Archives des Sciences Physiques et Naturelles*, and is reproduced in *Cosmos*. At the moment of observation (5.30 p.m., October 29th, 1887) the sky was almost entirely covered with cirro-cumulus, save in the east, where there was a broad band of black clouds rising about 15° above the horizon. These two kinds of clouds were separated by others partaking at once of the cirro-cumulus and the cirro-stratus, in which took place the phenomenon recorded. The moon seemed to be in this intermediate layer, and was surrounded by a well-defined halo of about 5° in diameter. The interior of the circle was of an orange yellow, and this colour gradually faded away outwards into a whitish shade. The distinctness of the halo struck the observer, who was astonished to see that the luminous disc which he had taken for the moon was not our satellite at all, for the moon just showed itself in a gap in the lower black clouds which had entirely concealed her hitherto. In about two minutes the mock moon disappeared, only the coloured circle still existed, and was evidently excentric to the moon, which was then at the edge of the lower belt of cumulus. In a few moments afterwards it disappeared behind the cirro-cumulus. The diameter of the mock moon was about the half or two-thirds of the lunar diameter. The distance between the false and the true moon was about 5°, the latter being then 13° above the horizon. Such a meteorological phenomenon does not seem to have been previously observed.

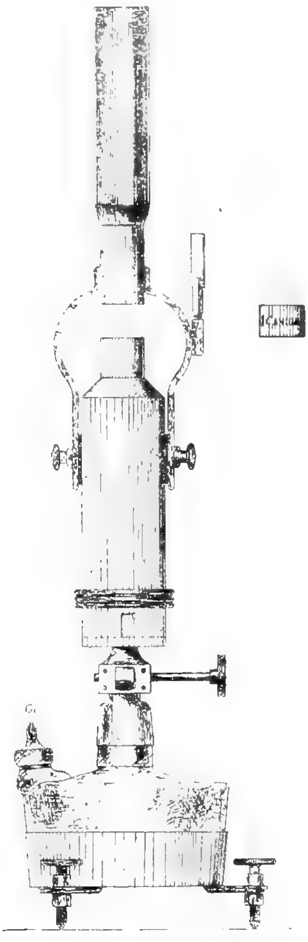
STANDARDS OF LIGHT AND ILLUMINATION.

THE fineness and precision of our senses in estimating quantities varies exceedingly, although they may be very sensitive to relative differences of magnitude or quality. One would think that the sense of vision was at least as well able to make a quantitative estimate as the senses of taste or touch. We have not much difficulty in guessing whether there are one, two, or three lumps of sugar in a cup of tea, or of telling by the muscular sense of weight whether a 'bus conductor has given two, three, or four pence in change; but it is very difficult to judge with the same amount of accuracy, small as this may be, whether a room is illuminated by two, three, or four candles; if they are placed close together, and their effect is seen, while they are themselves hidden from view. Indeed, it is not easy to see much difference between the illumination produced by ten candles and by twenty. The increase appears more like an addition of two or three candles only. Those who go early to a concert are often not aware that they have been sitting for some time in a room provided with about one quarter of the proper illumination, until the lights are turned up, when they suddenly realise that they have been waiting in semi-darkness. Neither the tea drinker or the *habitue* of the 'bus would allow himself to be thus deceived about sugar or pence.

There was no demand for a unit of light until the supply of gas became a subject of legislation. It was then enacted that the gas burned in an argand burner at the rate of 5 cubic feet per hour should yield a light equal at least to that produced by 16 sperm candles burning at the rate of 120 grains per hour. It is probable that the most unscientific legislator was conscious (if he thought twice about it, though this would be asking a good deal) that this was not a very accurate unit, but it is also probable that the most scientific was hardly aware of the numerous causes of error, the vagueness of the attempted definition, and the general untrustworthy character of the so-called standard. Spermaceti is not a definite chemical substance. No description of the wick is given, and not only can candles be prepared to suit either the producer or the consumer, but it is notorious that such candles have been made. But when the standard candles have been obtained, it is found that no matter what care is taken to avoid draughts or to provide uniform temperature, the illumination produced is constantly varying, and if two candles be found of exactly the same quality, and which burn at the same rate, they will not maintain the same light for even a few minutes in succession.

The very article for which the "Parliamentary candle" was to act as a standard, viz., the argand burner taking 5 c. ft. of gas per hour, has been put forward as a standard itself, it being claimed that when the flame is exactly three inches high, it gives a light of 16 candles, no matter what quality of gas is used. For disputes between the consumer and the producer of gas, or, indeed, any other illuminating agent, this is doubtless sufficient, but for anything of the nature of a measurement for the purposes of any scientifie determination, it falls far short of a reliable standard.

The French "bec Carcel" is an oil lamp which gives a light of about 9·5 standard candles. This is subject to nearly as great fluctuations as the candle while it is burning, while, of course, the most elaborate specification of its construction would not be sufficient to ensure a tolerable accordance between lamps produced by different makers, to say nothing of wicks and oil. A very simple device invented by Mr. J. Methven gets rid of the chief variations of the argand burner. He merely places a screen before it, and provides a rectangular hole which allows the light from the central part of the flame to pass, and the illumination is thus made independent of the height or the diameter of the flame. The quantity of light is evidently proportional to the intensity of the light of the flame, and this depends on the temperature of the combustion, and on the nature of the gas, although it is quite



HARCOURT'S PENTANE LAMP.

possible that the ordinary gas of commerce does not vary in quality to an extent sufficient to produce any serious error. A very excellent standard for most purposes, when it is in the hands of an experienced operator, is the pentane lamp of Mr. Vernon Harcourt. Pentane is a definite chemical substance which can be obtained with little difficulty, and different specimens may be relied on as identical. This lamp has no wick, and gives a very steady light. The original form of the lamp is only fit for a laboratory, for a current of air has to be maintained in an apparatus by which one volume of liquid pentane becomes vaporised and mixed with 576 volumes of air, forming a mixture, when vaporised, of 20 volumes of air to 7 of pentane gas.

Mr. Harcourt subsequently modified this lamp and exhibited it at the Manchester meeting of the British Association before the Physical Section. Instead of burning a mixture of air and pentane, this form of lamp burns pentane vapour only, and burns steadily, although it has no glass chimney round the flame.

From our illustration, which we owe to the courtesy of the Woodhouse and Rawson Electric Supply Company of Great Britain, it will be seen that the lamp is somewhat like an ordinary spirit-lamp, with a metal chimney above it.

The chimney is composed of two portions, an upper and a lower one, the latter being doubled so as to maintain the inner one at a constant temperature.

On lighting the lamp and placing the chimney in position the flame rises above the edge of the lower tube, and by suitable adjustment of the wick can be made to enter the upper chimney. In the latter are two slots diametrically opposite to each other, and the flame is raised so that its tip lies between the top and the bottom of these slots.

From experiments it has been learned that variations in the height of the flame do not produce much alteration in the amount of light radiated from its central portions; so to obtain a light of given candle-power it is only necessary to vary the distance between the upper and lower chimnies. To enable this to be done accurately, small gauges, one of which is shown to the right of the figure, have been made; one of these is placed on the lower chimney, the upper is lowered upon it, fixed in position by the clamping screws shown on each side of the lower chimney, and the gauge carefully withdrawn.

After the lamp has been burning for from ten to fifteen minutes there is scarcely any variation in the height of the flame, and consequently the light emitted is for all practical purposes constant.

The unit in Germany is a paraffin candle, 2 centimetres in diameter, with a flame 5 centimetres high. A lamp burning "pear oil," or amylacetate, without a wick is being introduced.

M. Violle has suggested a standard which should please those who are devoted to the French metric system. He proposes to take as a unit of light, the light emitted by one square centimetre of platinum at the point of fusion. Of course a larger quantity of the molten metal is used, and a screen with a hole of an area of one square centimetre is placed before it. A mixture of solid and of liquid platinum behaves like a mixture of ice and water. Although the ice may be melting, yet as long as there is any left, the temperature will be that of freezing point, and conversely if freezing is taking place. The addition or withdrawal of the heat only melts or thaws the ice, and does not alter the temperature of the mixture. This action ensures a constant temperature, and therefore a constant intensity of light, for the surface of the molten metal would be the same under all ordinary conditions. The original experiments were made with an oxy-hydrogen furnace of elaborate construction. Recent experiments, according to a paper by Mr. Dibdin, lately read before the Society of Chemical Industry, have been made with a thin sheet of platinum foil, with a screen in front, having a hole of a definite size, and a blowpipe behind, by means of which the temperature is raised until the metal melts, and a hole is pierced in the foil. The light, which was being continuously measured while it increased in strength, is considered to be of a standard intensity at the moment of the highest measurement, just before the foil melts. It is said that this gives more reliable and uniform results than might be expected. The foil is rolled off from one reel to another, so that the operation can be repeated with ease.

There are several important considerations as to the colour of the light which is to be measured, and its relation to the colour of the standard; for example, it is a matter of individual judgment rather than a matter of measurement to compare the light of a candle with that of an electric arc lamp. These considerations and the means of making the comparisons and measurements must be left for another occasion.

It is not, however, merely light which we want, but illumination. A badly arranged system of electric arc lights may give a considerable amount of light, but the illumination produced may be very bad. The amount of light required to illuminate a room is very difficult to calculate, since it depends not only on the superficial area of the floor, but on the reflecting power of the walls, and this is dependent on their colour and height. One authority gives 20 candles to 40 cubic yards of space, but it is impossible to apply such a formula to ordinary interior lighting. Out-door lighting is more easily reduced to rule, for there is but little assistance to be gained from reflection. For such cases Mr. Preece has suggested as a standard of illumination the illumination produced by a "bec Carcel" at the distance of a metre, which is equivalent to a "parliamentary candle" at 12·7 inches. The illumination at the foot of an ordinary lamp post is about one-tenth, and that of the full moon, on a clear night, is about one-thirtieth of this unit.

A New Cigarette Machine. — Messrs. Jadowsky and Schmitt have, after a long series of trials, perfected a machine for the manufacture of cigarettes, which is remarkable for its ingenuity and workmanship. The frame of the machine consists of a cast-iron table, supported on angle iron legs, and the various organs of the mechanism are geared to a main spindle, which receives motion either from a hand crank or by power from a belt. At each revolution of the spindle a complete cigarette with cardboard mouthpiece is turned out. The tobacco, slightly moistened, is placed in an open trough, the bottom of which is in part formed by an endless cotton band travelling forward under a knife, which automatically cuts off the quantity of tobacco required for one cigarette. This quantity is then pressed into a cylindrical form between a pair of semi-circular metal sleeves, and retained in this mould until a little piston pushes it into the paper envelope, which has, meantime, been prepared by another part of the machine. The tissue paper and the tape of cardboard for the mouthpiece are on separate rollers under the table, and the former is drawn between guide rollers under a printing roller, which prints the brand on to the paper. The paper band is then seized by a gripper, whilst a knife cuts off the length required to go round the cigarette, leaving sufficient length for the lap, which is gummed by being pressed against a roller. The piece of paper is next coiled over a mandrel, and then released from the gripper, which moves back to seize again the end of the paper tape, whilst the paper cylinder is pushed into a metal tube. Meanwhile the cardboard tape has undergone a similar operation, and a little cylinder of cardboard is pushed into the tube from the other end, where, through its own elastic expansion, it jambs itself tight into the tube of tissue paper. This receives now its charge of tobacco from the mould already mentioned, and the finished cigarette is thrown on to a travelling band, which deposits it in a box at the side of the table.—*Industries.*

Natural History.

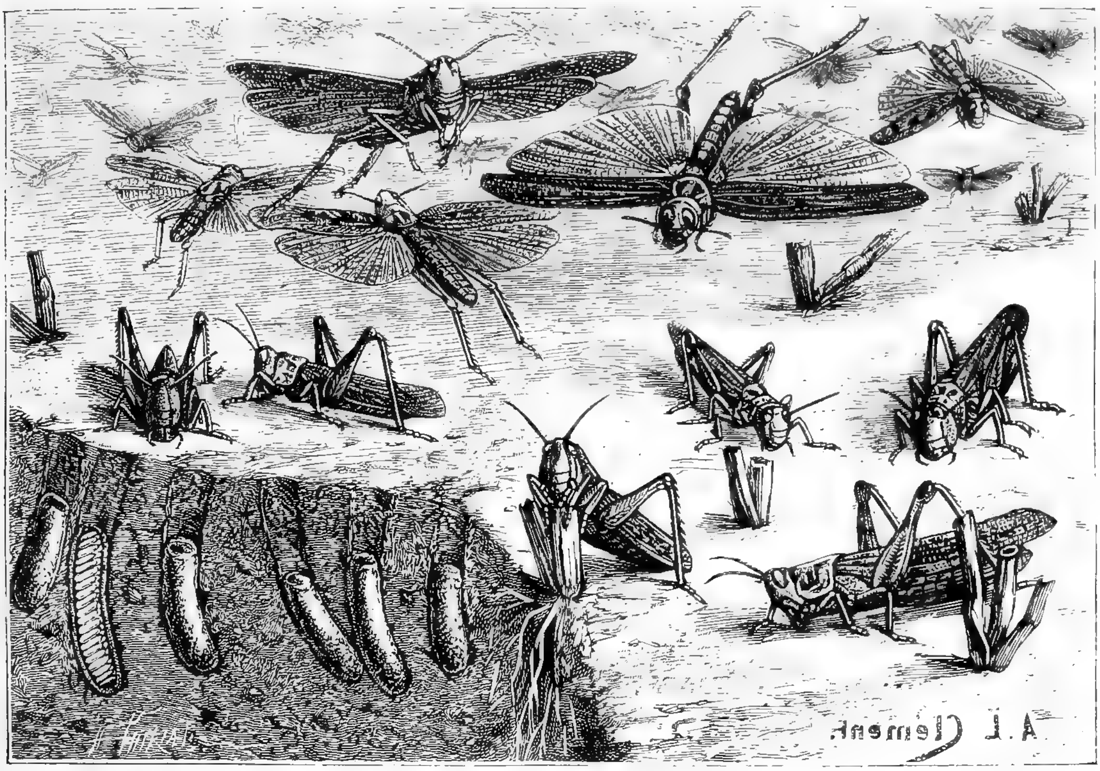
THE STAURONOTUS MAROCCANUS; ITS DEPREDATIONS IN ALGERIA.

M. KÜNCKEL D'HERCULAIS, the eminent French entomologist, gives the following report of his observations in the Algerian provinces attacked :—

In the district of Tiaret the surface covered by the eggs of these insects in 1886 was estimated at 8,400 hectares, a hectare being approximately 2½ acres ; in the district of Batna 130,000 hectares were infested; and in that of Setif the surface filled with eggs was more than 20,000 hectares. But these figures are far below the reality, since in the mountains there are immense egg districts which have escaped investigation.

Suppose that we are in April, and the sun begins to warm the soil. All at once, on the slope of the arid mountain where a deposit of eggs had been formed the year before, there issue from the earth thousands of small, white, feeble beings of about a quarter of an inch in length. On exposure to the light they soon take a dark-brown colour, and the earth seems sprinkled over with little black specks. Five men fell to work one day to count them into a quarter-litre measure, which held 12,285 individuals. This gives 50,000 to the litre, or 5,000,000 to the hectolitre. Hence we may calculate that each spot of 50 square metres may contain 25,000,000 of young locusts.

Six days elapse, when the little tender, delicate beings become strong in their limbs. Hunger makes itself felt, and they set themselves in motion, with a method, a regularity which many generals might envy. They do not march in column like the ants, or like our armies, but they advance forming a front of a more or less considerable extent. They do not appear to have any leaders, but they are doubtless directed by senses whose perfection we do not understand. Quitting the dry mountains, they march straight forward, traversing each day a regular stage. They travel from 9 a.m. to 3 or 4 p.m., and advance about 110 yards daily. They halt if a cloud overshadows the sun, and they suspend their march altogether if the temperature falls or if rain comes on. They undergo five successive moultings, and become more vigorous and agile. In two or three weeks they are half-grown and measure then about ¾ of an inch



LOCUSTS IN ALGERIA LAYING THEIR EGGS.

After the fifth moulting they measure 1 to 1¼ inch. The front of the army is now extended considerably. As long as the sun is above the horizon the invaders march on, running and leaping at the rate of more than 100 yards hourly. In the twelve days from May 21st to June 2nd they have been known to cross ten miles.

Their evolutions now become more interesting. Suppose we are on a fallow field ; we perceive the long and thick black line which marks the front of the invading army. We hear a peculiar rustling like that of a flock of sheep passing at a distance ; the army is at our feet and passes rapidly, but it reaches a field of barley and the pillage begins. It is wonderful to see the locusts nimbly climbing the stems. Five, ten, and more may be suspended to a single ear which bends beneath their weight. A few strokes of their mandibles cut away the protecting covering, and the tender grains are greedily devoured. The rear-guard eat up the fallen fragments and gnaw the lower leaves. In a few hours the promising harvest has disappeared, leaving merely the stubble as a sad witness.

When the army has thus marched for about 50 days, devouring all before it, it stops. The insects rest, their integuments split on the back, and they appear provided with wings.

They can still run and leap, but they can also rise in the air. For about a week they fly up and down, and then suddenly soar off in immense bands, flying at great heights as long as the sun is above the horizon. At sunset they descend and pass the night on the ground, resuming their flight the next morning. Soon they find upon the eastern or southern slope of a mountain, or on an arid plain, a spot suitable for depositing their eggs. The females run and leap about excitedly, sounding the ground here and there with their abdomen until a suitable spot having been selected, they bore the earth eagerly.

Nature has placed at their disposal admirable boring-tools; the extremity of their abdomen is armed with instruments having the appearance of hooks, but which we cannot describe here. The shaft is bored to the depth of nearly two inches, when they cease excavating and begin to lay. As the eggs are deposited they secrete a frothy liquid, which envelops them. At the same time each female covers her deposit with a layer of small grains of sand agglutinated together with great regularity. When thus covered, these egg-cases, buried to the depth of an inch below the surface, are so completely confounded with the soil that they escape even experienced eyes. Only the Arabs are able to detect them.

These egg-cases, or öotheca, shown in our illustration borrowed from *La Nature*, in which the report of M. d'Herculais is given in full, have the form of small cylinders slightly bent, rounded at bottom, and flattened at top. If we open one of these cases we find in it, symmetrically arranged, from thirty to forty eggs of a yellowish-white colour.

According to an old belief prevailing in Algeria, the locusts, miscalled crickets, which invade the country from time to time, belong to the species *Acridium peregrinum*. They are supposed to be brought by the Sirocco, from the Sahara and the Soudan. This is a mistake; they are bred in the arid and desolate mountains of North Africa, and belong to the species *Stauronotus Maroccanus*.

This insect, which of course belongs to the orthopterous family of *Locustidæ*, or, as the French prefer to call them, *Acrididæ*, is, when mature, of medium stature —the males being a little above an inch, and the females $1\frac{1}{2}$ inches in length. It is of a reddish testaceous colour, relieved with fawn-coloured spots. Its elytra are testaceous, with scattered brown spots and marblings. The wings are transparent. The design of the thorax renders it very easily recognisable. It has on each side a slight, oblique, and arcuated keel of a light yellow, bordered with brown within. On the sides is a round brown spot from which there issues a light yellow spot in the form of a crescent, more or less regular.

Sensitiveness of Plants.—It is not well known that plants, under certain circumstances, *e.g.*, in their alternations of sleep and waking, if subjected to variations of temperature, or if touched, perform certain movements which lead us to admit their sensitiveness, and compare certain of them with the lower members of the animal world, possessing not, indeed, distinct nerves, but what we may call a diffused nervosity. According to *La Nature*, M. Baillon has recently discovered a new fact in support of this view. The tendrils are one of the chief seats of the manifestations of that kind of sensibility which is observed in plants. Those of *Cissus discolor*, which the learned Professor of the Faculty of Medicine has studied, are extremely interesting. If one of the ramifications of a tendril are submitted to the slightest friction, there is formed at once a node which becomes the starting point of a curve. Mr. F. W. Oliver has also observed in the labellum of *Masdevallia muscosa*, a specimen of which flowered at Kew last year, some very curious movements. Some parts of the labellum possess such an irritability that the touch of a hair, or the wing of an insect, will make it assume quite abnormal positions.

The Fauna of Water-Mains.—Under this name Dr. Kraepelin (*Cosmos*) has studied the organisms found in the water supply of Hamburg. The water is taken direct from the Elbe without filtration. Hence many animal species living in the river are introduced into the underground conduits. Dr. Kraepelin has found about fifty species. Among fishes the most numerous are *Gasterostens aculeatus, Gadus lota, Pleuronectes flesus*, and especially the eel, some specimens of which reach the length of a foot. It has even happened that narrow pipes have been choked up by one of these fishes, just as it occurred some time back in the east of London. The Mollusca are represented by Gasteropods and bivalves. Insects are very rare, but small crustaceans swarm, and worms and polyzoa are numerous. The latter line the interior of the pipes with a mossy growth which interferes with the circulation of the water. Almost all fresh-water fishes, as well as most Articulata and their larvæ are absent. Species which breathe air from the atmosphere, and those which feed on plants perish; those which feed on detritus, and which breathe the air dissolved in the water, survive.

Locusts in Europe.—The same species which is laying waste certain districts of Algeria, is hard at work in Hungary over a vast extent of territory, especially in the counties of Moglod and Peczel, and in that of Pesth. The fields of wheat, barley, and maize, as well as the gardens, vineyards, and orchards, are being ravaged. Heavy falls of rain do not seem to have destroyed the insects. Another species is at work in Sardinia and in the neighbourhood of Rome.

A New Case of Parthenogenesis.—M. A. Ernst (*Cosmos*) believes that he has found a case of parthenogenesis in the vegetable world, in a plant which he has discovered near Caraccas. This plant, which yields fruits without having been fecundated, is named *Disciphania Ernstii*. The discoverer has cultivated several specimens of this plant with every precaution to prevent fecundation by the conveyance of pollen, either ot the wind or of insects.

Hatching Ova by Electricity.—Searching through some back numbers of the *Oesterrichische Landwirthschaftliche Wochenblatter*, we found it stated, on the authority of Dr. Virson, Superintendent of the Italian Experimental Silk Farm at Padua, that the hatching of silk-worm eggs may be accelerated by ten or twelve days, and a yield of at least 40 per cent. larvæ secured by exposing the eggs for eight or ten minutes to a current of negative electricity from a Holtz machine.

FRUITS.

CONSIDERED FROM A DARWINIAN POINT OF VIEW.

A STUDY of some of the common fruits that we eat at table gives us some excellent examples of the Darwinian theory of natural selection and the survival of the fittest.

Let us begin by comparing the botanical definition of a fruit with the structures popularly known under the term, "fruits." A fruit, as botanically defined, is simply the matured ovary of the plant after fertilisation has taken place; but in the case of many of the fruits we eat at table other parts of the flower are included.

The simplest form of fruit is simply a case enclosing a single seed; such a fruit is called an *achene.* The buttercup is a good example of this form of fruit, and each of the individual fruits of the strawberry is an *achene.* The seed case is known as the *pericarp,* and usually consists of three layers: an outer—the *epicarp*; a middle—the *mesocarp*; and an inner—the *endocarp.*

The simplest form of succulent fruit is the *drupe.* In this the seed case has become succulent and fleshy, and its three component parts are distinguishable, and have taken on different functions, for reasons we shall afterwards see. The epicarp forms an external, usually highly coloured skin; the mesocarp forms the succulent matter; while the endocarp forms a hard, protective covering for the seed. Examples of this form of fruit are the cherry, plum, etc. The blackberry and raspberry are formed by an aggregation of such drupes placed on the enlarged receptacle. These are known as *compound drupes,* and each separate fruit is a *drupel,* each drupel having, of course, the same structure as the cherry.

Such fruits as the above are *true fruits,* but let us now notice a few well-known examples in which other parts of the flower go to form the so called "fruit." These are *spurious fruits.* In the first place, let us take the *strawberry.* In this the red, swollen mass is simply the end of the stalk, which has become succulent, while the fruits themselves are the yellow bodies in the surface, which are commonly called seeds, each of these fruits, as we have seen before, being an *achene.* Again, the end of the stalk, or receptacle, instead of bulging out, as in the strawberry, may become hollowed out so as to enclose a cavity in which are placed the fruits. The fig is an example of this. The fig is thus a strawberry which has become, so to speak, invaginated. The type of fruit termed a *berry* is a succulent fruit in which the seeds are imbedded in a pulpy mass—*e.g.,* the *gooseberry* and *grape.* The blackberry, raspberry, and strawberry are therefore not true berries at all. Now let us take the *apple.* This is a still more modified form, as the calyx tube, in addition to the pericarp, encloses the seeds. The calyx tube has become fleshy and forms most of what we eat; the mesocarp also is fleshy; while the epicarp and endocarp form two horny cases. Finally, the most modified fruit is the *mulberry.* Here the group of flowers, the petals of which have become succulent, forms the so-called mulberry fruit. The pineapple is another example of this kind.

These few familiar examples will suffice to show what different parts of the flower go to form what are popularly known as fruits, and also what different parts may become succulent. In the cherry, blackberry, raspberry, etc., it is the true seed case which becomes succulent; in the strawberry it is the swollen stalk; in the apple the calyx tube; and in the mulberry the petals of the flowers themselves.

Now let us consider the reason why some fruits are succulent and others hard; why some are sweet and others bitter; and why some are highly coloured and others dull. The primary object of all fruits is the perpetuation of their species, by means of dispersing their seeds. It is obviously of advantage for the seeds to be scattered over as wide an area as possible, because only a certain number of plants can grow in a certain area. The seeds have no inherent power of locomotion; hence they must avail themselves of such opportunities as occur. The simplest agent in dispersal is the *wind,* and seeds which avail themselves of this means are either minute, so as to be easily blown about, or else they are downy, as in the dandelion, so that they can float a long way in the air. The second means of dispersal is by *animals,* chiefly birds, and such seeds avail themselves of this means which cannot be dispersed by the wind. Animals may cause dispersion of seeds in two ways. Firstly, by carrying earth with seeds imbedded in it in their claws. A good example of this is given by Darwin, who states that he obtained a piece of earth which had been found sticking to the leg of a partridge, and since then had been kept three years, but when wetted and placed under a bell-jar, he obtained no less than eighty-two plants from the seeds imbedded in it. This also shows the length of time that seeds retain their power of germination. Secondly, animals may disperse seeds by swallowing them as food. The seeds of such fruits are protected by a hard coat, which resists the action of the digestive fluids of the animal's stomach, and the seeds thus pass out in the excrement uninjured, and get dispersed during the peregrinations of the animal. Fruits which attain the dispersal of their seeds in this way become as succulent and sweet as possible, and acquire bright colours to attract the birds and other animals; but this does not take place till they are ripe, for otherwise they would be eaten before the seeds were mature. In other words, such fruits strive as hard as possible to get eaten. Take, for example, the wild strawberry; the young strawberry is green and sour, to prevent being eaten till the seeds are mature; when, however, the seeds are attaining maturity, the receptacle becomes red and succulent, to attract the notice of the birds; the latter swallow the pulpy receptacle and with it the small yellow fruits; the receptacle is digested, but the seeds pass through uninjured and so become dispersed by the flight of the bird.

Hence we see the reason for fruits becoming succulent and sweet is in order to make themselves attractive food for birds and other animals, and so ensure the dispersal of their seeds. Such fruits we may call *attractive fruits.* But this explanation will not account for the origin of the nuts or *deterrent* fruits. In these it is the seed itself which is nutritious, owing to the large store of albuminous material destined for the young embryo plant. Owing to this large store of food, these fruits *do not require dispersal,* hence do not make themselves attractive; on the contrary, they make themselves as repulsive as possible, and devote all their energies to prevent getting eaten and to preserve their nutritious seeds, as it is evident that these seeds, since they are digestible, will cause destruction of the species if they are eaten.

These *deterrent fruits* may be protected by a prickly coat, as in the chestnut, or a nauseous covering, as in the walnut; and it is interesting to note that it is the same part that becomes filled with bitter essence in the walnut which in the cherry or plum becomes sweet and eatable. Again, these fruits, instead of being highly coloured to attract the notice of animals, are invariably green while on the tree, and brown, like the soil, when they fall to the ground, so as to escape the notice of the animals. The extent of the protection depends on the animals to whose attacks the nuts are exposed. The European walnut has only a few woodland animals to guard against, while the American butter-nut has to withstand the teeth of the forest rodents.

Take, for example, the *cocoa-nut*. This contains a large store of food-stuff intended for the embryo plant. This accounts for the milk in the cocoa-nut, but not for the fibres on the outside! Let us consider the reason for the presence of these fibres. The cocoa-nut grows at a considerable height, and so has to fall some way to the ground when ripe; also it is subject to aggravated assaults from our revered ancestor, the prehensile ape. This accounts for the presence of the fibrous coat of the nut. It is remarkable to note that the fibrous coat of the cocoa-nut corresponds to the succulent part of the cherry and the bitter coat of the walnut.

Finally, Darwin has shown that there is considerable evidence for believing that the *peach* is derived from the *almond* by artificial selection. This is interesting, as it shows the actual conversion of a deterrent fruit, the almond, into an attractive fruit, the peach.

Lastly, let us consider the *origin of fruits*. The doctrine of natural selection tells us that in uncultivated plants—*i.e.*, plants in a state of nature—no part can be present that is not of direct use to the plant; and, in the case of fruits, no part can be present that is not directly concerned in the preservation and dispersal of its seeds. Hence it is absurd to suppose that fruits were created for man's special benefit, for if man was the chief eater of fruits, the latter would soon disappear from the face of the earth, from insufficient dispersal of their seeds.

The origin of fruits is due to natural selection, and furnishes us with some of the best examples of this law; for, in the case of plants, we at once get rid of the idea of voluntary effort, so difficult to escape in the case of animals; for we are apt to imagine an animal consciously striving to better itself. Take, for instance, the giraffe; we are apt to think of the animal as consciously endeavouring to increase the length of its neck in order to reach more food; whereas it is really those which have *accidentally* longer necks which survive. In the case of plants this is avoided, as we should never imagine a fruit striving to make itself succulent in order to attract birds.

Let us first consider the origin of *attractive fruits*. All fruits were not originally alike; some happened to be sweeter than others, owing to an accidental deposit of sugary matter in their tissues. These were at once eaten by birds, and the more sour ones rejected; the ones eaten consequently survived, and the sour ones went to the wall. The seeds of the ones eaten gave rise to others, which reproduced the characteristics of their parents; and the most attractive of these were eaten, and the others rejected, and so on, generation after generation, the fruits becoming more and more succulent, because the most succulent ones were eaten and survived. This process may be carried still further by artificial selection, so that the original object of the fruit is lost, and fruits can be produced which have no seeds. In this way, finer fruits are produced, as the nutriment originally intended for the seed now goes to the fruit.

We should naturally expect that attractive fruits did not appear on the earth till there were animals which would eat them; both must have developed simultaneously and in mutual dependence on each other. So we find no traces of the succulent fruits, even in so late a geological formation as that of the lias or cretaceous cliffs, for the simple reason that there were no animals to eat them; the birds of that period being carnivorous, while the mammals were mostly kangaroos or marsupial wolves. It is only in the modern tertiary period that we find the earliest traces of the rose-family, the greatest fruit bearing tribe of our modern world.

We now come to the origin of *deterrent fruits*. The origin of these is exactly the reverse of the origin of attractive fruits. The seeds of these, stored with food for the young plant, were exposed to the attacks of birds, monkeys, and other animals, and were thus destroyed. But as no two fruits are exactly alike, some happened to have a harder or more bitter shell, and these alone survived. The hungrier their foes, the more need was there for protection, and so the bitterness and hardness went on increasing generation after generation, and the nut which best survives on the average is that which is the least conspicuous in colour, has a rind of the most bitter taste, and is enclosed in the hardest shell.

Thus, as Grant Allen says, "Nature is a continuous game of cross purposes. Animals perpetually outwit plants, and plants in return once more outwit animals; or those animals alone survive which manage to get a living in spite of the protections adopted by plants, and those plants alone survive whose peculiarities happen successfully to defy the attacks of animals."

Reviews.

Whence Comes Man; from "Nature" or from "God"? By Arthur John Bell. London: W. Isbister, Limited, 1888.

Mr. Bell says in his introduction that he is "only an ignorant person," not possessing "any deep knowledge of theology, philosophy, or science," and pretending to "no more than an average amount of common sense." But we may safely supplement his remarks by adding that he has more than the average amount of courage—to give its noblest name to the quality he manifests—for he has in all his ignorance ventured far into the deepest problems of theology, philosophy, and science, and traversed the conclusions of men who surpass him in knowledge as much as he surpasses them in temerity.

We are sorry that Mr. Bell did not devote himself more earnestly to the serious effort needed for rightly understanding the meaning of the great men he takes to task; he would assuredly have met with his reward, for he seems to be possessed of that degree of intelligence which renders the achievement possible. As it is, he has in many instances misunderstood their meaning, just because "common sense" will no more enable a man to grapple with philosophical or scientific difficulties than it will enable him to navigate a ship or conduct a campaign. For example, he quotes Spencer as follows: "Self-existence, therefore, necessarily means existence without a beginning; and to form a conception of self-existence is to form a conception of existence without a beginning. Now, by no mental effort can we do this. To conceive existence through infinite past time implies the conception of infinite past time, which is an impossibility." On this passage he makes a comment which is nothing less than absurd. "I, that true?" he says. "I can certainly think a fortnight. Does it take fourteen days to 'think' a fortnight? Does it take a longer time to think a fortnight than to 'think' a week; and a shorter time than to think a month? When Mr. Spencer uses the word 'conception,' he is evidently thinking not of 'conception,' but of '*experience*.' Let us change the word 'conception' to the word 'experience.' 'To experience' existence through unfinite past time, implies the 'experience' of unfinite past time, which is an impossibility. Of course it is. But a *conception* of unfinite past 'time' is not. It is simply the thought of time *without* limit, and is simply what I call a 'private' idea, the formation of which presents no difficulty."

Now, all this rigmarole has come about because Mr. Bell has not taken pains to understand exactly what Mr. Spencer and other instructed and thoughtful people mean by the terms they use. Mr. Spencer certainly is not thinking of experience when he speaks of conception, and to change the one word for the other is to make nonsense of what he says. Mr. Bell's failure to grasp the meaning of the passage he quotes has led him not only into this injustice, but into the bewildering and ludicrous criticism he gives. When he began to write about "thinking a fortnight," he should have said, if he wished to parallel Mr. Spencer, that a fortnight necessarily means fourteen days, and that to form a conception of a fortnight is to form a conception of fourteen days; if he had done this he would have seen at once that such a line would lead him nowhere in particular, and he would have given it up. But he does not accurately follow accurate thinking, so his own thinking about it is muddled and confused, and he lands himself in absurdity. As to his remark about a conception of infinite, or unfinite, past time presenting no difficulty, we must say that its audacity would have been more startling had he refrained from showing us that he makes it on the ground that he can "conceive a million" years in *as short a time* as he can "conceive a moment."

Again, he quotes Mr. Spencer as follows: "To say that space and time exist *objectively*, is to say that they are entities;" and he comments—"On the contrary, it seems to me that only one of them—'space'—is 'objective,' and therefore an entity; while 'time' is the name of a thought, and therefore 'subjective.'"

Surely even common sense might have saved poor Mr. Bell from this blunder! Mr. Spencer quite plainly states that *if* space and time are *said* to exist objectively, then such an assertion is equivalent to saying that they are entities; whereupon Mr. Bell dashes at him headlong, and attacks a wholly imaginary statement to the effect that both *are* objective, and therefore entities.

After a long attack, conducted mainly on the principles displayed in the above examples, it is not a surprise when Mr. Bell tells us that it seems as if Mr. Spencer "could write hardly a line which does not provoke dissent." There is a well-known piece of advice which we cannot forbear passing on to Mr. Bell; it is a warning that when very obvious objections and very easy criticisms present themselves to the mind in dealing with the work of any man of great and special knowledge, it is the part of wisdom to stop and ask one's self one or two questions. Mr. Bell has not asked himself those questions; he has not played the part of wisdom. This is a pity, for he is capable of doing good work himself if he will only wait until he has learnt to understand other people's. In the book before us he has done bad work; he has wasted his own powers, and tried his best to dim the lustre of some of the greatest names of the age. Happily, his endeavour is ineffectual; but we fear that this foolish attempt to make common sense supply the lack of knowledge may give him a false conceit of knowledge which will render of no avail all his intellectual vigour. It can hardly be anything but this false conceit of knowledge which has led him to the astounding conclusion—the drift of his book—expressed in the statement of his belief that *Space* is *God*.

Proceedings of the Institution of Engineers and Shipbuilders in Scotland. Thirty-first Session, 1887-1888. April 24th.

The most important paper read was one by Mr. Lawrence Hill, on "Collisions at Sea; How to Avoid and How to Minimise their Disastrous Results." An incident mentioned deserves general publicity. That gentleman, an underwriter, told him that he was going to the Mediterranean on one occasion, and with him as fellow-passengers were two ship masters, who ridiculed the captain in charge of the vessel for his cautious navigation—one of them in particular for the captain's extreme caution in keeping clear of dangerous headlands, and the other laughed at him for giving so much searoom to a coming vessel. His friend made a note of these two masters' names, in order to trace their future career, and it was remarkable that the one lost his ship on the very rocks which he had laughed at the captain for giving a wide berth to, and the other's vessel was lost by collision near the place.

Journal of the Society of Telegraph Engineers and Electricians. Vol. xvii., No. 73. London: E. and F. N. Spon.

This issue gives an account of the proceedings at the 177th ordinary general meeting of the Society. The time was chiefly taken up with a discussion on Mr. Crompton's paper on "Central Station Lighting."

Mr. E. G. Tidd read a paper on the "Use of Electricity for Theatre-Lighting." Here he calculated that the decorations would last three times as long when the electric light was employed as under the old system of gas. He states that of the London theatres and music-halls lighted by electricity six work from the Grosvenor and four have their own plant.

Physical Apparatus for Beginners.—A firm in Dresden offer three sets of apparatus—for galvanic electricity, for influence-electricity, and for acoustics—at the remarkable low price of twenty shillings each. The first of these sets contains two Daniell elements, two carbon plates for fitting up Bunsen or chromic acid elements, a galvano meter, a Wheatstone bridge, an electrometer, an induction coil, a permanent bar magnet, a resistance equal to 1 ohm, two thermo-elements, two connecting clamps, and six metres of covered copper wire. The instruments are small and simple, but they are well constructed and work perfectly.

Abstracts of Papers, Lectures, etc.

NORTHERN INSTITUTE OF LITERARY AND SCIENTIFIC SOCIETIES.

The first meeting of this Association was held at Huntly on the 14th inst. Mr. Charles Proctor read a paper on the "Composition of the Atmosphere in the Early Geological Epochs." He pointed out that while all the solid and liquid portions of the globe were chemical compounds, the atmosphere was mainly composed of two free elements, these being the remains of the elemental gases out of which the earth had condensed. Water, probably one of the last combinations, would, when first condensed, be exceedingly hot, and would thus act with much greater force as a disintegrating agent than in its present form, especially in presence of much carbonic acid gas. Thus the character of such rocks as granite, gneiss, and metamorphic rocks could be accounted for. Mr. Proctor then proceeded to point out that independently of this theory of the evolution of the earth there was evidence of there having been much more carbonic acid in the atmosphere at the close of the Silurian and Devonian eras. Pointing out that coal was only the remains of ancient forests, and that these could only obtain their carbon from the carbonic acid gas in the atmosphere, he gave figures showing that even the workable coal known to exist in the world must have required 45 billions of tons of carbonic acid to produce it. And this he reminded the meeting was only a small proportion of the remains of actual vegetation now buried in the earth's crust. Turning his attention next to animal remains he pointed out that probably the bulk of all limestone rocks were originally the shells of living creatures, and that these had been enabled to leave such remains only through the agency of the same carbonic acid. At all events the great chalk formation of Europe was such, and these he calculated, quoting Sir C. Lyall's description of them, must have required 50 to 60 billions of tons of carbonic acid gas, which, added to that from the coal, gave at least 100 billions of tons—a quantity 40 times greater than is now found in the atmosphere, and this was only a small portion of the whole quantity that must at one time have been present. In such an atmosphere, even without the higher temperatures, disintegration and deposition of new rocks must have gone on at a much greater rate than in the present age.

Dr. J. O. Wilson, Huntly, contributed a short paper dealing with "Salmon Disease." The disease referred to was the fungus disease, which has attracted so much attention within the last ten years. It first assumed serious proportions in the Eden, in Cumberland, in 1877, and since that time has visited most rivers in the United Kingdom. In the Deveron it was worst in the autumn and winter of 1883-84; but has since abated. Dr. Wilson then gave a *résumé* of the character and course of the disease, pointing out that it began on the parts uncovered by scales, and afterwards spread to the rest of the body, destroying large areas of tissue by ulceration. The immense number of the spores that spread the disease was also pointed out, and the consequent helplessness of man in endeavouring to stamp out such a disease, Nature's remedy, sea-water, being the best and most efficacious, if the sufferer can only reach the healing waters.

SOUTH LONDON MICROSCOPICAL AND NATURAL HISTORY CLUB.

At the June ordinary meeting of this Club, the evening's gossip was opened by the President, Mr. Frederick Hovenden, who drew attention to the interesting phenomena presented by a thin film of water under the microscope. The film might be obtained by simply breathing on the blade of a knife, when the steam would condense and the disappearance of the water could be observed with a half-inch power. As the globules evaporated, they appeared to leap into the air, the actual point of final disappearance, however, being difficult to detect. Some curious questions as to molecular action were raised by this experiment, as well as by those which he suggested should be made in connection with thin sections of iron. In testing this metal for commercial purposes, a tension strain was used which caused the iron before it broke to ribbon out with considerable heat. Steel under a similar tension made a clear fracture without thinning out and without heat, and this was remarkable, as the tension required to break the steel was greater than in the case of the iron. He believed that if thin sections of iron were made, they would be found full of pores, whilst in sections of steel there would be but few. His theory was that the minute gaps were filled with air, and that the effect of the intense tension was to compress these spaces, thus generating the heat, which was immediately taken up by the iron with a consequent increase of temperature.

Mr. Suffolk observed that some years ago Mr. Sorby had worked out the subject of sections of iron and steel. He had viewed them as opaque objects, having been unable to obtain transparent sections, as the metal would not hold together. Gold would, however, do so, and transmitted light of a greenish tint. With respect to the pond-life exhibited, Dr. Hudson had taken *Brachionus* as the type of a rotifer, and a beautiful drawing of it was given in his work, with an account of its anatomy. The growing slide, Mr. Suffolk said, was not sufficiently used by microscopical observers. If they would only take u the life-history of a diatom, and trace it from its cradle to its grave, many of the so-called species would be found to be but different conditions of the same organism.

Mr. Dadswell explained that the exhibits he had brought to the meeting had all been collected in the neighbourhood of Epping Forest, within an hour's ride from the City. Volvox, stentors, corethra, brachionus, and the more unusual forms, were easily obtained in the locality he had visited.

A specimen of *Melicerta ringeus*, from Clapham Common, was exhibited by Mr. Neville, who stated that within the last few years the water-life of the Windmill Pond had considerably altered in character. Some years ago the pond literally teemed with the crowned rotifer, *Stephanoceros eichornii*. This had now disappeared, but in its place the brick-making *Melicerta* had sprung up, and might be obtained on the scanty vegetation that had managed to survive the building operations in the vicinity.

Mr. Oakden gave some interesting particulars with reference to the hydrachnidæ. The specimen under his microscope belonged to this species of water mite, and was a female. Only those acquainted with the subject were able to determine the difference of sex. The males were fewer in number and of a pale colour. About 40 different species were known of these arrennui, but only a small number were mentioned in the works of English writers. The larvæ had six legs, which were increased to eight on their attaining the adult state. After passing the larva stage the nymph was supposed to be parasitic on some of the water-beetles; but so little was known as to this that both the *Hydrachna*, or scarlet mite, and the *Limnesia*, or bog mite, afforded scope for practical and interesting work. The larva of the *Gyrinus*, a beautiful object, with branchia similar to the may-fly, would also repay observation. It kept close to the bottom of ponds, and was therefore not readily met with.

The president recorded his observations of an amæba, which divided into two parts. These eventually again joined and formed one animal.

Mr. Groves stated he had at first experienced difficulty in keeping chara for continuous observation, a temperature of over 70 degs. being fatal to the plant. By placing it in a very cool place, however, he had found it live and thrive. Having felt the difficulty of dissecting under the ordinary microscope, in which everything was reversed, he had adopted Mr. Stevenson's binocular, a form of which he exhibited, with large rests at the side for steadying the hands.

In reply to Mr. Sebastian Davis, who thought it desirable attention should be directed to the causes governing the group of special forms in different ponds, Mr. Groves stated it was interesting to watch the gradual development of vegetation in the pools of water that formed in newly-opened gravel pits. During the first year little else appeared than confervoid algæ; in the second, chara or nitella would be found; in the third, the water buttercup perhaps made its appearance; then some of the filamentous-leaved water plants, the chara or nitella being completely ousted from the pool; whilst the last to appear was the pond weed, with its flat leaves resting on the surface of the water. He presumed that with this succession of plants there was also a corresponding development of animal life.

THE ARTIFICIAL REPRODUCTION OF VOLCANIC ROCKS.

Translation of a Lecture Delivered by M. Alphonse Renard, LL.D., at the Royal Institution.

At first sight the study of the earth's crust appears, if one may so express it, entirely utilitarian. It almost seems as though it were absolutely forced on man by the necessity of exploring the strata of the earth for the purpose of extracting minerals, building materials, combustible matters, etc.

It is evident to anyone who casts a glance at the history of any of the sciences, that these sciences owe their origin in the first place to a definite, practical, and useful aim, that they have all passed through this initial phase, and have afterwards followed a regular development, the progress of which, as concerns geology, we will here endeavour to trace.

Man commences the exploration of terrestial depths in order to draw from them the materials necessary to supply his several wants. At first he does this at haphazard; but, as the miner's art develops, the search for mineralogical treasures is carried out with more method—he begins to observe the conditions under which minerals and useful rocks are found in close proximity in the depths of the earth. He does not hesitate to generalise from his observations and from the localities in which these rocks are found, and thus discovers the salient points of the architecture of our globe. In excavating into the bowels of the earth, one is forcibly convinced that the globe was not made at one fell swoop but owes its formation to successive epochs.

It is clear, therefore, that to rightly interpret the history of the earth, and the part played by various causes in its formation, it is necessary to make exhaustive studies of the solid crust, so as to be able to picture the state of our planet in past ages. By comparing the different strata of the globe with the formations which are developing before our eyes, we can succeed in retracing the conditions which were the chief agents in the formation of the layers of ancient periods. Thus, by the analysis of facts and the induction from generalised observations, the knowledge of the earth's crust enters into a new and truly scientific phase. The original attempt to discover some practical rule for the miner resolves itself gradually into a desire to unravel the history of the earth. A fundamental principle guides us in this reconstruction of the past of our planet—the fact that the essence of the forces which have acted upon the earth still remains unchanged. We must seek in geological epochs for the traces of those phenomena only whose nature is akin to that of phenomena which we ourselves witness, and which we can submit to critical direct observation. A vast number of documents on the history of our planet has accumulated since the latter end of the last century, when the inductive method was first applied to the study of the mineralogical masses forming the crust of the globe, to their architecture, and to the beings whose remains are fossilised in the different layers.

Let us see how, relying on this induction and putting this analytical method into practice, geology interprets the formation of rocks. Rocks are, as we know, the solid mineral masses which constitute the strata. Observation teaches us to distinguish a first group, characterised by the disposal in layers or in beds; these are sedimentary rocks. A second group, which does not show this stratified disposal, includes the rocks of a volcanic nature and massive structure. The widely-differing structures and compositions of these two great lithological divisions, lead us to the conclusion that they were formed under special conditions which have left their distinctive marks on each group.

The formation of the sedimentary rocks is at once understood if we observe how both river and marine currents deposit on their beds pebbles, sand, clay, etc. As the organisms living in these waters die away, their skeletons or their shells mingle with the mineral substances, and, with these latter, gradually raise the layer of sediments. The matter thus deposited naturally takes, from the manner in which it accumulates, a stratified appearance. All the particles of which these layers consist were originally isolated grains, and still bear traces of their origin; they are the remains of organisms, or the fragments of pre-existent rocks, which will subsequently all be unified again by physical and chemical action.

Now let us compare these modern sedimentary deposits, characterised by their stratified disposal, and the detrital nature of their constituents, with certain layers of geological formation. We see, on the surfaces of continents, masses owing their formation to geological periods, which present close analogies of aspect and structure with the materials which are deposited before our eyes by river and sea-water. This comparison leads us to suppose that the ancient stratified rocks were formed under identical conditions, and we accept them as sub-marine or fluvial deposits. Thus water is the main agent in the formation of sedimentary and detrital masses.

The second group, to which we will now give our particular attention, includes the rocky masses. Types of this group we can observe in process of formation during volcanic manifestations. The molten matter ejected by the crater, or injected into the sedimentary layers, solidifies as it cools. The minerals which constitute the lavas are individual crystals developed in the molten magma in which they are contained. These crystals present no detritus in the sense that we now attach to this word. Broadly speaking, these eruptive masses do not show the stratiform tendency of the sedimentary formations; instead of the primitive horizontality and the regular superposition of the stratified layers, we have in the lavas an aspect which clearly proves the forces of upheaval from below to which they are subjected at the time of their eruption. Finally, these massive rocks bear no traces of animal organisation.

Let us compare, in their turn, the contemporary volcanic products with certain ancient crystalline rocks—the granites, porphyries, trachytes, basalts. We notice that all these latter possess close analogies of structure and composition with the products of modern volcanic activity. From this resemblance of their common characteristic features, we may conclude that the massive rocks which traverse the sedimentary geological formation were, at first, like the modern lavas, forcibly upheaved from below, and that they share with these lavas an eruptive origin.

But while we may see the sedimentary rocks formed almost before our eyes, the conditions which influence their formation, carried out, as it were, in broad daylight, the eruptive masses are elaborated in the innermost recesses of the earth. Their genesis is, to a certain extent, surrounded by mystery; the eye cannot penetrate into the vast subterranean reservoirs where these molten masses first solidify, and whence they are ejected at periods of volcanic activity. Here the process of direct reasoning is rendered practically impossible; the finest analysis, the closest reasonings cannot replace the missing data—they are powerless to fully enlighten us as to all the causes at work in the formation of eruptive rocks.

To resolve our doubts, control and complete our observations, we must have resource to an artificial reproduction of volcanic rocks, and thence form a synthesis. Armed with the data of such observations as we have to act as guide, we endeavour by scientific manipulation to imitate the results of nature. The science of the earth, hitherto analytical, thus enters on a new phase and becomes synthetical. Although restricted by the available apparatus, these endeavours to imitate nature, originated and conducted by man's intelligence, enable us to produce results analogous to those which we wish to investigate, to direct and watch over the progress of the phenomena, to obtain an exact account of their relations to each other, and to vary at will the conditions under which they arise. The knowledge acquired by observation, the analysis, and the reduction are thus all, to use Bacon of Verulam's expression, "submitted to the iron and fire of experience."

We have given, in broad outlines, three standpoints in the onward march of the knowledge of the earth's crust. We have seen it at its earliest stage, when its aim was purely utilitarian, we have followed it later; when, guided by observation and reason, it rose to the dignity of a science. Geology, in its last phase, is, at the present day, transformed into an experimental science.

The study of the recent artificial reproduction of volcanic rocks amply proves the powerful assistance rendered by laboratory research to observation taken direct from nature. But before explaining the process of the synthesis of contemporary eruptive rocks, we must sum up all that analysis and the observation of facts have taught us on the constitution and mode of formation of these volcanic masses. The point of comparison of the synthesis is to be found in the natural lavas—they are the models which we wish to reproduce, and it is therefore necessary to thoroughly understand them in order to successfully imitate them in minute details.

Let us reconsider, then, what we know about these lavas and the conditions which influence their formation, although we cannot pause here to contemplate the great manifestations of the internal forces of the globe, nor the trains of accompanying phenomena—the formidable eruptions which shake the volcano to its very foundation, and project pulverised vitreous masses and red hot stones. In the middle of this disturbance the crater and the flanks of the mountain, fissured by the force of the upheaval, emit streams of molten lava which roll down the slopes and slowly solidify.

The chief feature of an eruption is the emission of lava or stream of molten matter which escapes from the crater. Broadly speaking, one may best compare this lava to glass liquefied by the influence of the high temperature which predominates under the solid crust of the globe. Direct observations of the temperature of the liquefied lava of the crater, made at the moment of its eruption, are fraught with dangers such as few observers care to face. Thus we possess on this point only approximate indications, although on some volcanoes where the expulsion of lava is never very energetic, but which are permanently in a state of moderate activity, as in the Island of Hawaii, it is possible for intrepid scientists to approach sufficiently near to the crater to attempt to estimate the temperature of the liquid mass. They have thus been enabled to average it as varying between 1,000° and 2,000°. But from the moment the lava begins to flow, the temperature of the surface rapidly decreases; the sheet of liquid is covered with a crust of scoriæ, beneath which the molten mass flows on like a stream, at about the temperature for melting steel. This mantle of scoriæ prevents irradiation, and enables the mass which it covers to preserve for some time a certain amount of viscosity.

A little later we will discuss the observations on the phenomena of the crystallisation which occurs in these erupted masses, still fluid and viscous, but on the verge of instant solidification. Let us consider, first, some of the essential characteristics of the structure and composition of the lava. These volcanic products are often full of bubbles (scoriaceous); sometimes, on the contrary, they appear as homogenous, glassy masses, more or less dark in colour, in which the naked eye can detect no isolated minerals. Sometimes, again, the mass is so full of minerals that the glassy paste which unites them is scarcely recognisable. The minerals thus imprisoned, when their development is perfect, present regular polyhedral forms, constant for each specimen—that is to say, they are crystals, perfect individual specimens of the mineral world. They have extracted from the primitive glassy mass the chemical elements of which they consist, and which group themselves according to their several affinities, just as we see, in a liquid saturated with a solution of salt, crystals reforming the substance of which was previously dissolved in the mother liquor.

Mineralogy teaches us to define the different kinds of minerals which crystallise in the lava, whilst chemical analysis furnishes us with valuable information about the composition of volcanic products. If we treat eruptive rocks by a chemical process, we find that they all contain a more or less considerable quantity of combined silicate, which sometimes amounts to even 65 % of the whole mass; these are acid or light lavas. Thence we pass by various transitions to basaltic and heavy lavas, in which the amount of silica, gradually diminishing, does not attain to more than 55 % or 45 %. This silica does not exist in a normal state in contemporary lavas, but is combined in the form of silicates, with aluminium, iron, lime, magnesium, potash, and soda.

We find in the slag of metallurgic industries products which bear close analogies to those of volcanoes, both in composition and formation. These artificial scoriæ are, like the lavas, formed of silicates, and a still stronger similitude lies in the fact that the lava scoriæ may be considered as the dross of the internal metallic nucleus, of which they form the upper layer. The differences which we find in their compositions result from the greater or less depths of the zones whence they are taken.

Our knowledge of eruptive rocks has been increased to an unlooked-for degree by the application of the microscope to lithology. We have no space here to record all the almost marvellous results obtained by this method of investigation, inaugurated by H. C. Sorby, but, to put it tersely, microscopical analysis has completely revolutionised the study of stones.

(*To be continued.*)

THE NEW YORK STATE ENTOMOLOGICAL STATION.—The building erected at Cornell University consists of two parts, a laboratory and a vivarium. The former includes a laboratory for the experimenter and his artist, a laboratory for an assistant, a room for photographic work, quarters for janitor, and a storeroom. The vivarium is in the form of an ordinary botanical conservatory, sixty feet in length, divided by a transverse partition into two equal compartments. One of these is to be used as a hothouse, the other is to be kept as nearly as possible at the temperature of the air outside. This vivarium is to enable the experimenter to keep the insects that he is studying alive upon growing plants where all the conditions can be controlled. An arrangement has been devised by means of which insects living upon roots of plants can be observed continuously without disturbing them. Another is to aid in the study of the relations between ants and plant-lice. Others are for experiments in the use of insecticides.—*American Naturalist.*

RE-FORESTATION IN AMERICA.—Professor Willitts, of the Agricultural College of Michigan, believes (*Popular Science Monthly*) that the moisture on the American continent is advancing westwards, and that the planting of forests will cause the rainfall to spread year by year further to the west. In Nebraska 700,000 acres of forest have already been planted—the cotton-wood and the willow first, and then the soft maple and the hard woods.

THE HEARING OF FISHES.

CAN fishes hear?

That is a question which must be variously answered, according to the sense in which it is propounded. If it be asked whether they hear at all, we must unhesitatingly reply in the affirmative. If information be sought as to whether they hear as we do, our decision may as unhesitatingly be given in the negative. And, thirdly, if it be suggested that, while submerged in the water, they can distinguish sounds in the air, we must treat the proposition as one open to considerable doubt. And to these three points let us now devote our attention in turn.

Do fishes, then, hear at all? We may reply, as already stated, without a moment's hesitation, that they do. For in them we find the first rudiments of the auditory organs which attain to such perfection in the higher vertebrates; and in many cases, to use a somewhat Hibernian expression, these rudiments are present in a fairly complete state. And the very character of the organs of hearing is such that, even in their most incipient stages, they must necessarily be of more or less value to their owner. One cannot imagine the work of evolution going on in any sensory apparatus if the actual practical utility of such apparatus were to be delayed until development were complete. The organs, upon such a supposition, would be of no possible value to their possessors while still rudimentary, and so would have no chance of preservation, still less of gradual development and perfection. And thus it seems evident enough that the mere presence of an auditory system, however incomplete, must imply that the sense of hearing is at least not wholly wanting.

It is true that fishes possess neither external ear, Eustachian tube, nor tympanic cavity; but that affords us no proof whatever that they do not hear. Water is so much more dense a medium than air that its vibrations are and must be carried to the brain of any animal submerged therein, whether that animal possess ears or no. And the internal ear in the fish is so formed that any such vibrations must be keenly felt and appreciated, although of course not in the same degree as in animals whose sensory apparatus is more perfectly developed.

But in no aquatic creatures do we find the external ears of any great dimensions. In the whales and the seals those organs are almost microscopical, in proportion to the bulk of the body. In certain semi-amphibious animals (I use the adjective in its popular sense) they are so formed that they close instantly upon submergence, and remain practically non-existent until the head is raised from the water. And the reason is evident enough. Water, as a denser medium, transmits vibrations with so much greater intensity than air that a submerged animal possessing ears adapted for the reception of atmospheric sound would be literally stunned by such a shock as that resulting from a heavy blow upon the surface. The North American Indian, walking over a frozen river in mid-winter, sees a beaver swimming below him, and immediately brings down his club with all his force upon the ice. The shock is borne to the water, and through the water to the brain of the beaver, which, stunned by the concussion, is drawn out through a hole hastily cut in the ice before it recovers its senses. Were a whale gifted with ears corresponding in size to its bodily dimensions it would probably be killed by the shock resulting from the first blow of its own tail upon the water; seals in the same way would suffer greatly from their own evolutions, and from those of their comrades. And any one who wishes to test for himself the qualities of water as a conductor of vibration can do so by submerging himself two or three feet, and allowing a companion to strike with a stick or an oar the surface immediately above him. The experiment is one which he will not find it necessary to repeat.

Whether fish can appreciate sound, as we understand the word, is another question altogether, and one which can be almost certainly answered in the negative. For sound, in our ordinary acceptation of the term, is an atmospheric phenomenon only, and cannot be transmitted from the lighter medium of air to the denser medium of water. Let the sceptical reader again dive a foot or two beneath the surface of a pond, a stream, or the sea, and he will find that sounds in the air above are perfectly inaudible. A companion may shout or sing, or even fire a gun, and he will hear nothing whatever so long as the water itself be not disturbed. How, then, can we hold that fish hear atmospheric sounds, seeing, moreover, that they possess no external ears whatever, and that even the internal auditory apparatus is so very far inferior to our own? Vibration, even of the water itself, must necessarily reach them with greatly diminished intensity: and how is it possible for them to succeed in hearing sounds which to animals with senses far more highly organised are, and must be, perfectly inaudible?

But how, it may be asked, are we to account for the many reports of fishes recognising the sound of a bell, the blast of a bugle, or the shrill call of a whistle, and hastening to the accustomed feeding-places in anticipation of food to follow? Stories more than one of such a character have from time to time been given to the world, and backed, in some cases, by quite unimpeachable authority. How is evidence such as this to be set aside?

Again the explanation is obvious enough. In one at least of the instances referred to, and in that which is best authenticated, the custodian of the fish was invariably accustomed to drive to the reservoirs in a tolerably heavy cart; and it is evident enough that the sound which brought the fish to the feeding places was not the stroke of the bell by which they were apparently summoned, but the vibration caused by the wheels, which was conveyed through the earth to the water. Sound cannot be communicated from the lighter medium to the denser, but from the denser to the lighter it can. And the rumbling of a heavy cart would certainly be quite audible to fish in a neighbouring pond or stream. Even a heavy footstep near the bank will frighten the fish lying beneath it, as many an angler has discovered to his cost; he who wishes to capture them must tread lightly, in addition to keeping himself concealed. The vibrations of a heavy bell, again, might possibly be transmitted to the earth through the body of the ringer, and from the earth to the water, and so to the fish. And in none of the cases referred to does any precaution seem to have been taken to prevent the fish from discovering the presence of their keeper by other means than that of atmospheric sound. Even an approaching footstep, to fish born and bred in captivity, would be sufficient to attract their attention: and as by long association they would connect such a footstep, coming at regular intervals, with the supply of food, it is hardly to be wondered at if, on hearing it, they should manifest the eagerness and excitement described. But we cannot hold that they hear either the whistle or the bugle, or even the footstep in the ordinary manner. No impression whatever would be conveyed to their auditory organs by the former; the latter would communicate vibration to the soil—which is an excellent conductor of sound—and the earth in turn would pass it on to the water. And so it would reach the fish.

But the appreciation of vibration conveyed in such a manner, and reaching the brain without passing through external auditory organs *en route*, is not hearing in the strict sense of the term; it is merely the shock arising from a veritable blow, differing only in degree from that which stuns the beaver as he swims along below the ice. And thus fishes, in the ordinary interpretation of the term, do not hear. Such auditory apparatus as they possess, however, enables them to appreciate with greater nicety vibrations which would probably be in some degree appreciable had they no such apparatus at all; they can detect sounds in the water without difficulty, and sounds in the earth, if not too far from land, with tolerable ease. But sounds in the air, it is not too much to say, they cannot hear at all, unless in some way associated with, or implying, a corresponding concussion of the water.

A BIG THING IN GUNS.

FOR two or three years past the subject of heavy ordnance has engaged the attention of public men, and the question whether the old style of built up cannon could be superseded by others solidly cast has been discussed in all its bearings. At last the matter got into Congress, and, in March, 1887, twenty thousand dollars were set aside for the purchase of solid steel guns, provided that they could be made.

Bids were asked from the different steel men in the country for the production of a cast steel gun made by either the crucible, open hearth, or Bessemer processes. It was expected that there would be a very general response to this invitation. On the contrary, only two bids were received—one from an open hearth concern in Eastern Pennsylvania, and the other from the Pittsburg Steel Casting Company.

The contract made by the manufacturers with the Government called for the delivery of the gun in Washington ready for rifling on or before the 1st of April. Then the Government allows itself seven months more before expressing its opinion as to the merits of the gun. Three of those months can be spent in finishing the gun, and the other four in testing it at Annapolis.

Appreciating to the full the importance of the work he had undertaken, Superintendent Hainsworth's preliminary steps were characterised by the utmost caution. There must be no mistake about the quality of steel used, and its component parts must be judged with undoubted accuracy. A long familiarity with the metal enabled him to manufacture it with just the particular qualities he required for his work. Before doing this, however, the mould for the gun must be prepared. A pit, twenty-five feet deep, was dug in the moulding shop within easy reach of the great converter, and in this was made the mould. A special sand was used, and soon the exact shape of the exterior of the gun, muzzle down, could be seen in the pit.

By January everything was ready for the cast. The mould was carefully inspected for the last time, and sixty men lent their assistance to the process of pouring the white molten steel into the pit. The immense converter ceased its roaring as it turned over, the infernal stream poured forth, and in little more than sixty seconds the mould was full. The metal was poured into a "gate" or pipe that ran to the bottom of the mould, so that the steel entered the mould at the bottom and welled up to the breech at the top.

For half an hour there was nothing more to be done. Then the pit was surrounded by anxious faces, and the superintendent, his eyes shaded, peered into the hole. His long experience in steel making enabled him to take in at a glance many signs of success that would have been hidden from any one but an expert, and he pronounced the "cast" a success as far as it had gone. As to the quality of the steel he must wait for it to cool before he could give an opinion. The total length of the casting over all was $276\frac{3}{4}$ inches. The sinking head, which was made in two diameters, was 72 inches in length. The part immediately above the gun, which was 48 inches long, was $16\frac{1}{2}$ inches in diameter at the top and 17 inches at the gun. The smallest section, which was 2 feet high, was 15 inches in diameter at the bottom and $14\frac{1}{2}$ at the top.

The finished length of the gun will be 193·53 inches, the total weight of the metal 18,490 pounds, the length of the pattern for the gun proper being $204\frac{3}{8}$ inches.

The gun was in the mould five days. At the end of that period it was cool enough to be removed. A very thorough examination of it was then made, every inch of its surface being closely inspected, and several pieces cut off the sinking head for chemical tests. Not a flaw could be found, and the experts who were permitted to examine the gun declared it to be a perfect piece of Bessemer.

The next process was the rough boring. The solid cone was placed in a lathe, and a tool of the finest steel began to cut a tunnel through it, beginning at the muzzle. The bore was $5\frac{1}{4}$ inches in diameter. For over a week the tool went through the hard steel, the turnings being carefully preserved and tested at intervals.

These tests showed the steel to possess in a remarkable degree the qualities which are essential The result of a test made upon a piece of the metal cut from the angle of the trunnion showed :—Ultimate strength, 92,700 pounds; elastic limit, 51,960 pounds; elongation in 2 inches, $12\frac{1}{2}$ per cent. Samples taken during casting under cold bending tests, gave the following results :—Pieces forged from 2-inch square ingot to $\frac{5}{8}$-inch square, and allowed to cool, were bent cold to an angle of 161 degrees without fracture.

As the bore was cut through it was carefully watched, an incandescent electric light bulb being used to examine the interior of the gun when the cutting tool was withdrawn. Two or three hours was sufficient to dull the edge of the tool, and it had to be taken out and ground at frequent intervals. The time when this became necessary was unerringly indicated by the heating of the gun caused by undue friction. At last the bore was cut through, and nothing but satisfaction could be expressed. The Government inspectors were at the mill every day, and it is safe to say that the big gun received as close attention as any mother vouchsafed to her first babe.

Now came the annealing. This was a delicate operation, and upon its results depended very largely the success or failure of the gun. A bricked up furnace, deep enough in the ground to enable the gun to be placed in it muzzle downward, with but a few feet above the surface, was prepared. Into this the gun was carefully lowered. Then it was slowly heated by natural gas to a temperature of 1,400 degrees, allowed to cool, again subjected to the 1,400 degrees, and again allowed to cool. It was in the annealing that Mr. Hainsworth made his boldest departure from the accepted methods of preparing steel for trying work. In talking about it the other day he said :—

"We do not use the old-fashioned oil tempering process. Oil tempering has been tried in England, and it is an open question whether oil does or does not temper steel. By our process we can give the steel used in the 'chase' or barrel of the gun ductility, and that in the chamber excessive toughness. Steel guns tempered with oil are liable to develop weakness in the 'chase.' We have our process thoroughly under control, and can give the steel special physical characteristics as required in different parts of the gun. Thus, in the 'chase,' we want ductility supremely, while in the chamber tensile strength and elasticity are mainly required."

The claim made by Mr. Hainsworth for his annealing method was thoroughly borne out by the result of the process in connection with the gun. In about a fortnight from the time it was placed in the annealing furnace it was taken out and placed in the lathe once more. Scarcely was it secured when workmen attacked the test pieces around the trunnion with cold chisels. The resistance of the metal to the chisel was greater than the men had ever experienced before, and many were their admiring comments as they chipped and chipped away. It needed but a superficial test of the pieces thrown off from the trunnion to show experienced men that the steel was as tough, close, and smooth as could be desired. The men next went to work at the breech, cutting off a portion of the sinking head to be subjected to official tests in Washington. Ere the test piece was quite severed from the breech Lieutenant Eaton, the Government Inspector, placed his mark upon it and authorised it to be cut off.

At Washington it will be rifled, polished, and made ready for the firing tests at Annapolis. There will be no child's play, and the gun will not be humored in any way. It will be loaded up with a one hundred pound ball and as much powder as can be forced in at the breech and touched off. This will be repeated as fast as the gun can be charged. Ten shots in eleven minutes is the rate at which it is expected the gun will be fired. The contract requires that the ball shall travel at the rate ef 2,000 feet a second as it leaves the muzzle, and, to attain this velocity the pressure upon the gun will be tremendous. If the gun is as good as its maker believes, it will stand this ordeal without a sign of weakness. It is tested to stand a pressure of fifteen tons to the inch at the breech and five tons to the inch at the muzzle.

Supposing that the gun passes the regulation test satisfactorily, it is expected that it will be put to still severer tests, each one greater than the last, until it blows to pieces. The gun will be lost, but it will convey a lesson in the manufacture of heavy ordnance that it is hoped will be worth millions of dollars to the people of the United States.

The contract price for this gun, which will be paid only in the event of its withstanding all tests, is 3,300 dols. A built-up gun of the same calibre would cost 22,000 dols. These figures speak for themselves, proclaiming unmistakably the revolution in gunnery that will take place if solid steel cannon become the ordnance of the world. —*New York Herald.*

METEORITES AND LIGHTNING.

At a recent meeting of the Royal Meteorological Society a paper was read on "The Non-existence of Thunder-bolts," in which it was sought to demonstrate that the fall of material substances during thunder-storms, as being in any way connected with the same, was a fallacy—a sophism that should be relegated to the myths and superstitions of the past.

I think, however, that there may be reasons for connecting the two phenomena, and that a thunder-bolt, meteorite, aërolite—or whatever we may choose to designate the falling substance—may occasionally be *permitted* to reach the earth by the aid of an electric discharge.

Recent researches have shown that about four hundred millions of telescopic meteorites enter our atmosphere daily, and become dissipated into vapour on reaching that part of our aërial envelope which is sufficiently dense to raise the temperature of these supramundane bodies to vaporising-point.

The pressure of our atmosphere at sea-level equals about $15\frac{1}{2}$ lbs. per sq. in., but, as the increment of elevation arithmetically progresses, so the decrement of density and pressure geometrically progresses; thus, at three miles the pressure is reduced to about $7\frac{1}{2}$ lbs, while at six miles it is but little more than $3\frac{1}{2}$ lbs.; beyond this height it must rapidly graduate into an etherial substance of extreme tenuity; hence a meteorite travelling towards us would meet with continually increasing resistance owing to increasing speed and increasing air density, so that the nearer it approached the earth the less likely would it be to reach it.

From the results of the observations made by Ekholm and Hagström, at Upsala, we find that clouds attain a higher altitude than was formerly supposed. The highest cirrus clouds observed reached 41,000 ft., the numerous other types being found at varying distances below this. It was also observed that the summits of cumulus clouds attained their greatest height *during thunderstorms*, the bases of the same remaining nearly always constant.

It is supposed that clouds at a height of five miles consist of crystallised water, and that the intense cold of such high altitudes as 20 or 30 miles probably reaches 100° C. below freezing point.

From the above facts we may, I think, infer that certain supramundane bodies are drawn towards the earth without undergoing any change through friction or air-compression during the first part of their journey; let us assume also that during the second stage the heat generated by an increasing density of air would be counterbalanced by the intense cold and clouds of frozen moisture, it must be apparent then that after this stage the most formidable barrier would remain in the shape of a rapidly-increasing density and temperature.

In this last zone would be found a critical point, upon the reaching of which the previously uninjured meteorite would become incandescent and disappear.

(I presume this critical point would vary considerably, depending, of course, upon the nature of the meteorite and the state of the surrounding atmosphere; it would be interesting to know, however, the nearest point to the earth at which incandescence has been observed to commence.)

We now require to find some agent capable of dispersing this final barrier of denser air: Now we know that an electric discharge from any given thunder-cloud displaces the air in its passage and forms *pro. tem.* a vacuum; we know, too, that a discharge is not of necessity "forked," but that it may reach the earth in the form of "well-refined ribbons or lines of light;" if, therefore, an aërolite were approaching us under the conditions I have named above, and should enter a thunder-cloud at the moment of an electric discharge, and in a direct line with that discharge, is there any reason why it should not escape dissolution by travelling *in vacuo* in the wake of such a discharge and reach the earth simultaneously with it?

Surely, we may assume that out of the millions of meteoric bodies which enter our atmosphere *some* may *occasionally* pass through the conditions I have indicated, and, reaching the earth simultaneously with the flash, be designated veritable "thunderbolts." CECIL CARUS-WILSON.

Bournemouth, July 20.

HABITS OF THE HESSIAN FLY.

Last year we were told, on evidently good authority, that the exceptionally dry, sunny weather had promoted the multiplication of this vermin to an extent not likely to recur for some time. But this year we learn, on the authority of Mr. F. Enock, F.E.S.—certainly an excellent observer—that "the damp, muggy weather, is decidedly favourable for the development of this pest." If both these views are well founded, the Hessian fly must have a very accommodating constitution. ONE PUZZLED.

A CIRCLE PROBLEM.

Nothing can excuse my carelessness in copying 7896 instead of the next figure 7926 from Whitaker.

I am perfectly familiar with the algebraic demonstration of this problem, but I did not send it to you in the first instance until I found that a number of people who are equally familiar were "caught" in thinking it to be more difficult, or rather more tedious, than it really is. At the same time, "Kuklos's" explanation of the "principle," as he calls it, is—simple though it be—intelligible only to those who have some acquaintance with algebra, while I endeavoured to make it clear to "general readers." A. P. T.

THE COSMICAL ORIGIN OF HAILSTONES.

Replying to "F. M.," p. 70, I must refer him back to my account of the formation of such hailstones. He will there see that the conditions are such that they must be produced simultaneously in countless numbers, forming clouds of ice particles; therefore must visit our earth under special conditions, and in this respect differ entirely from the falling of isolated meteoric stones. (I should add, by the way, that the view there expounded of the modes of formation of the hailstones is my own, suggested by Schwedoff's theory. I have only read an abstract of his paper.) An encounter with such a multitude of ice particles must of necessity produce considerable atmospheric disturbance, especially in summer. If such a cloud of hailstones entered the upper regions of our atmosphere with any approach to planetary velocity, their friction would bring them into the condition of the particles of water forming the cloud produced by Armstrong's hydro-electric machine, which Faraday investigated experimentally, proving that every particle of water therein was intensely charged with positive electricity by its friction against the jet nozzle and the surrounding air. Therefore, if I am right, every terrestrial hailstorm should be accompanied with "special terrestrial weather," *i.e.*, usually with stormy weather, and frequently with lightning, which is notoriously the case, especially in summer. W. MATTIEU WILLIAMS.

THE LANTERN FLY.

In reply to "An Old Entomologist" (SCIENTIFIC NEWS, Vol. 1, p. 525), I beg to say that I have never seen an insect vary its light, nor do I think that the different-coloured light indicates a different species, as I have never detected the slightest difference in the insects. The lights are quite under the control of the insect, as it can shut them off at pleasure, and when in captivity and at perfect rest these lights are quite invisible, but immediately show up as the insect is roused. T.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

TESTING FORCE.—A device for testing the force of projectiles has been patented by Mr. A. Harrison. It consists essentially of a disc mounted upon one end of a rearwardly directed and counterpoised bar encircled by a spring, and supported upon anti-friction rollers carried by a fixed framing, and having the force of impact indicated by a pointer worked from the bar.

MAGNETIC APPLIANCES.—A magnetic appliance for medical purposes has been patented by Mr. R. Lonsdale. The invention consists in employing strips of magnetised soft iron and of magnetised steel. These strips are formed into a compound magnet by fixing at each side of a strip of magnetised soft iron a very thin strip of plated hard magnetised steel. When not connected as thus described, the strips of iron and steel are arranged alternately within the case.

ELECTRIC BATTERIES.—Porous pots for electric batteries have been patented by Messrs. E. L. Mayer and H. Liepmann. The object is to so make them that they will always offer a constant resistance to the passage through them of the electrolytes with which they are employed, and it consists in impregnating them with a chemical reagent, and causing this to act upon another chemical reagent, so that a body, which shall not itself enter into any chemical action with the electrolytes detrimental to the action of the battery, may be separated and deposited in the pores of the porous pots.

PIN PLIERS.—Mr. J. C. Young has patented an invention relating to securing the punches in the one jaw and enabling a broken punch to be replaced in pin pliers used for punching holes at varying distance apart. The punches are formed with a head at one end so as to pass through the back of the perforated jaw, and then secured by a plate clamped across the jaw by set screws. The other jaw is formed with a slot into which the article to be punched is placed and held there during the operation. By this arrangement the punches can be more easily replaced when broken.

FRUIT.—A method for preserving fruit has been patented by Mr. W. F. Reid. The invention consists in placing the fruit, which must be perfectly sound, in a layer upon a level surface covered with a layer of mould in a well drained spot. Upon this layer of fruit is placed uniformly sifted mould about two inches in depth for apples or pears. On top of this earth is another layer of fruit, and so on till sufficient has been stored. The sides and top of the heap thus formed is covered with mould about six inches deep, to protect the fruit from atmospheric influences.

RACKETS.—A lawn-tennis racket has been patented by Messrs. F. H. Ayres and A. Foster. The object is to prevent the racket from breaking at the shoulder while in use. Between the frame and wedge piece is placed a piece of elastic material properly coated with glue, and the whole is then put under pressure to set. The holes to receive the strings are made single, and central for a certain distance on each side of the wedge piece; these holes are bushed with metal, so as to increase the strength of the frame by limiting the extent of the material weakened by these perforations, and to lessen the tendency of the stringing to split the wood.

TORPEDO.—Messrs. J. O'Kelly and B. A. Collins have patented a torpedo which is self-steering. To render a torpedo self-steering in any previously determined direction, a fish-shaped one is used, divided into air-tight compartments as usual for containing the explosive charge, the propelling charge, and the engine, and, according to this invention, provided with another air-tight compartment for containing the automatic steering gear. In constructing this gear a compass is employed, together with storage batteries, electrical contacts, electro-magnets, and armature levers operating upon the rudder by suitable gearing and connections to ensure the travel of the torpedo in the direction required.

PARALLEL RULER.—A parallel ruler has been patented by Mr. H. H. Lake on behalf of M. B. L. Aguettant. A ruler and cylinder are united at their ends by connecting pieces through which pass screws attaching them to the cylinder and ruler, and which serve as axes for the cylinder and ruler to turn upon. At one end of the ruler is attached a scale whereby the distance between each line to be ruled is obtained. When not required for use this scale is folded and passes under the rule. When a sheet is to be ruled, the ruler is placed parallel to the head of the sheet, a rotary motion is then imparted to the cylinder with the left hand, the ruler follows the cylinder, and when stopped is always parallel with the head of the paper.

DISTRIBUTING OIL.—Mr. S. Wilding, on behalf of Mr. C. Boye, has patented apparatus for distributing oil over the sea. The invention consists of a bag which is stiffened by bands, and to which are attached rings for convenience of handling the bag. The mouth of the bag is provided with a metal face having perforations through which the oil is intended to flow. Over the inner surface of the perforations slides a correspondingly perforated plate. The travel of the plate is controlled from the outside by means of a suitable handle turning a worm engaging with a rack upon the plate, and the size of the orifices may thus be regulated for the quantity of oil required to flow. The opposite end of the bag has a removable lid through which the bag is filled.

SAFETY LAMP.—A safety lamp has been patented by Mr. G. Smith. Over the wick-holders of a duplex lamp is placed a pair of loosely-fitting tubes provided with the usual shutter, and connected together by a suitable connecting-piece. To a place resting on the body of the lamp-burner between the wick tubes is secured a pair of standards, each carrying a lever, the inner ends of which are connected together, and to a weight by a chain while the outer ends take under the connecting piece. A hole is made in the centre of the body to allow a small threaded conical tube to pass through and be screwed to the plate between the wick tubes. Pendant from this tube is a support carrying the weight, to which is secured a wire bridge-piece, and to this piece is attached the chain operating the lever arms. If the weight be caused to swing the levers raise the extinguisher tubes and puts out the light.

ANNOUNCEMENTS.

Institution of Mechanical Engineers.—The summer meeting will be held in Dublin on the 31st inst. and two following days, and transferred to Belfast on Friday, August 3rd. The Chairman of the Dublin Committee is the Right Hon. the Earl of Rosse, F.R.S., and Vice-Chairmen the Lord Mayor, the Provost of Trinity College, the Rector of the Catholic University, the President of the Institution of Civil Engineers of Ireland, Sir Robert Ball, F.R.S., the Observatory, Dunsink, Sir Howard Grubb, F.R.S., Rev. Dr. Haughton, F.R.S., and a large number of gentlemen connected with the Institution of Engineers and with other professions. On Tuesday, 31st inst., the first meeting will be held in the examination hall of Trinity College, when the President, Edward H. Carbutt, Esq., and the Council will be received at 10 o'clock by Lord Rosse and the members of the Local Committee. The President will deliver an address, and papers will be read and discussed. At 1 o'clock the Reception Committee will entertain visitors to luncheon in the dining hall, and at 2 o'clock will give them a trip in Dublin Bay in a special steamer kindly lent by the London and North-Western Railway Company, to view Alexandra Basin, the departure quays, the dredging apparatus, the Bailey Lighthouse, and Kingstown. At 7 p.m. the annual dinner of the Institution will be given in the great hall at Royal University. On Wednesday the reading and discussion of papers will be resumed at 10 o'clock in the examination hall, and after luncheon, at 1 p.m., the visitors will be taken by special tramcars to the works of the Great Southern and Western Railway at Inchicore, or to the Rathmines Water Works; and in the evening there will be a conversazione at the Royal Irish Academy house in Dawson Street. On Thursday visits will be paid to Powers' distillery and Guinness's brewery, and in the evening a special train leaving Amiens Street Terminus at 7 p.m. will carry the visitors to Belfast. Such as desire to see the Bessbrook and Newry electric tramway will proceed by the ordinary 2 o'clock train. On Friday at 9.30 there will be a reception to the President and Council by the Mayor, Sir J. Haslett, and other members of the Local Committee. At 10 o'clock they will visit Harland and Wolff's shipbuilding yard and marine engine works and other places in the town which contain engineering works of interest. At 1 o'clock the visitors will be entertained at luncheon in the Town Hall by the Mayor and Local Committee, after which they will have a trip round Belfast Lough, by invitation of the Belfast Steamship Company, to see the new dock dredging operations and view Island Lighthouse, and at 8 p.m. a conversazione in Queen's College, Belfast, will terminate the meeting.

SELECTED BOOKS.

The Coleoptera of the British Islands, Part XVI. By the Rev. Canon Fowler, M.A., F.L.S. Vol. I., 14s. Large paper, with 36 coloured plates, 48s. Vol. II. 18s. London: L. Reeve and Co. Price 5s.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, July 16th, 1888. Specially prepared for Scientific News from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	50·1 degs., being 3·0 degs. below average.	6·8 ins., being 1·4 ins. above average.	433 hrs., being 9 hrs. below average.
England, N.E.	50·8 " " 3·9 " " "	5 6 " " 0·7 " " "	345 " " 96 " " "
England, East	54·1 " " 2·8 " " "	5·4 " " 0·5 " " "	381 " " 137 " " "
Midlands ...	53·6 " " 2·9 " " "	6 2 " " 0·8 " " "	358 " " 91 " " "
England, South	54 0 " " 2·2 " " "	6·0 " " 1·6 " " "	382 " " 86 " " "
Scotland, West	52·3 " " 1·1 " " "	8·7 " " 2·4 " " "	440 " " 36 " above "
England, N.W.	53·1 " " 2·7 " " "	6·0 " " 0·6 " below "	381 " " 72 " below "
England, S.W.	54·4 " " 2·1 " " "	7·2 " " 0·9 " above "	442 " " 57 " " "
Ireland, North	52·7 " " 2·2 " " "	8·1 " " 2·0 " " "	403 " " 23 " above "
Ireland, South	54·9 " " 1·1 " " "	8·4 " " 2·0 " " "	417 " " 7 " below "
The Kingdom...	53·0 " " 2·4 " " "	6·8 " " 1·2 " " "	398 " " 50 " below "

The sunshine value for the kingdom, after having steadily risen week after week, until 422 hours for ten weeks was attained has for the above period fallen to 398 hours; the maximum period of sunshine for 1888 is therefore past. The excess of, rainfall has now attained an inch and a quarter for the kingdom, its distribution being much more equal; temperature for the kingdom has fallen from 2 deg. below the normal in last week's report, to 2·4 deg. below.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

Another series of Mr. Spitta's experiments were made by dissecting, so to speak, the representative planet, cutting a hemispherical shell into first a central segment of 30 degs., then a series of annular segments or zones from 30 degs. to 60 degs., from 60 degs. to about 70 degs., and from 70 degs. to 90 degs., and making transits over these. The results of these experiments, briefly stated, were that when the little moon with albedo of 0·13 advanced towards the artificial planet with the central segment *in situ*, or removed, no apparent change was due to this removal; the same occurred when the moon was placed on the limb; and the same again when the moon was placed on the zone at about the angle of 65 degs. to 70 degs.; in like manner the removal of second zone made no difference; but when the moon was placed on a portion corresponding to about the angle of 60 degs. it appeared *exceedingly black* while the central portion remained, but recovered most of its brilliancy when the central portion was removed, it then merely appeared "rather more tinted than usual;" when the second as well as first zone removed, the moon recovered its original brilliancy.

I must not be tempted into proceeding with further details, but must refer any readers who desire to study the subject further to the Monthly Notices of the Royal Astronomical Society of November, 1887, where they will find the original paper. I have no doubt that all who read it carefully will agree with me in regarding it as a very able and important contribution to physical astronomy and optical science, worthy of far more attention than it appears to have hitherto received.

It will be noted, of course, that in both cases of planet and satellite we are dealing with spheres that reflect the radiations from the sun. If the surface of the orb were perfectly polished all the sides curving away from us would be invisible; only the central portion would be seen, and this, if sufficiently magnified, would present to us a mirrored image of the sun.

Thus, a moon as big and as near to us as our existing satellite would display merely such an image diminished to a brilliant speck of light. That we are able to see the hemispherical rotundity is due to the kind of reflection, the "scattering" reflection, which is common to all ordinary surfaces, and by virtue of which ordinary objects become visible in their actual form. If all the objects in a given apartment had perfectly polished surfaces, and a gas flame were the source of light, nothing more than a multitude of gaslights would be visible.

But the sun is spherical, and is visible by virtue of his own luminosity. How is this apparent luminosity affected by the obliquity of various zones in reference to our line of vision?

This question has been the subject of many experimental investigations. Omitting those relating to the spectrally dissected rays, I may quote Pickering's results for the general light. Calling the sun's centre 100, and dividing the radius of the visible disc from centre to limb into 100 parts, he found that at 10 parts distant from the centre the luminosity was reduced to 98·8, at 40 to 94, at 50 to 91·3, at 60 to 87·0, at 75 to 78·8, at 85 to 69·2, at 95 to 55·4, and at 100, *i.e.*, at the very edge of the limb, to 37·4.

From this it appears that the loss of light due to obliquity is far less than in the case of Spitta's ball of plaster of Paris.

Our mathematicians affirm, on theoretical grounds, that "an incandescent sphere of metal or an illuminated globe of white glass (like the shade of a student-lamp) appears sensibly of equal brightness all over, the foreshortening of each square inch of surface inclined to the line of sight just compensating for its diminished radiation" ("The Sun," by Dr. Young, chap. viii.); and they attribute the diminishing luminosity of the different zones of the sun, proceeding towards the limb, to the absorption of his light by his own atmospheric envelope, this absorption increasing, as it evidently must increase, with the obliquity, simply because we are looking through a greater depth of such atmosphere when our line of sight is oblique than when it is perpendicular. This difference corresponds to that of our daily experience in our own atmosphere. The sun appears far less bright on our horizon than overhead, because when on the horizon we are looking at him not merely through the depth of our atmosphere, but also through a great thickness in horizontal direction.

The sun certainly has a great atmosphere of his own, and if Spitta's results apply to self-luminous bodies as well as to those illuminated by scattering reflection the diminution of solar luminosity as we proceed from centre to limb should be greater, not less, than in the case of the plaster of Paris ball.

Some experiments that I made about twenty years ago supply a solution of this enigma. They were made with the photometric apparatus of my old friend Mr. Jonathan Wilkinson, the Official Gas Examiner to the Sheffield Corporation, and with his valuable assistance. My object was to learn whether a flame is transparent to its own radiations, or, stated otherwise, whether a flame of given intensity and exposing to the photometer a given area gives out an increased quantity of light proportionate to increased thickness or depth in the line of sight. Our experiments were numerous, as the earlier experiments proved the necessity of precautions that were not self-evident *à priori*. Thus we found that two jets from the same-sized holes, and each burning the same quantity of gas when placed in contact one behind the other, gave more than double the light of either, 2·15 times, and three jets gave 3·2, five jets gave 5·35, although the supply of gas was regulated respectively to double, treble, and five times the quantity supplied to the jets when burning singly.

Without entering into further details (for which see "The Fuel of the Sun," chapters vii. and viii.), I may describe the most conclusive experiment which was made with five simple round jets arranged in line about one inch apart, and each with a separate tap. These were adjusted to equal heights, and the row presented broadside to the photometer, so that all the jets were separately radiating towards it. They were then turned so that, instead of five jets being presented to the photometer screen, only the end one was presented to it, and thus the radiations from all the other four must pass through this one. The photometer indicated no difference, though in the first case five times the area of flame was presented. The observer was so placed that he only saw the disc of the photometer, the luminous object being completely hidden from him. We turned the row of jets round and round several times, changing places as observer and manipulator, and could not tell which presentation, whether broadside or endwise, was made; our guesses, based upon supposed increase of light, were as often wrong as right.

Similar experiments have since been made by others who used fishtail and batswing burners, turning these as we turned our row of equal jets. They found, as we did in our preliminary experiments, that the edge presentation of these gave less light than the broadside, but failed to learn the reason. It is that such flames have irregular summits, and that the edge view includes something more than thickness of flame—viz., a thickness of gas and vapour between the tips of the luminous tail-summits through which the hinder tail summits must radiate. It is well established that such vapours are especially opaque to the radiations from the flame of which they are the product.

Applying this fact of free radiation of flame through flame to the case of the sun, and assuming that the photosphere of the sun consists of flaming matter of considerable depth, we have in such depth a compensating factor to the varying depth of solar atmosphere presented to us. The visual depth of atmosphere and the visual depth of flame will vary equally with the different distances from the centre of the visual disc.

I may add that the above-described experiments were made in order to ascertain whether the great energy of the solar radiations could be explained without recourse to violent hypotheses concerning the temperature and intrinsic luminosity of the solar material—without calling upon the scientific imagination to create forms and affections of matter different from those existing here on our earth.

THE FOURTH EXPEDITION OF THE "HIRONDELLE": NEW DEVICES FOR DEEP-SEA DREDGING.

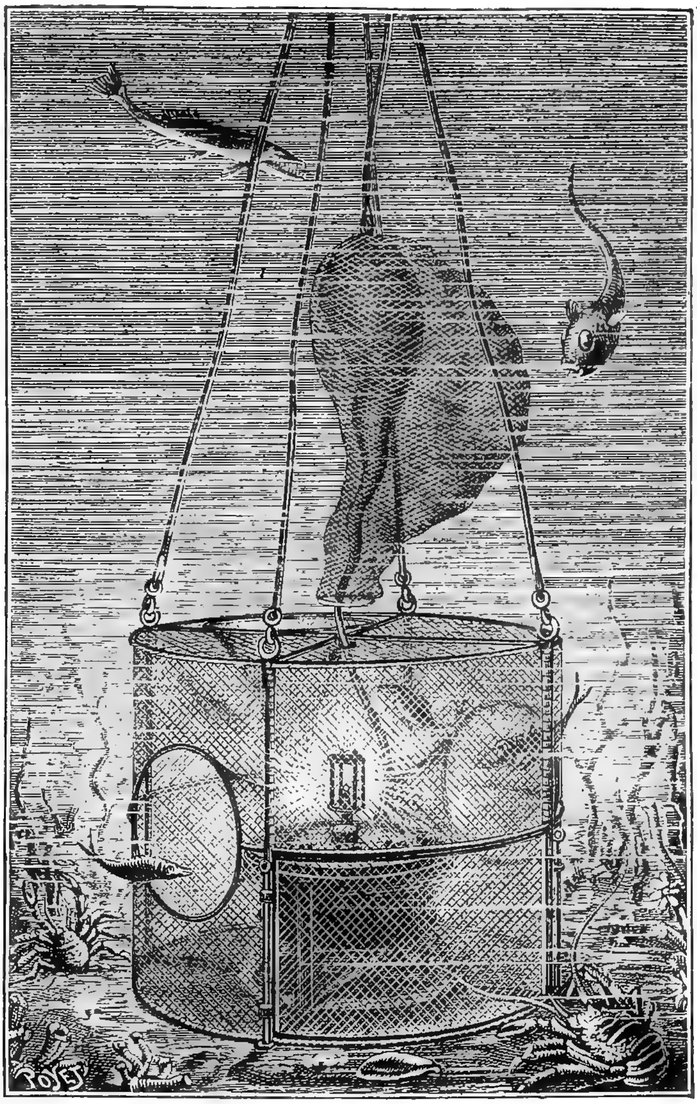
SOME mention has already been made of the *Hirondelle*, which under the command of the hereditary Prince of Monaco, continues with success the explorations of the *Talisman* and the *Travailleur*. This vessel, admirably equipped for a scientific cruise, has just sailed from L'Orient for the Azores, in order to dredge at great depths. The appliances for the expedition are numerous. We must first mention the cable for lowering the other apparatus to the bottom. It is more than 4,500 yards in length, and is formed of six strands of steel wire, forming a rope not so thick as a penholder, but capable of bearing a strain of more than 2,200 lbs. It realises, therefore, all the conditions required. It is coiled upon a drum, and consequently does not prove an encumbrance; it is not heavy, and still it is capable of resisting the severe strain required in drawing back the dredges from great depths. The vessel carries also sounding-leads of a new model for bringing to the surface the mud from the sea bottom for the study of the numberless organisms which swarm therein. Self-registering apparatus will record at every moment the condition of the sea, the height of the waves, and the movements of the vessel. Lastly, the improved dredges will enable the explorers to search the abyss with more care than has ever been done before.

Amongst the instruments of an entirely novel type embarked on board the *Hirondelle*, and doubtless destined to yield unforeseen results, are what may be called abyssmal traps.

The article on the "Sea Dredge," SCIENTIFIC NEWS, vol. ii., p. 60, has made everyone acquainted with the general manner in which deep-sea dredging is effected. A kind of large bag, held open by an iron frame, is attached to the ship by a strong cable; this drags the dredge after it, and thus scrapes the bottom of the sea. It will be seen that if this method be in a manner convenient, it is imperfect. The dredge accumulates as much mud as animals; however strong it may be it is liable to be torn upon the points of rocks; if it collects delicate organisms, which often happens, it makes a complete paste of them. Further, it catches only those animals which crawl at the bottom. Every agile creature easily gets out of the way. Hence we know little as yet of the wonders of the abyss. Two of the explorers of the *Hirondelle* have sought to entice the animals of the deep by means of baited snares, and from this idea there have sprung the baskets of the *Hirondelle* and the electric appliance of Dr. P. Regnard.

The traps are very like those used on our coasts for catching lobsters, only in place of being a few inches in length they are two yards. Our figure, taken from *La*

Nature, shows one of these contrivances which can be dismounted, so as to take up less room on board. When wanted for use it is merely required to connect the two halves by hooks in order to have a closed basket, into which is put a little bad fish, and which is then let down by means of the steel cable. At the top is placed a floating buoy, and the apparatus is then left in the sea. On returning in a day or two and raising it briskly an ample harvest is secured. This is not merely hope or conjecture, as the former voyages of the *Hirondelle* have already given surprising results.



In 1886 and 1887 traps of this sort were let down: one day one of them was raised containing more than 60 lbs of fishes and crustaceans. Unfortunately the hemp cables then in use were not strong enough and gave way, abandoning all this treasure to the sea. No such accident can happen with the steel cable.

Dr. Regnard has had the happy idea of lighting up one of these apparatus. It is known from recent investigations that beyond 400 yards there does not penetrate into the water light enough to act upon the most sensitive plates. Such a plate, which is over-exposed in $\frac{1}{100}$ of a second, may remain uncovered for 10 hours at great depths, and yet be perfectly unacted upon. The animals of the abyss are therefore deprived of light; they live in complete darkness, and their eyes serve merely to see the phosphorescence of their own bodies, or the feeble light which other beings diffuse. But from this to the electric light is a long step. Yet Dr. Regnard wishes to introduce it into the depths. He wishes to use it as a bait to capture the special forms which it may attract, or at least to learn if the inhabitants of the abyss flee from the light, like those of caverns, or if they seek the light.

This is not the earliest attempt to use light in fishing. It generally attracts animals. Moths come to burn themselves in candles; sea-birds dash against the lenses of lighthouses with such force that they are often killed, and their dead bodies are found at the foot of the tower. Fishes flock so readily to a light that fishing by torchlight is forbidden by law in some countries. Indeed, whatever shines attracts the inmates of the waters; a fragment of a broken plate is a good bait for lobster pots.

The notion of lighting up the sea for fishing has presented itself to many minds. Three years ago the *Talisman* drew behind her a lamp immersed some metres in the sea. A short time ago an English scientific society set out from Liverpool on board the *Hyaena*, and tried illuminating the sea to the depth of some fathoms.

But to convey the electric light to depths exceeding 1,000 yards is a much more difficult problem. The first suggestion was to let down an apparatus communicating by a cable with the ship in which the electric current was generated. This proved absolutely impracticable. The sole expedient is a battery let down to the bottom and left in the trap. But then there appeared a new difficulty. The apparatus will have to support a pressure of as many atmospheres as there are above it multiples of 32 feet of water. At 4,000 yards it would have to bear, approximately speaking, 400 atmospheres, a pressure which few materials and few connections can support. Dr. Regnard's invention consists in doing away with the pressure at whatever depth, or, at least equalising the inside and the outside pressure. This he effects as follows:—

The trap which he uses is cylindrical, with three apertures and a door. On the bottom rests a "Cardan" suspension containing a sort of iron pot closed with a lid. This lid closes with iron pins, which press upon a ring of caoutchouc. Into this recipient are put seven Bunsen elements, in which chromic acid is substituted for nitric acid. Each of the cells of these Bunsens is closed with a plate of caoutchouc to prevent the liquids from getting mixed by any sudden movement. All these elements, combined in tension, feed an Edison lamp of 12 volts enclosed in solid glass. The inside and outside pressure are equalised by the following arrangement. Above the trap is a balloon of caoutchouc enclosed in a net which supports it during the immersion. A tube leads from this balloon into the interior of the pot containing the battery.

On lowering the apparatus into the sea the balloon is compressed, and it injects into the iron pot so much air that the inside pressure is just equal to the outside pressure. All that is required is to calculate the capacity of the pot so that it may be proportionate to the capacity of the balloon and the depth to be reached. The same principle is applicable to all kinds of apparatus.

MECHANICAL REFRIGERATION.

CONSISTENT with many other theories, and in accordance with the old methods of scientific thought, the idea of "an imponderable fluid" called caloric was used until the end of the last century to explain the phenomena of heat. Lord Bacon, as he is generally called—though his name was either Francis Bacon, or Lord Verulam, for we do not speak of Lord Disraeli—had long before expressed his opinion that heat consists of a "kind of motion or brisk agitation of the particles of matter." In that remarkable work, the *Novum Organum*, which the classical scholar generally thinks is a dry list of scientific facts, but which is full of quaint ideas and amusing theories, after recounting a number of sources of heat, among which he alludes to the friction of trees rubbing against one another in a high wind, he says: "From these examples, taken collectively as well as singly, the nature whose limit is heat appears to be motion;" "the very essence of heat, or the substantial self of heat, is motion and nothing else." Unfortunately there was but little method in the scientific thought of these days, the theory-making was little else than guess-work. Neither enough evidence was collected, nor was sufficient care given, first to sift it, and then to reason upon it in a really scientific manner.

Count Rumford and Davy completely disproved the material or caloric theory of heat, and showed by experiment that an unlimited amount of heat could be obtained by purely mechanical means.

According to the old theory, the caloric fluid permeated the substance of bodies, and could be squeezed out, like water from a sponge. The heating of a piece of iron by the blows of a hammer was thus explained. The idea of the presence of caloric in a body was sometimes mixed up with the notion of "latent heat," and some persons have been led to think that because the caloric theory has been completely exploded, that the theory of latent heat is also unorthodox.

"Science is measurement," and before proceeding to discuss the subject of heat, it is necessary to have some definite ideas about its measurement, and the units by which it is measured. The English unit of heat is that which will raise one pound of water one degree Fahrenheit; strictly speaking, from freezing point to one degree above, for at high temperatures a little more heat is required. If we take a lump of ice weighing one pound, and apply sufficient heat to raise one pound of water one degree, the temperature of the ice will not alter, but some of it will become melted. On applying another unit of heat, a little more will melt. We should have to supply as much heat as would raise 142 lbs. of water one degree Fahrenheit, or one pound of water about 142 degrees, before all the ice was melted; and, until all the ice had disappeared, the temperature of the mixture would remain unaltered. Where has all the heat gone? It has become latent in altering the water from the solid to the liquid state. It exists no longer as heat, but as the energy of motion of the molecules of the water. To freeze the water again, 142 units of heat must be abstracted.

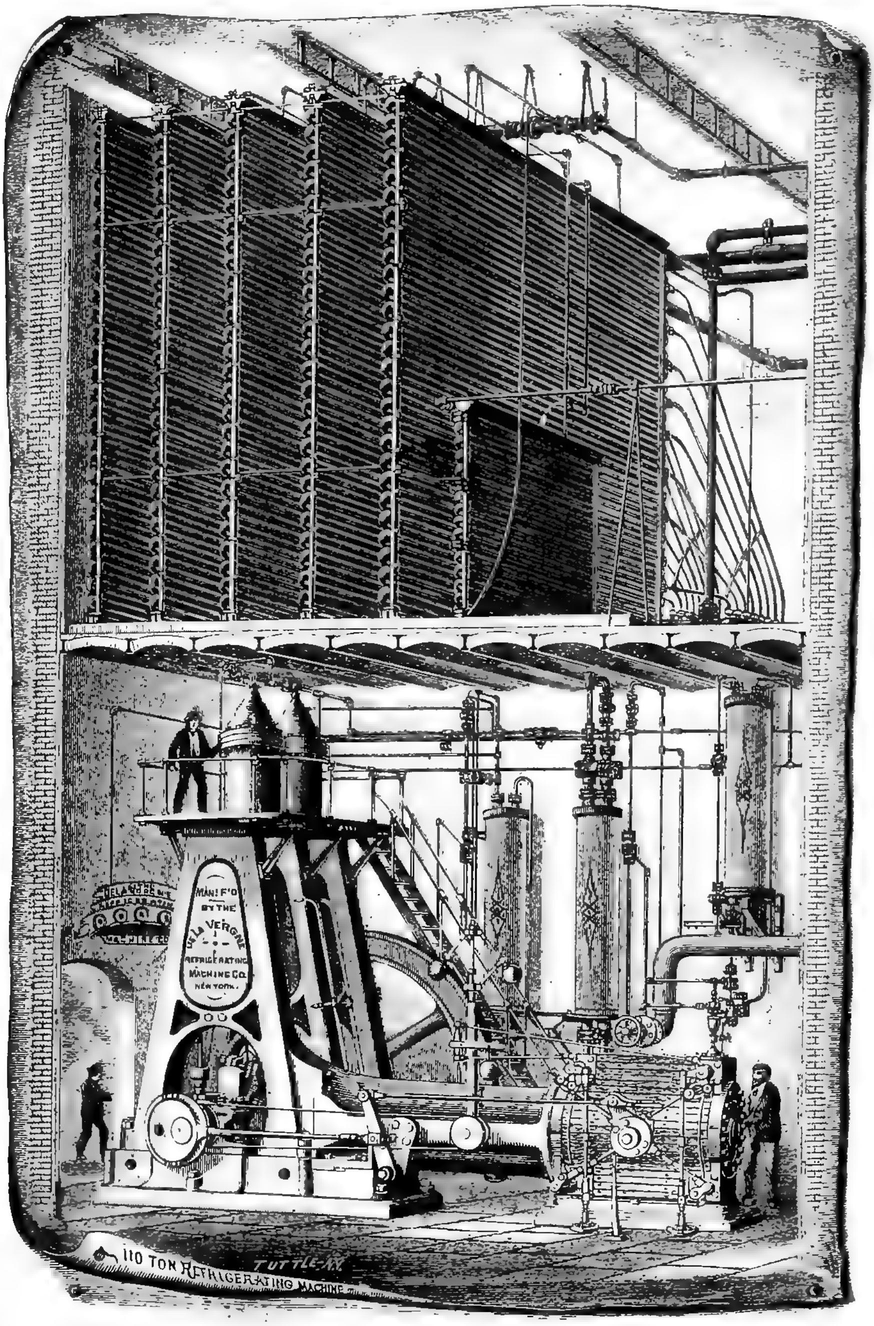
It is easy enough to produce heat by mechanical means, in fact it is impossible to avoid doing so to some extent whenever work is done, for in every machine there is some friction, and where there is friction there is heat. To produce cold is not so simple.

Most substances expand when they are heated, and contract when they are cooled. And conversely, when they are compressed their temperature rises, and it falls when they are allowed to expand.* If a piston carrying a bit of tinder be suddenly thrust down a well fitting brass tube, closed at the bottom, the air will be heated enough to set fire to the tinder; such an appliance was once common in Germany.

If the piston be allowed to spring back at once, the heat which was generated by the compression is absorbed by the air, as it returns to its original bulk. But if, while compressed, it be cooled by a spray of cold water; when it expands it will be reduced in temperature. On this principle most of the refrigerating machinery on board the ships which carry frozen meat is constructed. The

* Indiarubber is an exception. If an elastic band be suddenly extended while it is touching the lips it will feel warm, and when it is relaxed it will feel colder.

air is easily reduced to many degrees below freezing point, and is blown into the chambers in which the meat is placed. One advantage of this system is that the whole of the air in the chamber is reduced to the cold temperature, and while it surrounds and passes over the meat in a continuous current, it ensures a thorough chilling, and complete ventilation as well. One great difficulty, however, is that any moisture in the air is thrown down as a shower of snow. This is liable to obstruct the air-passages, and boys have to be sent through them to clear it away. Even if the atmosphere be comparatively dry, the spray of water used to cool the air after it has been compressed, will load it with moisture. Compressed air, however, will not hold so much vapour as at ordinary pressure, and, when it is compressed, the water becomes a cloud of mist or fog. When it expands this fog is absorbed again. When the spray of cold water is injected, it makes most of the fog settle, in fact it washes it out of the air, and leaves only as much vapour as it can hold at that pressure, so that we have the curious paradox that it is possible to dry air by wetting it.



If we take instead of air, some gas or vapour which when compressed, can be liquefied, we can make use of the latent heat of liquefaction, which disappears when the liquid reassumes its gaseous form, precisely as heat disappears when ice loses its solid form and becomes water.

Bulk for bulk, we can get the same effect from 42 cubic feet of ether as from 100 cubic feet of air. But ether is inflammable and expensive, and we can get the same effect with only 23 cubic feet of anhydrous ammonia. Ordinary *aqua ammoniæ* or "spirits of hartshorn" is a solution of ammonia gas in water. The greediness with which water will dissolve ammonia is used in another form of refrigeration which is not strictly mechanical, and which we must leave for another occasion. The ammonia compression system is the same in principle as the compressed air method, but the ammonia gas itself is not liberated in the chill rooms, but circulates in iron pipes.

One of the most perfect systems of ammonia refrigeration is that of the De La Vergne Co. of New York, and in the hands of Messrs. L. Sterne and Co., of Westminster and Glasgow, it is being most successfully introduced into this country. Few passengers in Gracechurch-street during this uncertain and muggy weather, know that within a few feet of the pavement there is an unvarying temperature of about 22° Fahrenheit, in which thousands of carcases of mutton are stored in chambers, tons of Russian hares and game, waiting until they are "in season," or to be consumed by the owners out of season. The meat seems as hard as stone, and a pair of fowls knocked together ring like flints. The air is so dry that it is difficult to believe that the temperature is ten degrees below freezing point.

Electric light glistens on the hoar frost which lies thick upon the pipes that run along the ceilings; they are provided with cast-iron discs, which afford a large surface for the absorption of heat. In these pipes the ammonia gas is passing. On leaving the chill-rooms the ammonia, in the form of a gas at about 15 to 18 lbs. pressure, enters at the bottom of a compressing pump which is worked by a Corliss engine. With the gas, mineral oil is forced in. This seals the valve and stuffing-box of the piston rod, and some of it is carried up with the piston, sealing the valves with which it is provided, and lubricating the cylinder at the same time. At the end of the up stroke, not only is all the gas expelled, but some of the oil as well. The ammonia is now at a pressure of 150 lbs. The pure gas has so much better a result than a mixture of ammonia and water, that the cooling is not effected by a shower of water as in the air compressing system, but it is led through long coils of pipes, shown in the illustration on the floor above the engine. A stream of water flows over these pipes, and the warm gas entering at the bottom, gradually exchanges its heat with the water, which runs off below at about the temperature of the warm ammonia, while the gas which reaches the top is at the temperature of the cold water. In the language of the caloric theory it would be said that the warm water leaving the cooler, carries off the caloric which has been squeezed out of the ammonia by the pump. Very little of the gas reaches the top, for the cooling combined with the pressure liquefies it, and as fast as it becomes condensed, it runs off by the pipes shown at the right-hand side of the cooler. It now is stored in a tank as cold liquid ammonia, the oil having been separated by a system of tanks which we have no space to describe. From the tank, the liquid is led to a row of valves provided with very small wedge-shaped openings, by which very accurate adjustment can be made. These valves open into the circulating pipes which run through the chill-rooms. In the cooling coils, the ammonia parted not only with the heat generated by the compression in the pump, but with the latent heat which would be necessary to boil it from the liquid into the gaseous state. As it rushes through the valve into the circulating pipes, and resumes the form of gas, the latent heat is abstracted from the pipes, and these becoming intensely cold, chill the surrounding air. In addition to the chill-rooms, the same machinery is used for making ice. For this purpose the ammonia in expanding, circulates in a set of pipes like those of the cooler shown in the illustration above the engine. A stream of strong brine flows over them, and becomes chilled to a temperature of about 23°. It is then pumped into a large tank, in which are placed a number of cans containing distilled water. This water being not only pure, but also free from air, freezes into blocks of ice as clear as crystal; and solid all through. These are so much below freezing point when removed from the cans, that if two are left touching they will instantly freeze hard together.

BIRDS' NEST, OR ELEPHANT ISLANDS.

Part I. of Vol. XXI. of the *Records of the Geological Survey of India* furnishes some interesting information concerning this remarkable group called by the Burmans Ye-eigent-thaik (lit., sea-birds' nests) at the southern extremity of Burma. It is a small group of six marble rocks, the highest and largest of which, 1,000 feet in height and above one mile in length, is oval shaped, and rises very abruptly out of a depth of only five fathoms. The sides are partly clothed with vegetation wherever a break in the limestone has left a cleft in which moisture and dust can lodge. Conspicuous is a species of tree-fern which grows at any angle, but only above a height of 200 feet from the water. The face of the rocks is reddish, and where cliffs exist most beautiful stalactites are in course of formation. But the great feature of the group are the birds' nest caverns, which, as a rule, open into the sea, the entrance being below high-water mark. At half-tide a tunnel opens under a wall of rock at the head of a deep cove in the big island; this tunnel has a roof-covering with large stalactitic knobs. Passing through this, one emerges into another circular basin with perpendicular sides, which gives the impression of volcanic action. Great caverns opening into circular basins exist in other parts of the island, and Commander Alfred Carpenter, R.N., who writes the account, states that the impression gradually forces itself on one that these circular basins were at one time the floors of huge caverns, and that, in days gone by, the islands were far higher with cavern piled on cavern, and that the work of disintegration by moisture is slowly going on pulling down these marble monuments of the past.

Progress of the Asbestos Trade.—The output of asbestos at the Canadian mines has risen from 300 tons in 1879, to 3,458 tons in 1887. It is now considered to yield the best and safest returns of any kind of mineral. A somewhat curious fact is that in China asbestos ranks among the medicines for inward use, being regarded as a tonic.

General Notes.

Professor J. C. Houzeau.—We much regret having to put on record the death of Professor J. C. Houzeau, the eminent Belgian meteorologist.

Strange Impurity in Milk.—Hermann Thoms alleges, in the *Pharmaceutische Zeitung*, that he has detected ultramarine in a sample of milk as offered for sale.

An Artesian Well in Queensland.—An artesian well has just been completed at Blackall, in Queensland. A bed of good water was struck at the depth of 1,600 feet, and a flow of 280,000 gallons daily is secured.

Height of Waves.—According to *Ciel et Terre* the waves of the sea may exceptionally reach the height of 56 feet. D'Urville records waves of 90 feet in height, which is more than double the figure given by other observers.

The Cultivation of the Senses. — The *Popular Science Monthly*, discussing industrial training, says:—"We expect a well-developed perceptive power in the senses, delicacy of touch, a minutely trained ear—yes, even nose." Surely the nose is of far greater importance in science than the ear!

British Museum Library.—It is understood that the name of Mr. Edward Maunde Thompson, Keeper of the Department of Manuscripts in the British Museum, has been submitted to Her Majesty by the Principal Trustees of the Museum for appointment to the post of Principal Librarian, in succession to Mr. Bond.

Japanese Honours.—The Emperor of Japan has been pleased to confer the fourth class decoration of the Order of the Rising Sun on Professor J. M. Dixon, M.A., F.R.S.E., of the Imperial University in Tokio, Japan. Professor Milne, the well-known seismologist, who is on the staff of the same institution, was also decorated.

British Association's Visit to Newcastle.—A Local Committee has been formed in connection with this visit, and it has been decided to prepare a Local Guide giving a brief sketch of the industries, natural history, and general history of the Northern counties. The three editors are, Historical Section, Dr. T. Hodgkin; Natural History, Prof. Lebour; Industries, Dr. Wigham Richardson.

Danger of Refrigerated Water.—According to the *Medical Press*, twelve workmen died lately at the manure works of Prairie-au-Duc. The disease was pneumonia, and it was ascribed to inhaling phosphates (volatile fluorides?) or the dust of dried fecal matter. On inquiry, however, it appeared that the premises were irreproachable from a sanitary point of view; but it appeared that the men, when heated, were in the habit of drinking freely from a vat in which refrigerated water was kept for certain uses in the factory. This is a warning for the lovers of iced water.

Loofah.—The *Börsenzeitung* directs attention to the growing use of loofah as a substitute for sponge. This curious substance is the skeleton-like, fibrous covering of a species of cucumber which grows in tropical climates. The proprietors of the extensive loofah works at Halle were the first to recognise its value as an adjunct of the bath, and to make of it an article of commerce, and they have created a considerable industry in collecting, preparing, and converting it for use. Enormous quantities are exported to all the principal markets of the world. A large quantity is now manufactured into inside soles for shoes. The latest development of the trade is to apply it to the under side of saddles, its principal merit in the application being that it tends to keep the horse's back cool.

Consumption and Coal Miners.—Dr. Nasmyth's results, given in our Abstracts, must be regarded as not a little remarkable, for it seems to have been clearly demonstrated by geologists and others that phthisis is always more prevalent where the soil and air are unusually damp, and that conversely the drying up of the moisture by drainage has always resulted in a marked decrease in the mortality from this cause. And yet, according to Dr. Nasmyth, we have here a very low proportion of lung disease among men who habitually work in air which is "nearly always saturated." If statistics from wider coal-mining areas bear out these observations it would certainly appear that some other cause than mere dampness has a share in inducing consumption; and as the ground beneath and around the mine must be saturated with water, while the temperature is shown to be closely similar to that obtaining above-ground, it is not, in the present state of our knowledge, very easy to see what other influential factor could enter into the question.

Structure of a Flash of Lightning.—M. E. L. Trouvelot, during the storm of June 24th, at Paris, succeeded in obtaining the photograph of a flash of lightning, and submitted the proof to the Academy of Sciences on the 9th inst. This flash, which seemed to connect the earth to a cloud, subtended an angle of 40°. The flash appears divided in four main branches, brilliant and strongly-marked. But there were others less visible, some so faint that they could not be seen in the negative without the help of a lens. The total number of the branches, large and small, is thirty-seven. A microscopic examination of the image of the flash shows that it is like a long ribbon, taking all the forms which a ribbon might present if plunged into a slowly-moving liquid. This ribbon seemed to be traversed vertically by a multitude of rays more or less close together, and more or less brilliant. They are seen almost everywhere upon the flash, even upon its faintest ramifications. They correspond in general with the fracture of the zigzags which seem to make up the flash.

The Distillation of Sea Water.—The Government is fitting a distilling apparatus in many of the new ships, which has several features to recommend it. It has been necessary heretofore to have a donkey boiler, or to set one main boiler aside for use in distilling, and either plan has its inconveniences. As steam will be used constantly in the new ships for power purposes, with the new arrangement, the same boiler can also be used for making fresh water without the oily unpleasantness that usually accompanies distilled water made from a boiler fed from a surface condenser. Steam from a special boiler is led through a series of coils, which are contained in a vessel supplied with sea water. The steam is condensed, or partly so, and falls in the condenser. A portion of the sea water is evaporated and is carried into a second coil, in which it is also condensed, and this water is of excellent quality. The first vessel is fitted with blow-off and brine cocks, and occupies very much less floor space than a donkey boiler of the necessary capacity would do. A test made with one of these arrangements, having 52 square feet heating surface in the evaporator, maintained a pressure of 51 lbs., and had a capacity of 900 gallons of water per day.—*Industries.*

Burmese Diet.—A correspondent of the *Rangoon Times* gives a curious account of the Burmese *cuisine.* They utterly reject milk—which in hot climates is admittedly questionable—as also butter and cheese. On the other hand, they have a fondness for putrid fish. The blood of a monkey is thought to be a very strengthening draught. Frogs, lizards, snakes and their eggs figure largely in the Burmese bill of fare. A monkey, roasted whole, is considered a certain cure for dysentery. The greatest peculiarity of these people is insect-eating. A large red ant (*Myrmica*) is caught in great numbers and pounded up as an ingredient of chutney, to which they give a peculiar acidity. The writer had set before him at tiffin a small basin nearly full of honey, in which were large white grains, like oversoaked grains of rice. He found the mixture delicious, "tasting like very delicate bits of marrow, cooked in honey. It consisted of bee-grubs stewed in honey." Some of their insect delicacies are much more questionable, such as the larvæ of a beetle (*Scarabaeus*) that rolls up balls of cow-dung. A mole-cricket (*Schizodactylus monstrosus*), called in the native tongue *jhingur* is consumed, as are also the larvæ of a palm-weevil (*Calandra*).

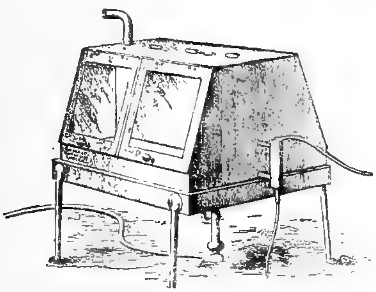
Electrical and Allied Trades.—A preliminary meeting was held on July 27th at the offices of the London Chamber of Commerce, Botolph House, Eastcheap, to consider the desirability of forming a section, or Committee, in connection with the Chamber to represent the electrical and allied trades. Mr. R. E. Compton presided. In a circular convening the meeting, issued by Mr. K. B. Murray, the Secretary to the Chamber, it was stated that the proposed section, if formed, would not interfere with the work of existing associations, but would only deal with matters that were purely commercial. The section, it was added, would be an integral part of the London Chamber of Commerce. Among the matters with which it was suggested that the section might deal were mentioned Bills before Parliament, foreign tariffs, treaties of commerce, customs classification, arbitrations, business extensions in India and the colonies, electric lighting legislation, fire insurance rules, and telephone and telegraphic matters. The Chairman of the section, or Committee, would possess a seat on the Council of the Chamber. In opening the proceedings the Chairman stated that two meetings had already been held recently on the subject. Previous efforts had been made to form a Committee for the electrical trades, but they had not been successful, as they had not represented the entire trade. After some discussion a resolution was passed appointing an organising committee for forming the section, the Committee to report to a future meeting of the Electrical Trades Committee.

Death of Professor Carvell Lewis.—Scientific men in general, and especially geologists, will hear with regret of the death of Dr. H. Carvell Lewis, Professor of Geology, Philadelphia, U.S.A., which occurred on Saturday last at Manchester. Professor Lewis arrived at Liverpool on the 11th inst. by the steamer *Alaska* from New York, being accompanied by his wife and a party of friends, among whom were Dr. G. H. Williams, Professor of Geology at the John Hopkins University, Baltimore, and Professor H. Langden Mitchell, son of Dr. Weir Mitchell, of Philadelphia. The main object of their visit was to attend the annual meetings of the British Association and the British Archæological Society, and in the intervening time it was intended to make visits of geological investigation to the mountains of Westmoreland and Cumberland and to Norway, and Professors Lewis and Williams were pursuing studies in microscopical geology at Manchester in connection with the latter of these projected expeditions. It seems that Professor Lewis had contracted an illness, now believed to have been due to drinking impure water before leaving New York, and that what was subsequently thought to be ordinary sea-sickness was probably a continuation of the same malady. He appeared to improve towards the end of the voyage, but some time after reaching Manchester symptoms of typhoid fever supervened, which terminated fatally on Saturday. Dr. Lewis was only thirty-five years of age, and leaves a widow and one child. English geological readers will remember his contributions to glacial geology which gave rise to considerable discussion at the British Association meeting last year, and will join their American brethren in regretting his untimely decease.

The Public Health.—The Registrar-General's return for the week ending July 21st shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 16·0 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Brighton, Nottingham, Hull, Derby, Blackburn, and Cardiff. In London 2,385 births and 1,297 deaths were registered. Allowance made for increase of population, the births were 374, and the deaths 539, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had slowly increased in the five preceding weeks from 14·2 to 15·7 further rose last week to 15·8. During the first three weeks of the current quarter the death-rate averaged 15·4 per 1,000, and was 5·7 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,297 deaths included one from small-pox, 25 from measles, 14 from scarlet fever, 15 from diphtheria, 33 from whooping-cough, eight from enteric fever, 62 from diarrhæa and dysentery, two from choleraic diarrhœa, and not one either from typhus or ill-defined forms of continued fever; thus, 160 deaths were referred to these diseases, being 388 below the corrected average weekly number. In Greater London 3,127 births and 1,589 deaths were registered, corresponding to annual rates of 29·5 and 15·0 per 1,000 of the estimated population. In the Outer Ring 11 deaths were referred to whooping-cough, 10 to diarrhœa, and 7 to diphtheria. The fatal case of diphtheria included three in Croydon and two in Walthamstow subdistricts. In our abstract of the Registrar-General's previous report Bristol should have been placed first among the six healthiest places for the week ending July 14.

IMPROVED LABORATORY OVEN AND BATH.

THE accompanying illustration represents Professor Reynolds' improved water oven and bath for laboratory use. It is a well-contrived and most useful apparatus, and we have much pleasure in recommending it to chemists and physiologists. The illustration shows an enclosed chamber on one side, with a glass door, and there is a similar chamber on the opposite side, with a space between the backs of the two chambers. There is also an enclosed space about 3 ins. deep under the two chambers, which is filled with water. The water is supplied through the upper tube at the end, and it is kept at a constant level by an overflow pipe inserted in the short vertical tube shown in the figure. If there be any waste water it is carried away by the bottom tube at the end. At the opposite end (not shown in the figure) there is a water gauge, by means of which the water level can be seen at any time. The water is heated by a Bunsen lamp underneath, and the whole of the apparatus is made of copper which conducts heat readily without much loss from radiation. Any temperature up to 100 degs. C. (212 degs. F.) can be steadily maintained, and this cannot be said of the water baths generally in use. Each of the enclosed chambers is fitted with shelves to receive test tubes, etc., and in each there is provision for a thermometer. On the top of the casing there are three or four openings fitted with covers to receive evaporating dishes, and at one end is a curved tube, through which the steam or water vapour escapes. This tube can be connected with a condenser, and then distilled water can be obtained. The apparatus has been neatly made by Messrs. Becker and Co., of 34, Maiden Lane, W.C., and it has evidently been designed by one who not only has a practical acquaintance with what is required, but who also has a knowledge of the scientific principles on which its success depends.



REYNOLDS' IMPROVED OVEN AND BATH.

SIMPLE EXPERIMENTS IN PHYSICS.

TO all matter must be attributed two essential qualities; first, that in virtue of which it occupies space, and which is known as extension; and second, that which allows only one particle or atom of matter to occupy a given space—the property known as impenetrability. That matter occupies space is appreciated by our senses, and needs no particular proof, but that two portions of matter cannot occupy the same space at the same time sometimes seems anomalous, as is shown by some of the following experiments. Into a tumbler filled with alcohol may be crowded a hatful of loose cotton without causing the alcohol to overflow. The success of the experiment depends the slow introduction of the cotton, allowing the alcohol to invest the fibres by capillarity before they are fairly plunged beneath the surface of the alcohol. In this experiment the penetration of alcohol is only apparent; the fibres displace some of the alcohol, but the quantity is so small as not to be observable. If the cotton were compressed to the smallest possible volume it would be found to occupy but very little space. So small a body would be incapable of raising the level of the alcohol enough to be appreciable by an ordinary observer. A more puzzling experiment consists in slowly introducing some fine sugar into a tumblerful of warm water. A considerable quantity of sugar may be dissolved in the water without increasing its bulk.

FIG. 1.—A HATFUL OF COTTON IN A TUMBLERFUL OF ALCOHOL.

FIG. 2.—SOLUTION OF SUGAR IN WATER.

Here the physicist is forced to acknowledge that either the water is penetrated or its atoms are so disposed as to receive the sugar between them, possibly in the same way as a scuttle filled with coals might contain also a bucketful of sand. This latter view is adhered to, and the atom or ultimate particle is held to be impenetrable. In the case of the mixture of water and alcohol, or water and sulphuric acid, a curious phenomenon is presented. Take alcohol and water, for example. Two equal volumes of alcohol and water, when mixed, occupy less space than when separate. If the sum of the volume of the two separate liquids is 100, the volume of the mixture will be only 94. In the case of the mixture of

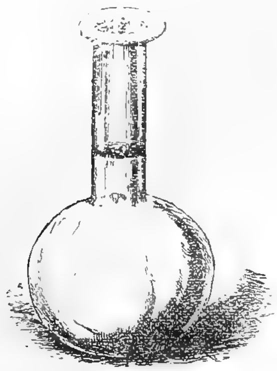


Fig. 3.—Representing Volume of Unmixed Alcohol and Water.

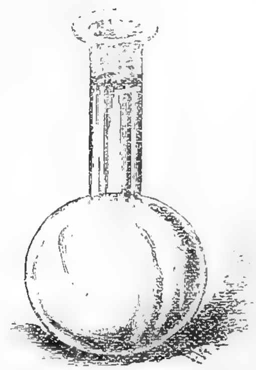

Fig. 4.—Reduction of Volume of Alcohol and Water Mixture.

sulphuric acid and water, the difference is greater. An easy way to perform this experiment is to fill a narrow-necked flask up to a line which may conveniently be marked by a rubber band round the neck, then removing one-half of the water, measuring it exactly, and replacing it with a volume of alcohol exactly equal to that of the water removed. It will be found that when the liquids are mixed, the mixture will not fill the flask up to the original mark. The only reasonable explanation of this phenomenon is that the molecules of the two liquids accommodate themselves to each other in such a manner as to reduce the pores, and thus diminish the volume of the mixture.

THE NUMBER OF CENTENARIANS.

Within the memory of the present generation an able and influential writer, Sir George Cornwall Lewis—not to be confounded with G. H. Lewes—sought to show that there were in modern times no authenticated instances of persons reaching the age of one hundred years. Perhaps the first fatal blow to his theory was given by the well-known case of Professor Chevreul, the date of whose birth has been satisfactorily authenticated, and who has spent the greater part of his 102 years under the eye of the scientific world.

M. Emile Lavasseur has recently made a communication to the Academy of Sciences on the centenarians now living in France, taking his data from the census of 1886.

He admits that there are persons of the age of one hundred years, though their number is less than it is popularly believed. Old men, sometimes, out of vanity, represent themselves as more aged than they really are. Octogenarians who have been consulted as to the age of their senior relatives are led to represent them as older than is really the case, having always known them older than themselves. Thence spring illusions and exaggerations of the number of centenarians.

The head of the Statistical Department of Bavaria was the first to check over the declarations of alleged centenarians by occasion of the census of 1871. There were said to be 37, but on examining the dates of birth there was found only one person, a woman, who had lived for more than a century.

About the same time a similar inquiry was made in Canada, a country which had enjoyed for some time the reputation of longevity. Mention was made of 421 persons said to have died at the age of 100 or upwards, but on close scrutiny only nine persons, five men and four women, were found who had demonstrably lived for more than a century.

In France the first reports sent in, judging from the census returns of 1886, gave the number of centenarians as 184. On the first scrutiny it was found that 101 persons had been wrongly inserted in this category. Of the 83 persons still pronounced to be centenarians, 67 had no more definite evidence than the assertions of their neighbours. Authentic documents, such as certificates of baptism, were found only in 16 cases. Among these is a man (Joseph Ribas) born at San Esteran de Litera, in Spain, and baptised August 20th, 1770, and who consequently was in 1886, 116$\frac{3}{4}$ years. He lives, or at least he was still living, at Tarbes. He was married at the age of fifty, had seven children, and became a widower at 100. If this man has not appropriated the baptismal certificate of an elder brother—which is improbable, since there exist in France documents dating back to a time when he could have no interest in exaggerating his age—he is an authentic instance of an unusually advanced age. The rest, 82 in number, were from 100 to 105 years; a widow was said to be 112 years old, but her age seemed very doubtful.

Women formed the majority (52, women, 37 men). There were naturally few married couples, six celebates of the male sex, and sixteen of the female, twenty-three widowers, and forty-one widows. One of them, aged 103, Madame Rostkowski, born Mazurkiewicz, daughter of a chamberlain of Stanislas II. and sister of a general of engineers, went through the Polish wars as assistant surgeon-major along with her husband, who was captain adjutant-major; she had gone through twelve campaigns, and had been twice wounded. She still lives, on a pension of sixty francs per month allowed her by the French Government. The majority of the centenarians are in a state of indigence. Seven only are in easy circumstances, twenty-two in actual poverty, and the remainder in a very humble position.

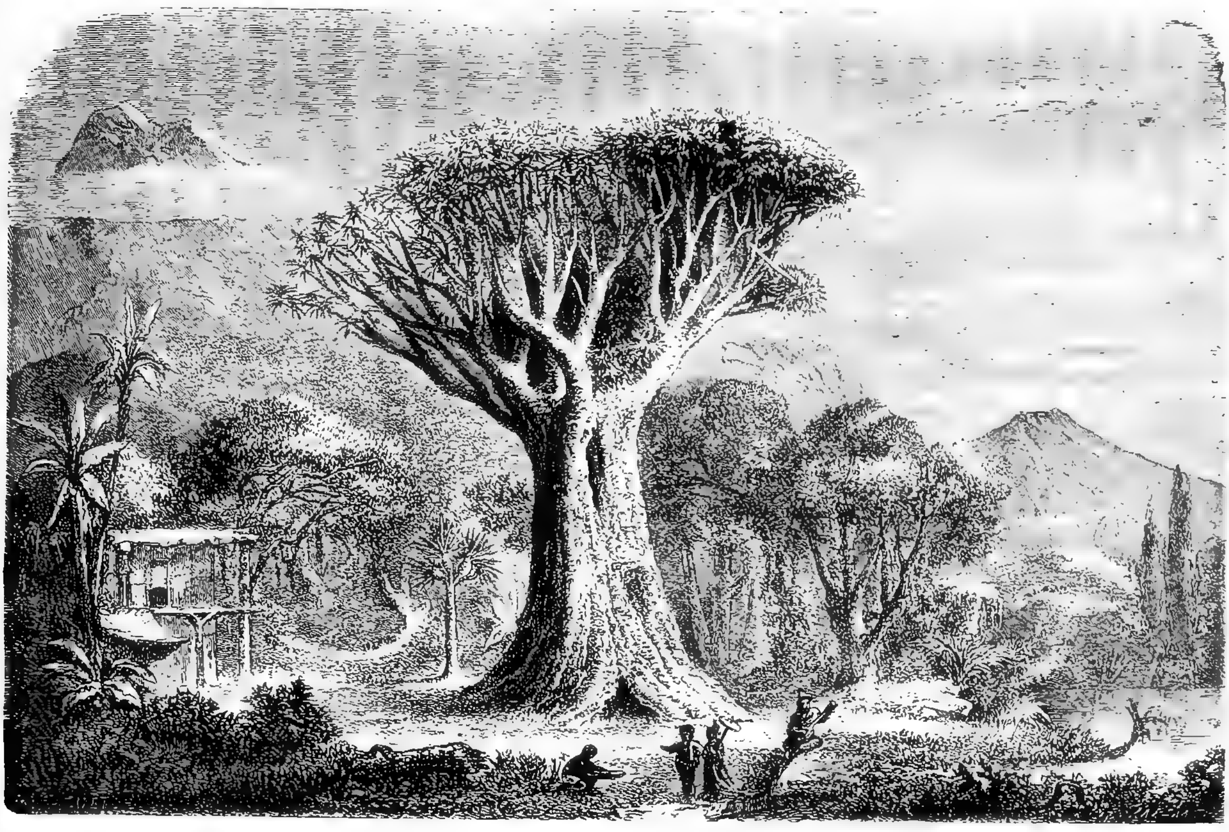
There is no reason to believe that the number of centenarians in France is either increasing or decreasing, and there is no evidence that in past centuries persons reached a higher age than they do at present. For about twenty years the registers of deaths give a yearly average of 73 centenarians, a number probably exaggerated like that in the census returns.

According to these returns more centenarians exist in the south-western departments than in the rest of France. This is confirmed by the registration of deaths, since one-fourth of the centenarians dead from 1866 to 1885 belong to six departments in the south-west. According to a table drawn up by M. Turquan, the basin of the Garonne, from the Pyrennees to the Puy de Dome, contains as many centenarians as all the rest of France. If we, to allow for possible exaggerations, reduce the number of centenarians dying yearly to 50, we find that the chances of a person in the nineteenth century reaching the age of 100 are 1 in 18,800.

Natural History.

THE DRAGON TREE.

THE dragon-tree (*Dracæna draco*) is the chief type of the *Dracænæ*, a genus of endogenous evergreen trees belonging to the natural order of the *Liliaceæ*, and distinguished for the most part by their handsome palm-like appearance. This genus once contained at least thirty-six species, but, it was remodelled and very considerably reduced by Dr. Planchon, who practically only included the dragon-tree species in his new classification. The chief characteristics of the dracænæ are their tree-like stems, either simple or divided at the top, and the crowded heads of long lanceolate leaves, of a powdery olive green, which terminate the branches. The leaves encircle the branches, and as they fall off mark the stem with circular ring-like scars, similar to those described in the article on "Buds" on p. 34 of this volume. The flowers form a terminal panicle, and are individually small and greenish white in colour. In our ordinary greenhouses these plants are most frequently unbranched, being only in the so-called "first age," which lasts, even in their native country, from twenty-five to thirty years. The "second age" is the period of maturity and reproduction, and is of indefinite extent, as is also the "third age," or period of gradual decay. During the second age the original leaf scars disappear to a certain extent, and the thickness of the trunk is increased by the formation of branches, and consequent constant deposit of new matter, while during the third, glandular excrescences and, occasionally, aerial roots are formed. The dragon-tree proper never branches until of very great age, and Humboldt asserts that, both in its size and immense longevity, it closely rivals the baobab in its claim to distinction as the "oldest inhabitant" of our planet. He inclined to the opinion that the patriarchal specimen which he saw in 1799 in the gardens of the Marquessa de Sauzal, in Orotava, Teneriffe, must have been, at the very least, of greater antiquity than even the Pyramids themselves. By comparison of his measurements of this mighty tree with those taken by the French adventurer, Béthencourt, in 1402, he found that the tree had undergone but very slight change during almost four centuries, its slow growth and enormous size thus furnishing an incontestable proof of its marvellous age. The tree in question was first described by the above-mentioned Béthencourt in 1402, who assigned to it the same dimensions as, in later years, Humboldt, Sir G. Stanton, Ledrw, etc., did, viz., a height of from 70 to 75 feet, a circumference, near the base, of 40 or 50 feet, and a diameter of 16 feet at the base, 12 feet at a height of 10 feet from the ground. The trunk tapered but slightly, but rose like a huge rough pillar, comparatively short in proportion to its thickness, dividing at the top into a close cluster of thick branches, terminated by tufts of long, sword-shaped leaves, very tough and leathery, and with a powdery bloom like that seen upon cabbage leaves. The trunk was hollow, and a staircase had been ingeniously constructed inside, reaching up to the roof, if one may so



DRAGON TREE AT OROTAVA.

describe it, formed by the commencement of the branches. A little rustic door guarded the entrance to this strange retreat, which was used by the Spaniards of the island as a chapel for the celebration of holy mass as far back as 1493. Although of such wonderful antiquity, this tree flowered annually, covering its entire crown with a perfect mantle of white blossom, which presented a striking and most poetic contrast to the gnarled and weather-beaten trunk beneath. In 1819 a storm carried away about a third of its branches, but did not seem to affect the main structure very seriously. Unhappily, however, this magnificent specimen of arboreal growth, this living silent record of long-past centuries, was (according to a statement by a recent writer) utterly destroyed by a terrific hurricane in the year 1867. The largest specimen now extant is, we believe, the one outside the gates of the cemetery in the steep little village of Icco del Alto in Teneriffe. As a writer in the *Journal of Forestry* remarks, "The dragon tree has a grim, weird, antediluvian appearance about it, suggestive of the idea that it is a survival of ages past, and that it may have witnessed the struggles for existence whose records are written in the strata of the earth. It was an object of Druidical veneration for centuries before Christianity appeared on the earth, and the hollow trunks of some of the trees were used by early Christians as a place of worship." Tradition asserts that it was deeply revered by the Guanchos, the ancient inhabitants of Canary Isles, who apparently made use of the resin which they obtained from it in the embalming of their dead, since this resin has been found in their ancient sepulchral caves. Humboldt induces this fact as a proof that the Guanchos were not so completely isolated from the natives of Africa and Asia as was commonly supposed, since these trees originally came from India, a question, however, which we have no space to discuss here. Wherever may have been its original home, India or elsewhere, the dragon tree has been cultivated since the most distant ages in the Canary Islands, Madeira, and Porto Santo, and is now never met with farther east than the Isle of Socotra.

The *Dracæna draco* is supposed to have derived its popular name from a red resinous exudation from its leaves and from cracks in its trunk, known in commerce as "dragon's blood," which once formed a considerable export from the Canaries, and which has even yet scarcely fallen into complete disuse. It was formerly used in medicine as an astringent in dysentery, hæmorrhage, etc., but is now scarcely recognised by modern druggists, who use instead the resin of *Pterocarpus draco*, a large South American tree, although that also is now almost out of date, having been superseded by the more modern discoveries and inventions which flood the market in medicine as well as in aught else. The true dragon's blood, or gum dragon, of the present day is mostly obtained from the fleshy fruits of an East Indian palm, the *Calamus draco*, a native of India, Sumatra, the Moluccas, Malay Islands, etc. It is an opaque, reddish-brown resin, brittle and smooth, with a shining shell-like fracture. When burned its odour somewhat resembles that of benzoin; it is almost insoluble in water, but is soluble in alcohol, and the solution thus obtained is used as a permanent stain for marble, leather, wood, etc., and for colouring various tinctures, dentifrices, etc. It is also soluble in oil and turpentine, and in this form is used as a colouring ingredient in clear spirit and turpentine varnishes; and it is used in the preparation of gold lacquer. Another variety of this gum dragon is said to be yielded by the red sandal wood tree (*Pterocarpus santalinus*) of the East Indies, and a somewhat similar substance by the *Dalbergia monetaria*, a tree of the same order indigenous in Guiana. An astringent resin is obtained from the *Eucalyptus resinifera* of New Holland, which is known there by the same name of dragon's blood, and in Mexico another resin of the same kind, obtained from the *Croton draco* (of the order *Euphorbiaceæ*) is still extensively used in medicine.

A New Silk-worm.—Among the silk-producing insects of India *Cricula trifenestrata* should not be overlooked. It is noticed by Mr. Wardle as being very common in Assam, where it is known as the Haumpottonee. It feeds on the "soon" tree, forming an open net-like cocoon of a beautiful yellow colour and of a rich lustre. The silk is spun in the same manner as that of the "eria" cocoon (*Attacus ricini*). It is also met with in Moulmein, where the caterpillars are said to feed upon the cashew-nut tree (*Anacardium Orientale*). This silk-worm is very productive, there being two generations in each year. According to Dr. O. Witt, of Berlin, it yields an excellent fibre, and is likely to prove of importance in the silk trade.

An Advocate of Parasitic Vermin.—According to the *Medical Press*, a Mr. James Grahame actually said in an address to the students at the Glasgow Hospital for Skin Diseases that "the parasites which irritate the cuticle were sent by a beneficent Providence to promote that necessary surface excitement required by the skin, and were not altogether without a beneficial influence on the health of the community!"

Stature of the Extinct Irish Elk, *Cervus megaceros*.—According to a writer in the *Field* the two largest skeletons of this species known (in the Science and Art Museum, Dublin) are respectively 6½ feet and 6¼ feet at the shoulders, the spread of the antlers being 9 feet 2 inches and 11 feet 7 inches. Sir J. Ball states that this species occurred not only in the British Islands, but extended to the eastwards as far as the Altai. Ireland was probably its most recent locality.

A Strange Migration.—The Red Admiral butterfly, which is generally said to be much scarcer in the South of England and in the Midlands than was formerly the case, is becoming very abundant in the North of Scotland.

Hysteria in a Dog?—Mr. T. Byron Place mentions, in the *Field*, that a greyhound bitch suffered for about a month from what seemed to be paralysis. She was unable to move her head, and the whole body was rigid. Whilst on the lawn one day a rabbit started; she immediately followed in pursuit, jumped down the sunk fence, and fell head over heels. She got up perfectly well. This seems to be an instance of the class of recoveries known as "faith cure," "scare cure," or "excitement cure," according to the kind of emotion called into play.

Tracheæ of Hexapods and of Spiders.—J. S. K. (*American Naturalist*) considers the tracheæ of these two divisions of the arthropods not homologous; since in the one they are clearly modified appendages, whilst in the other they occur on segments where well-marked appendages exist.

OUR KNOWLEDGE OF THE BACTERIA.

WE have repeatedly had occasion to refer to the part played by certain of these minute beings in transmitting diseases as well as in originating and keeping up important changes both in living and lifeless matter. It now strikes us that a more systematic description of these beings—avoiding, of course, technical specialities—may be interesting to not a few of our readers. For this purpose we shall avail ourselves, to a considerable extent, of a summary of "bacteriology," contributed to our contemporary, *Humboldt*, by Dr. Carl Günther, of Berlin.

The bacteria are the smallest living beings of which we have any knowledge. They are very widely distributed in nature—a privilege which they owe to the tenacity of their life, the simplicity of their vital conditions, and, above all, to their extremely rapid multiplication. If we wish to make their acquaintance we need merely pour a little water upon some animal or vegetable substance—such as a bit of meat, a little hay, a few peas, grains of rice, a crust of bread—and let the whole stand over-night in a warm place. The water will be found to have become turbid, and, if we examine a drop under the microscope with a sufficiently high power, we shall see a crowd of minute colourless beings of very simple forms. Some of them have the shape of rods, varying greatly both in length and thickness. In length they do not exceed a few thousandth parts of a millimetre (a millimetre, it will be remembered, is 39 hundredths of an inch), whilst their breadth is measured only in the ten thousandth parts of a millimetre.

Besides the rods we find tiny globules, differing in size, and, like the rods, sometimes occurring detached, and sometimes in clusters or united in chains. All these beings, which are at once distinguished by their minuteness from the yeast cells and moulds (which are much bulkier), are called *bacteria*. The little rods are known as *bacilli*, and the globules as *micrococci*. A third form of bacteria, also to be found in infusions, though less plentifully, appear as minute forms, either spirally curved like a cork-screw, or as thin, short, curved rods, and are known as *spirillæ* and *comma-bacilli*.

If we examine such a mixture of bacteria in a recent infusion we see the individual specimens in constant motion. The bacilli and micrococci dance up and down, to and fro, but without any great change of place. This is merely the case of molecular movement, called pedesis, or Brown's movement from its discoverer, and which is always observed in minute solid bodies suspended in liquids. But in addition to this molecular movement, which is common also to lifeless matter, many bacteria are capable of independent motion. This is most distinct in the spirillæ. They screw through the liquid with the speed of an arrow, and then occasionally remain for a time quiescent. Among the bacilli only certain kinds are capable of independent motion, the remainder being, like the micrococci, stationary. The independent movements of the creatures where they exist seem to be executed by means of *flagella*—threads like a whip-lash attached to the extremities of each.

Their reproduction is effected ordinarily by fission. A single individual grows in length, becomes divided transversely in the middle, and is thus resolved into two individuals, each of which is again subdivided in a similar manner. The parts, or the offspring, if we may so call them, may either entirely part company or they remain connected together, forming ultimately chains or links by continued fission. We then call them *streptococci*, or chain-cocci. The bacilli form, in a similar manner, threads. Sometimes bacteria, after fission, remain together in heaps or clusters, apparently adhering together by means of a cement. These clusters are known as *zooglœa*. In some species of micrococci the fission takes place not in one, but in two or three directions. Thus we have groups of four cocci, forming a square, or bale-shaped heaps each of eight cocci, or *sarcinæ*. Among bacilli we sometimes observe under unfavourable circumstances, such as the exhaustion of the nutrient fluid, the appearance of small, shining corpuscules, which are formed within the body of the bacillus. These corpuscules, which are known as *spores* from their analogy to the spores of fungi and algæ, play a similar part to the latter. They are discharged from the maternal body in a shower, and are capable of remaining dormant, if needful, until suitable nourishment is to be found.

Dr. Dallinger, however, in his most recent researches has established that the bacilli do not continue to reproduce themselves by fission, however favourable the surrounding conditions. After a number of successive fissions they seem to become exhausted, and form and discharge a crowd of spores as just described. The enveloping membrane, which is all that remains of the primary bacillus, sinks to the bottom of the liquid, apparently dead.

The spores, set free, if they meet with suitable nutriment, grow up to bacilli, and increase by fission as before.

(To be continued.)

POISONS IN THE WORKSHOP.

(Continued from page 77.)

SINGULARLY enough, the compounds of the metal chromium are often overlooked by writers on poisons. Some of these substances are not less to be dreaded than arsenic, whilst they are used on a very large scale in the arts. The most common form in which chromium occurs in trade is as chromic acid and its compounds with potash and soda. The bichromate of potash forms splendid orange-red crystals, which dissolve readily in water and possess an intensely disagreeable taste. On this account, as well as from its vivid colour, it is little likely to figure as an agent either in malicious or accidental poisoning. The first danger connected with this substance is in its manufacture. We need not here describe the process, but the men employed are liable to suffer from perforation of the cartilage which divides the two nostrils, so that the cavity of the nose becomes single. We do not, however, know that the mischief ever spreads farther, so as, *e.g.*, to attack the palate.

The use of this bichromate of potash in dyeing has its perils. It is consumed to a vast extent in dyeing black upon wool and woollen cloths, which are boiled along with logwood and a certain quantity of bichromate. Of course, the hands of the workmen often get splashed with the liquor, especially when the goods are drawn out of the dye-pans and spread out. Upon some men the solution takes no effect. Others find their fingers becoming swollen and inflamed, and if such continue at this kind of work ulceration sets in, and the fingers or the whole hand might be lost. In all the large dye-works, however, where alone such cases are likely to occur, susceptible men are removed at once to some other department of the works. Thus serious injury from this cause is of exceedingly rare occurrence.

Bichromate of potash is also used along with sugar of lead in dyeing different shades of yellow upon cotton yarns. The liquid used is cold, and the men in consequence touch the material freely with their hands. Either from this cause or from the alkaline nature of the liquid, the hands are more affected than in dyeing chrome blacks upon wool, and cases of impunity are much more rare.

We must, however, remember that certain compounds of chromium, such as the green sesquioxide, are absolutely harmless to prepare and to use. The reason of this is that they are absolutely insoluble, and cannot be volatilized. This is a fortunate circumstance, since the chrome greens (Guïgnet's green) can be used with safety instead of the arsenical greens in the manufacture of wall-papers.

This naturally brings us to arsenic, generally regarded as the most formidable of the mineral poisons. The fact that it is colourless and tasteless, and therefore may find its way unsuspected into articles of food and drink, ought to lead to the abolition of its use wherever there is no absolute necessity. Thus we can see no justification for the employment of arsenical preparations in the manufacture of paper-hangings. Still worse is the case when tarlatans are got up with green arsenical colours, Paris green, Scheele's green, etc., mixed up with starch and not firmly fixed upon the fibre. The air of a ball-room where such tarlatans are worn must contain a certain proportion of arsenical dust.

Now it will be generally admitted that if the wearers of such arsenical tissues and the inmates of rooms hung with arsenical papers are in danger of being attacked, the workmen employed in making such colours or in applying them to the paper and the cloth will scarcely escape with impunity. Now is this, in fact, the case? According to Dr. Jabez Hogg, who has made a special study of the action of arsenical pigments, "workmen while engaged in stripping off old wall-papers from rooms preparatory to re-papering are frequently obliged to leave their work from attacks of diarrhœa and other stomach derangements."

But what must we say of the manufacture, and consequent use, of arsenical pigments where the poison plays no demonstrable part at all in the production of the colour desired? Yet reds, blues, greys, and browns have, on analysis, been found to contain arsenic. Whether this arises from some unscientific method of manufacture or from the careless use of impure materials it is not our place to pronounce.

Arsenic was in former days very generally found in aniline colours. The reason was that magenta was at that time chiefly manufactured by the arsenical process (Medlock's patent), and as a variety of other colours were obtained from its transformations, the aniline colours came to be regarded as, generally speaking, poisonous. To a very great extent this process is now abandoned, and where it is still used the product is purified with such care that arsenic is not to be expected in the aniline dyes sold by the more eminent makers.

Arsenic is used to a considerable extent by calico-printers in the so-called "dung-substitutes." In those styles where a piece of calico is dyed after it has been printed with various mordants it has to undergo a cleansing process, called in France *dégommage*, and in England dunging, because it was performed with the dung of cows suspended in water. To supersede this unpleasant substance, certain preparations were devised, under the name of dung-substitutes, and were composed chiefly of arseniates of soda. Probably none of this arsenic would remain on the tissue to the injury of the future wearer; but the spent liquors and the rinsing waters would convey a certain quantity of arsenic down into the sewers and the rivers, and if not precipitated in an insoluble form would be exceedingly apt to turn up where it was by no means wanted. We forgot to mention that the waste waters from chrome-black and chrome-yellow dyeing also find their way into the streams.

A great channel for the promiscuous distribution of arsenic is the manufacture of sulphuric acid, which is to the chemist what iron is to the engineer—in use always and everywhere. Now, by far the largest quantity of the sulphuric acid of commerce is obtained from iron-pyrites (sulphuret of iron), a mineral which most unfortunately is rarely, very rarely, absolutely free from arsenic. Hence the poison finds unsuspected access into a vast variety of products. A cheap and practicable method of producing sulphuric acid free from arsenic is one of the prizes for which chemists are earnestly striving.

(To be concluded.)

WORK FOR NATURALISTS' CLUBS.

III.—The Structure of a Feather.

It is not easy to find a better subject for an evening's demonstration than a feather. The following materials should be collected:—a few quills, some body-feathers of a fowl, pheasant, or partridge, a peacock's plume, and a fresh pigeon or other bird, unplucked of course. If a lantern can be had, it will be useful to put up between glass plates a piece of the peacock's feather, a double-shafted body-feather of one of the gallinaceous birds named above, an emeu's feather, and also some photographic copies of good drawings. Plate 1 of Nitzsch's Pterylography (Ray Society) is recommended, but various illustrated text-books may be drawn upon for figures of the simpler points. An effective model of the shaft, barbs, and barbules may be made of pieces of card cut to the proper shape, and fitted by means of saw-cuts into wooden bars.

Observe first the primary divisions of a feather, viz., the quill, shaft, and vane. The shaft is occupied by a dense pith; the quill is empty, except for some light and dried-up capsules, which form a chain within it, and which represent the shrivelled remains of the formative follicle. At the bottom of the vane, and on the inside of the feather, will be seen a scar, the umbilicus. Down to this point the originally cylindrical feather has split along one side; below, the tube remains complete. Show by means of a paper model that if a closed cylinder be split open in its upper half, while it remains entire below, a passage into the inside of the tube must exist where the closed and open parts meet. In immature feathers the apex of the formative papilla can often be seen to project from the umbilicus (see figure).

The structure of the barbs which compose the vane may next be considered. Each is a knife-blade, having its thick edge turned outwards, *i.e.*, away from the body of the bird. The barb carries a double row of barbules, which must be shown under the microscope. It will facilitate the demonstration if a piece of the vane of a quill is soaked, first in alcohol, and afterwards in glycerine. Cut out a small bit of the vane so prepared, and tease it with needles as required. Notice the different forms of the two sets of barbules which project from every barb. One set bears hooks, the other is simple or merely notched. The component parts of the vane will be more readily understood if a bit of peacock's plume, with disconnected barbs, is first thrown upon the screen. The barbs and barbules will be clearly seen. After this, it is easy to explain that in the close vane of a quill the barbs lie parallel, each giving off at an open angle close-set barbules. Every barbule crosses a number of others belonging to the next barb, and at every such crossing the uppermost barbule developes a hook, which grasps the barbule beneath. Where the hooks are absent, as in the tail-coverts of the peacock, the feather, though it may serve for covering and ornament, is useless for flight.

Double-shafted feathers may then be described. The accessory shaft (or after-shaft) has the same structure as the principal one, and may be, as in the emeu, of equal length. The primitive cylinder has been split along two opposite lines, instead of one, to furnish the double shaft and vane. The after-shaft is always turned towards the body of the bird. Where the feathers serve only for protection and warmth, as in large flightless birds, it is easy to see the advantage of the double shaft. Twice as many feathers can be crowded into the same surface of skin. But this arrangement becomes impossible when the feathers are directly concerned in flight. They must then admit of being rapidly spread, and also of being neatly folded together when the wing is closed. Accordingly, the quills of the wing and tail in a flying bird never show a vestige of after-shaft.

The pigeon may be used to point out the different kinds of feathers, such as quills, body-feathers, down-feathers, and filoplumes. These last are readily found by plucking part of the breast; they are very long and thin, nearly devoid of vane, and without pith in the shaft. Herons and some other birds have "powder-down patches," consisting of peculiar feathers, which crumble to pieces as fast as they are formed.

The colours of feathers deserve some notice. Pigments, similar to the pigments of hair, can be extracted by a rather troublesome process; the range of colours is not very great, most of the effects being obtained by shades of brown and yellow. Other colours, however, occur, and some of them are very curious. The sealing-wax tips of the Bohemian wax-wing are well known. Still more singular is the Turacin found in the crimson quills of the Touracos, or plantain-eaters. This pigment is soluble in water, and washes off in heavy rain. Many of the iridescent colours found in birds' plumage are not due to pigments at all, but to light reflected from thin films. They are due, in fact, to the same cause as Newton's rings, the iridescence of mother of-pearls, or the colours of the soap-bubble.

Moulting is an interesting subject, which will bring out the knowledge of observant naturalists. Professor Newton's remarks in the article "Birds" (*Enc. Brit.* vol. iii.) will serve as a basis for some preliminary explanations.

The development of the feather must on no account be left out. It is essentially a horny scale, formed out of the epidermis, like the scales of reptiles, but differs from these in being tubular below, and much divided above, whereas the reptilian scale forms a broad plate of simple form. A conical papilla of the dermis, or vascular layer of the integument, supplies the growing feather. The papilla is invested by a double layer of epidermis, pushed inwards from the outside of the body. Its surface is marked by a branched system of sunk lines, which correspond to the shaft, barbs and barbules respectively, and into this mould the nearly fluid cells of the epidermis are forced. The feather is, in short, a horny cast of the surface of the papilla. At first the vane surrounds the conical tip of the cylindrical papilla completely, but it is extremely thin along a line opposite to the shaft, and here it readily separates, opening out into a flattish sheet as it becomes free from the skin. The outermost epidermic layer forms the sheath, which at first adheres strongly to the quill, but is free from the vane. When a feather first pushes through the skin, it is almost entirely hidden within the sheath, from the summit of which a pencil-like bunch of barbs projects. Afterwards the sheath crumbles entirely away. The apex of the feather forms first, and may be quite complete while the base is still pulpy, or altogether undistinguishable. Since the same part of the papilla cannot be used a second time as a mould for the deposit of feather-substance, fresh growth takes place at its base, and the apex of the papilla is gradually pushed upwards. In an immature feather, the tapering and shrivelled tip of the papilla may often be seen projecting from the umbilicus (see figure). After its living substance has been absorbed, the papilla is seen to consist of a chain of inverted conical capsules, joined by a central filament. These cones may always be found within the quill. After the vane has been formed, the surface of the papilla becomes smooth, the horny matter moulded upon it takes the shape of a simple tubular quill, and the feather is complete.

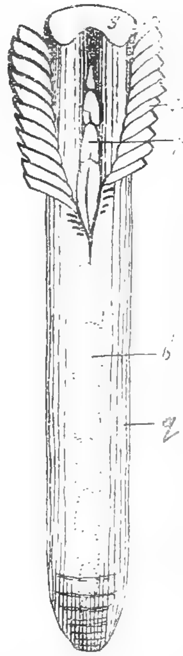


Diagram of a Feather. *s*, shaft, cut short; *b*, bases of barbs; *p*, dried-up papilla, projecting from the umbilicus; *p'*, ditto within the quill; *q*, quill.

THE PURIFICATION OF SEWAGE.—MM. P. Chaotaing and E. Barillot, in a communication to the Academy of Sciences, state that irrigation, a system possessing numerous partisans, is applicable where vast surfaces are available, where the soil is suitable, and where the water to be purified is not heavily loaded with putrescible matters. The chemical procedures, though much decried some time back, deserve the greatest attention in consequence of the improvements already effected, and of those still possible. From the results which the authors quote, it seems distinctly established that the purification of sewage by chemical methods is really efficacious; that it can be applied without interruption and without nuisance, and that the nitrogen and phosphoric acid thus obtained are easily available in agriculture.

Reviews.

Pallas's Sand Grouse (*Syrrhaptes paradoxus*) *; its History, Habits, Food, and Migrations; with Hints as to its Utility and a Plea for its Preservation.* By W. B. Tegetmeier, F.Z.S. London : Cox.

It is rare indeed that any ornithological fact occasions so much general sensation and gives a plea for so much ink-shed as the recent advent of the Asiatic sand grouse. The majority of the British public unfortunately look on birds as mere animated targets created for the edification of the shot-gunner. So long as this feeling prevails the extirpation of any species, aboriginal or immigrating, is averted merely by its rapidity of multiplication or by its being inconspicuous.

Now Pallas's sand grouse, as a novelty, at once attracts attention, and fares accordingly. It visited this country once before, a quarter of a century ago, and was duly extirpated. This year they have reappeared in larger numbers, and earnest efforts, at any rate, are being made for their protection. To such protection it has a fair claim. It is not merely harmless, but positively useful, since its food consists chiefly of the seeds of notorious and troublesome weeds, such as docks, knot-grass, chickweed, and the like. We are sorry, however, to learn that its flesh is edible.

Ornithologically speaking, this bird is the type of a new genus, *Syrrhaptes.* It is distinguished from its nearest allies, the sand grouse of Southern Europe, Northern Africa, and South-western Asia (*Pterocles*) by the peculiar structure of its feet. It has no hinder toe, and the three short, blunt, anterior toes are connected together by a "leathery pad," covered closely with small round wart-like prominences. The legs are short, and on the ground it has a waddling gait, almost like that of a parrot when travelling on a level surface.

The genus approaches most nearly to the pigeons, the grouse, and the plovers, but it is severed from all of them by well-marked characters. It differs from the pigeons by laying three eggs instead of two, and by the fact that the young can pick up seeds as soon as hatched. The want of the hind toe clearly sunders them from the pigeons, the fowls, and the true grouse. Their flight is more rapid and sustained than the grouse, though unlike the pigeons, they do not glide on outspread wings. The bird is not polygamous, and both parents take a share in incubation. The eggs are of a buff colour, with dark-brown spots. The keel of the breast-bone, and of course the pectoral muscles, are very largely developed. Here, as in some [illegible]r species, the greater pectoral, which pulls the wing downwards, is dark, whilst the smaller pectoral is white. Mr. Tegetmeier remarks that this difference between the two pectoral muscles in their colour and texture presents an unsolved problem. In the majority of birds, however, swift in flight no such distinction is found.

The general colour of the plumage of this bird is sandy, barred with brown and black, the sides of the neck and throat orange. On the breast is a narrow band of black-edged feathers, and on the flanks and across the abdomen is a broader and darker band. The back, scapulars, and upper tail coverts are barred with black and dark brown. The wing is remarkably pointed, and the primaries are of a delicate lavender with dark tips. The tail consists of sixteen feathers; the central pair are prolonged at the tip into pointed filaments, extending in the male three inches beyond the others. The female has not the orange at the sides of the neck; the chest-band is indistinct, and the middle tail feathers are less prolonged. The weight of the birds is from $10\frac{1}{2}$ to 11 ozs. The length of the male, from the beak to the point of the tail, is 15 inches; the female is rather smaller.

A difficulty in the preservation of these birds will arise from the circumstance that they deposit their eggs on the sand without any attempt at concealment.

Electricity versus Gas. By John Stent. London : Swan Sonnenschein and Co.

The pioneers of electricity have much to fight against, and those into whose hands this brochure may fall will assuredly cry "Save us from our friends." There is already too much wilful misleading by company promoters and vendors of primary batteries; but here we have an author who candidly informs us that "he is no expert in electrical science." Then *que diable allait il faire dans cette galere?* He appears to make this statement, rather to excuse the absence of technical terms and phrases, than to apologise for his presumption in penning even 79 pages on a subject upon which he has neither right nor title to scribble. He pleads that "he is only one of many who find it necessary to understand enough of what is going on around them, not to be, and to feel, and appear stupid in the presence of discussions in the press, and in conversations that are of common occurrence." With his feelings we have little to do, but we differ most distinctly with the writer as to the amount of knowledge which will save him from being and appearing, not only stupid, but lamentably rash, in venturing to put forth such a work, even at the price of sixpence, without either making a decent acquaintance with the subject itself, or with some one who would revise his proofs, and rewrite a page here and there.

It is interesting to learn that the filament of a glow lamp "is inserted before the globe is exhausted of air." The interest comes in in trying to guess how else it could be done. We are informed that "M. Faure sent a box charged with electric energy from Paris to Sir Henry Thompson in London." We are not in a position to deny that M. Faure was so obliging, and doubtless Sir Henry was gratified, but *the* box which created such a stir in May, 1881, was sent to Sir William Thomson. The extraordinary theory is put forth that the sun would give no light "were it not that the atmosphere is pervaded by countless material particles, which become white hot, and so give us light." The author is not speaking as might be supposed of the sun's atmosphere, for he continues, "If the air were completely purified from all these material particles, the sun might go on shining brightly, but he would give us neither light nor heat. Alpine climbers and balloonists prove the truth of this by finding both temperature and light diminishing as they rise towards the sun, whilst every snow-capped mountain in Switzerland and India and elsewhere corroborates the statement." This wild assertion, "proved and corroborated" though it be, is furnished with the following foot-note: "Phosphorescence hardly comes in under the generic word light." What is probably meant is that in the absence of any atmosphere the sun would blaze as a brilliant ball in a black heaven, but the light and heat would be greater, as every alpine climber can well appreciate.

We are informed that arc lights produce graphite "which is nearly equal in weight to the carbons used and will make a sensible return to the companies producing the light." As a matter of fact, there is a little tip of graphite about the size of half a pea, at the end of the negative carbon of which an inch or so is left, and is worth about as much as the stump of a cigar.

We are not aware if Mr. Stent has studied any other branch of science. His ideas of heat are of about the same standard as his light and electricity. "If the poker be left long in the fire, the extreme end will become hotter and hotter; but if a length of wire or a rod be attached to the rod in the fire, the heat will pass into it, and continue to travel along the wire to almost any distance so long as the one end is hot."

The last page tells us that electricity "is becoming visibly a real light. Its triumph not only over *darkness*, but over all other *forms of artificial light*, is so obvious that," etc. The italics are ours, but that darkness is a "form of artificial light" is a discovery which distinctly belongs to Mr. Stent.

The Architect's Register, being a publication devoted to Art, Architecture, Engineering, Building, and matters pertaining thereto, established to form the nucleus of a Register of Papers read before Architectural and kindred Societies throughout the United Kingdom. Issued Half-yearly. Vol. III. London: W. Pope.

This volume comprises papers on "Old House Work"; on the "Relations of Architect, Surveyor, and Builder"; "Optical Refinements in Architecture"; "Horace Walpole, his Life and Times"; "Notes on some Building Stones"; Theatres and Public Buildings and their Arrangements for Public Safety"; and "Theatre Construction." To the two last we must call particular attention. The former, by Mr. Walter Emden, M.S.A., gives a very elaborate survey of the entire question. From the statistics given it appears that during the past eleven years 2,056 persons have perished from fires in theatres, being a yearly average of 186·9. Out of 252 theatres only three remained for a century without being destroyed.

The author, not unjustly, denounces the present medley of laws for the prevention of accidents as occasioning much hardship to the proprietors without affording the necessary protection to the public. He urges the necessity of legislating for the whole kingdom, and not for London alone, and wishes to place all theatres, music halls, etc., throughout the entire realm in the hands of the Lord Chamberlain, together with funds for carrying out such supervision, on the satisfactory grounds that his office is the only one possessing the knowledge necessary for dealing with the question.

The author then passes to the construction of safe theatres. Very naturally he deals firstly with the means of cutting off the stage from the auditorium, and that with rapidity and completeness. For this purpose he recommends as the best material, asbestos cloth. Iron curtains, from their weight, require powerful and complicated machinery for raising and lowering, and may very conceivably happen to be out of order just when wanted. Here we may mention that Mr. Gordon Hoskins insists on the necessity of raising and lowering such curtains before every performance, and frequently testing them if the theatre be temporarily closed.

The next point discussed is the prevention of panics, and, of course, the supply of safe and easy exits. Here the author contends that there should be two exits from every part of the building, conspicuous, always available, and free from all obstruction, distinct from all connection with other parts of the house, and especially kept well apart from each other. He considers that extra exit stair-cases should lead directly into the street, not into courts or narrow passages leading under or between shops and warehouses.

He advocates the use, in addition to the gas or electricity employed for the general illumination of the house, of a set of lamps fed with vegetable oil to light up the exit doors, corridors, and stair-cases.

Mr. Emden is scarcely fair to the electric light. He says:—"Unlike gas, electricity gives no warning, there is no smell." But in the majority of fires due to gas there is also no smell, because there is no escape. The mischief is due to the decorations, scenery, etc., being by prolonged exposure to the heat of the gas-flames not merely dried to tinder, but rendered in some cases probably spontaneously combustible. At all events, the whole is in such a state that if brought into the most momentary contact with a spark or a flame—which a current of air may occasion—the material is ignited.

The case as between electricity and gas seems to us to lie thus: with electricity there is absolutely no danger if the installation be thoroughly good. But with gas no perfection in the system of piping and no absence of escapes can afford any protection.

Mr. Emden then discusses the use of certain solutions applied to the wood-work, canvas, etc., for rendering them uninflammable. His views here are very judicious. He admits that such a soaking does for a time give protection against the spread of fire, but he raises the unsolved question: for how long? It has, indeed, not been experimentally decided in how far light wood-work, textile materials, etc., soaked in tungstate of ammonia would retain their non-inflammability after a year's exposure to the temperature of 140° F., as is the case with the decorations of theatres where gas is the illuminating agent. He concludes, therefore, that such fire-proofing agents may be useful auxiliaries, but that to depend upon them solely would be "rank madness." In concluding this notice of a very useful memoir we cannot help taking exception to the following passage:—"The stage is still, to a large extent, ignored by the State and by science. Science has, of late years, turned industrial. She makes railroads, steam-engines, factories, and mills; she tins meat and condenses milk; but she has not troubled herself about the stage, and is only now waking to its necessities." We have here the misuse of the term science against which Herschel, Humboldt, Whewell, Grove, Lewes and Crookes have all in turn protested, but, as we see, in vain. Science does not make, tin, or condense anything. She discovers facts, traces out their relations, and reduces them to laws. The utilisation of such facts and such laws she leaves to industrial art, over whose doings and omissions she has no control.

THE UNIVERSITY OF SALERNO.—Mr. G. Foy, F.R.C.S., in a retrospect of some famous Italian Universities, mentioned that the medical schools of Salerno were open to women. Constantia Calenda graduated there as M.D., Sentia Guerna lectured on medicine, Abella Mercurialis practised medicine and published medical works at Salerno. Trottula held a professorial chair in the University.

Abstracts of Papers, Lectures, etc.

ROYAL SOCIETY OF EDINBURGH.

At a special meeting held on the 9th ult., under the presidency of Professor Sir Douglas Maclaren, a paper was read by Dr. T. G. Nasmyth on the air in coal-mines considered especially in regard to its influence upon the health of the miners. Before entering on the results of his own observations he described the condition of ventilation in coal mines twenty years ago, which he showed was such as no miner would now be expected to work in; and said he had been told personally by miners of the air being often so bad that lamps would not continue to burn themselves, but had to be constantly trimmed by small boys, who were engaged for this purpose. Dr. Nasmyth, in his observations, had employed means, which he described, for ascertaining the conditions of temperature, and estimating the amount of organic matter, and for determining the quantity of carbonic acid gas and of micro-organisms present in the mines. He then referred to the means of ventilating coal mines at present in use, the arrangement of downcast and upcast shafts, and the distribution of air to the working faces by branches, instead of the old method of circulating it by a single main gallery, where if an obstruction occurred anywhere it affected the whole of the workings. He pointed out among other defects of the present system that the production of micro-organisms and carbonic acid in the stables rendered it desirable to have these near the upcast shaft. Giving the results of his observations, which in his paper were recorded in a tabulated form, he showed that the temperatures taken at a thousand yards from the downcast shaft differed but little, and that only in the direction of greater uniformity, from the temperature observed in the open air, while he found that the air was nearly always saturated. The tests for carbonic acid showed that a coal mine in this respect was in no worse condition than that of one-roomed houses and badly-ventilated schoolrooms and factories. With regard to the effect of the miner's occupation upon his health, Mr. Nasmyth gave statistics showing the improvement made in recent years in this important matter, and the comparative immunity at present of the miner from chest diseases. In the parish of Brith, the population of which is almost entirely composed of miners, the death rate from pulmonary consumption was upon the average 1·33 per thousand per annum—1·01 among men and 1·72 among women. It was shown from returns for twelve years that the mean age of death was 43·1 among miners.

Summing up, he argued that the state of the air in coal mines was wonderfully good, and, taking into consideration the nature of the products which go to vitiate the air in them, that it would not be easy to ensure its being as good if the work were carried above ground. His own experience was that phthisis was not common among miners, and he knew of no disease either peculiar to them or existing to excess among them. His belief was that the miner's occupation was surrounded by conditions as favourable as those of any other workmen.

At the meeting held on the 16th ult., the Rev. Dr. Flint in the chair, Dr. Traquair read an obituary notice of Mr. Robert Gray, one of the Vice-Presidents of the Society, who died in February, 1887. There was laid on the table a paper "On Some Relations between Magnetism and Twist in Iron and Nickel," by Professor Cargill G. Knott, of the Imperial University of Japan. Professor Crum Brown announced a communication by Mr. Alexander Johnstone on the action of carbonic acid on olivine. Two communications by Mr. George N. Stewart were also laid on the table—the one entitled "Is Talbot's Law True for very Rapidly Intermittent Light?" the other being on certain colour phenomena caused by intermittent stimulation with white light. Lord M'Laren laid on the table a paper on "The Solution of Homogeneous Equations between Variables." Mr. R. Kidston gave a summary of a communication on the fossil plants in the Ravenhead collection in the Liverpool Museum. The plants, he said, had been obtained some years ago by the Rev. H. H. Higgins during the cutting of the railway at St. Helens, near Liverpool, and presented by him to the Museum. Some of them showed a construction which made it difficult to fix their relation to existing species. Dr. H. R. Mill made a communication on the specific gravity of the water in the Firth of Forth and the Clyde sea area. He explained the mode in which the observations had been taken on board the yacht *Medusa* of the Scottish Marine Station, by means of one of the *Challenger* hydrometers. In all, 850 observations had been taken. After showing on a bathymetrical chart the depth of the water in various parts of the Clyde sea area, he explained the distribution of salinity in the region. The observations pointed to the conclusion that the salinity on the surface varied according to the rainfall, and most notably in the districts shut in by high mountains, such as Loch Fyne, Loch Long, and Loch Goil. In those districts where the hills were lower, as in Gairloch, the variations were less pronounced. The saltest surface water in the Clyde occurred, not in the neighbourhood of the sea, but in the Otter Spit in Loch Fyne. Off the Mull of Cantyre the water at the bottom was frequently found to be less saline than on the surface. This occurred in no other part of the system, and was apparently due to the strong tides. Some very salt water was found at the top of the Arran basin, but much depended on the weather in the locality. Mr. Buchan pointed out that the district of which Dr. Mill had spoken was the rainiest part of Scotland. Dr. J. MacDonald Brown read a paper, which he illustrated by the use of diagrams, on "Arrested Twin Development," making special reference to the case of an Indian boy at present being exhibited in this country. In the course of some remarks on concluding the session, the Chairman said it was extremely gratifying that the supply of appropriate papers had never been more abundant than during the session now closed. They had numbered in all 105, or 25 more than those of last session, and had been in every way worthy of the reputation of the Society. The Society had been promised a series of communications on the results of the investigation carried on in the physiological laboratory recently instituted in the Royal College of Physicians, which would be of great value. The membership during the year had increased by the number of 38. After some observations on the aims and objects of the Society, Dr. Flint concluded by referring in some detail to the losses it had entailed by the death of a number of its members, specially mentioning Colonel Balfour, Professor Dickson, Dr. Charles E. Wilson, Robert Chambers, Professor Wilson, and R. Mackie Smith.

SOCIETY OF ENGINEERS.

The members of this Society and their friends paid a visit to the new Precipitation Works at Barking Sewage Outfall, on July 24th, 1888. At the present time the whole of the sewage of the Metropolis north of the Thames is conveyed to Barking Creek by three culverts, each 9 feet high by 9 feet wide, and is, in the first instance, delivered into a covered reservoir divided into four compartments and altogether extending over an area of nine acres. The sewage is stored in this reservoir during eight hours of each tide and discharged into the river at high water at the top of the ebb. This reservoir is situate on the east side of the sewer and immediately adjacent to the river bank.

The new works consist of covered precipitation tanks adjacent to this reservoir on its north side, and occupying the ground between the Outfall Sewer and Barking Creek, an area of between ten and eleven acres. There will be thirteen of such tanks, each 31 feet 6 inches wide and averaging about 1,000 feet long. Communications will be made between the Outfall Sewer and each of these tanks, each fitted with two penstocks, so that communication may be opened or shut off at pleasure.

The sewage will be admitted into each of the tanks in succession, and after being allowed to remain quiescent for a sufficient time to admit of the deposit of the solids in the sewage, the precipitation of which will be expedited by the admixture of 3·7 grains of lime and 1 grain of proto-sulphate of iron per gallon, the effluent will be run off over a weir which will fall as the water in the tank lowers, so that the top film of the effluent only will be taken off, and the tank emptied gradually so as to prevent any disturbance of the solids by the operation.

The effluent after flowing over the weirs (of which there will be ten in each tank) will pass into culverts carried transversely under the tanks and extended, some into the compartments of the existing reservoir, and some into a chamber under the Outfall Sewer through which, at present, the sewage is discharged into the river from the existing reservoirs. When the level of the tide will admit, the effluent will be discharged through this chamber direct into the river, but when the water in the river is too high to admit of this the effluent will be conveyed by the other culverts into the several compartments of the present reservoir, and stored there until the level of the water in the river will admit of its discharge.

When each compartment is emptied of the effluent, the sludge, which will be in a semi-liquid state, will be discharged through culverts passing under the Outfall Sewers into a collecting culvert, from which it will be conveyed by pipes into a receiving well or sump, and pumped into a series of twelve tanks placed side by side and situated between the Outfall Sewer and the river. These tanks will each be 20 feet wide and 140 feet long, will cover an area of over an acre and a half, and, like the precipitation tanks, will be covered so as to prevent nuisance.

The sludge will be allowed to remain quiescent in them so as to allow of a further precipitation, and the effluent water will be discharged over weirs into a culvert which will convey it into a store under the tanks, from whence it will be lifted and discharged through pipes to the liming station, there to be mixed with lime which is used for precipitation.

The settled sludge remaining after this further precipitation will be discharged through culverts into a sludge store situate under the tanks, and will be lifted thence and conveyed by pipes along a jetty, and to a landing stage to be erected in the river, and there discharged into ships which will convey the sludge to sea. In the event of the ships being detained by stress of weather there is a further store for sludge at a lower level extending under the whole of the area occupied by the upper stores.

On the north side of these sludge settling tanks will be erected engine and boiler-houses and workshops in connection, to contain engines and machinery for lifting the sludge in the settling tanks, and the settled sludge into the ships, as well as for pumping the sludge effluent to the liming station.

The lime for assisting the precipitation of the solids of the sewage is introduced in the Outfall Sewers at a point about 700 yards and the proto-sulphate of iron about 530 yards above the precipitation channels.

The liming station will comprise a lime store, floors for slacking the lime, and six tanks for mixing the slacked lime with the effluent water from the sludge settling tanks or with sewage taken direct from the Outfall Sewers, an elevated lime-water tank or reservoir built above the lime store, and into which the lime-water will be lifted by pumps, for which machinery and the requisite engine and boiler-houses will be erected adjacent to the lime stores. From this elevated tank the lime-water will be conveyed to and injected into the sewage passing along the Outfall Sewers, through cast-iron injectors placed in the sewers.

There will be means of turning the lime-water into any one of the three lines of sewers and of regulating the supply by means of sluice-valves fitted to the pipes leading to the injectors. The injectors consist of cast-iron chambers 4 feet 6 inches in length, 6 inches wide and 6 feet in height, fitted with a number of nozzles, through which the lime-water will be injected and mixed with the volume of the sewage as it flows past.

The iron-water station comprises timber sheds for storing the proto-sulphate of iron, a mixing shed in which the iron will be crushed and mixed with water, an engine shed to contain engines and machinery for crushing the iron and mixing it with water, as well as for raising water for boilers and into mixing tanks. The iron-water will be conveyed by stoneware pipes, carried underground and along the top of the Outfall Sewer into a service tank, from which it will be carried by pipes into each of the three Outfall Sewers, and injected into the sewage through perforations in a pipe fixed vertically into each of the sewers. As with the lime-water, there will be appliances for regulating the supply of iron-water to each of the sewers, to meet the varying requirements of the discharge.

There will be a large settling pond, covering an area of $1\frac{1}{4}$ acre, situate near the river, divided into six compartments, each 60 feet by 60 feet, and about 7 feet deep, into which water will be received from the river and allowed to settle; the clear water being afterwards filtered and used for the supply of the several boilers, for slacking the lime, and for mixing with the proto-sulphate of iron.

The jetty, which will extend 576 feet into the river from the present river bank, will be 15 feet wide, and will be a timber structure supported upon piles. At the river end will be a timber landing stage 300 feet in length and 20 feet wide. The iron pipes for conveying the sludge to the ships will be carried under the platform, and will be furnished at the end with a delivery pipe, socketed to admit of a vertical movement, so as to discharge the sludge into the ship at varying levels of the tide. A tramway will be laid along the full length of the jetty connecting it with the whole of the works. The surplus earth from the excavations will be used in forming the banks for the tramways, and in raising the general level of the ground, which is now 6 or 7 feet below the level of Trinity high-water.

The quantity of sewage to be dealt with will amount to about 90,000,000 gallons per day, and the quantity of lime used in precipitation to 23 tons per day.

ROYAL HORTICULTURAL SOCIETY.

At the last meeting of the Scientific Committee a further discussion took place on the Plague of Caterpillars, in the course of which Mr. O'Brien alluded to the abundance of earwigs (*Forficula*) this season. Mr. Wilson drew attention to the local distribution of the caterpillars. In one garden in his neighbourhood none of the pests were found, while in others there was scarcely a leaf left on the trees. At Wisley, Mr. Wilson had found that exposure to east wind was associated with the presence of the insects; thus the trees in one line of plums, fully exposed, were stripped of their foliage, while in another line of the same variety close by, on the same description of soil, but where the trees were sheltered by a furze fence, not a leaf was injured.

From the editor of the *Journal of Horticulture* came a letter written by a Guernsey grower detailing the course of the well-known, or rather these two well-known tomato diseases. The writer's plants were in a span-roofed house, 60 × 25 feet, and were affected last year, when sulphur was applied without effect. After the removal of the crop the grower took the precaution to have the walls washed with lime, to renew the soil, and adopted every known means to secure healthy growth, but this year the disease is worse than before. One grower was mentioned as having seven houses, each 350 × 45 feet, decimated with the disease and not a pound's worth of saleable fruit in them. Mr. W. G. Smith referred to the full description and illustration of the several fungi known to attack the tomato given in the *Gardeners' Chronicle*, in 1881, November 12, and in 1887, August 6, October 1 and 29, by Mr. C. Plowright and himself. Dr. Masters suggested the trial of sulphate of copper in fine powder, mixed with precipitated lime, and dusted over the foliage, as used in the French vineyards.

SCOTTISH METEOROLOGICAL SOCIETY.

At the meeting held on July 24th, Sir A. Mitchell in the chair, Mr. H. N. Dickson read a paper on the "Temperature of the Air and Surface Water of the North Atlantic." The paper gave the results of observations, in the extreme months of February and August, of the area of high atmospheric pressure called the Atlantic anticyclone, of which the centre lies in about 35° north latitude, and of the area of low pressure, whose centre is situated between Greenland and Iceland.

Dr. Buchan submitted a communication on the climate of the Isle of Man, sent by Mr. A. W. Moore, Douglas. In this paper, which contained the observations of fifty years, Mr. Moore arrived at the conclusion that the temperature of the Isle of Man was more equable than that of the surrounding coasts, being somewhat higher in autumn and winter and similar in spring and summer; that there was comparatively little frost and snow, but a considerable amount of raw, damp weather, which to certain constitutions was more trying than a lower temperature in combination with a dryer atmosphere, and that its sunshine was much greater than in the surrounding districts. Its winds were equal in strength and frequency, though felt more in such an exposed place, and its rainfall rather more than on the surrounding coasts.

Mr. Dickson read a note on the earth-currents on Ben Nevis in connection with anti-cyclones, prepared by Mr. R. T. Omond, in continuation of a series of observations begun by Mr. Dickson himself in 1885.

Dr. Buchan then read a paper by Mr. Rankin on St. Elmo's fire, observed at the Ben Nevis Observatory. The writer stated that up to the present only 15 cases of the appearance of the fire had been recorded, and all occurred at night. It was not at all improbable, however, that the phenomena occurred during daylight, its faintness rendering it invisible; indeed, on one occasion it had been heard, the peculiar sound with which it was accompanied having been identified. Mr. Rankin had connected the phenomenon with the prevailing weather over north-western Europe. It occurred in times of depression, when there was an electrical condition of the atmosphere and a succession of cyclones. In almost all cases the appearance of St. Elmo's fire meant not only that a cyclone had passed, but that another was coming, and thus one more had been added to the weather prognostics quietly accumulating at Ben Nevis Observatory.

THE ARTIFICIAL REPRODUCTION OF VOLCANIC ROCKS.

Translation of a Lecture Delivered by M. Alphonse Renard, LL.D., at the Royal Institution.

(Concluded from p. 91.)

Let us consider some of the conjectures about recent volcanic products, suggested to us by this new process, whose delicacy, certainty, and elegance have never been surpassed in any other branch of natural science. It has not only facilitated the verification and control of hypotheses, but has guided them to the ultimate remarkable discoveries, which we will enumerate. Formerly the eye, even when aided by the strongest magnifying glasses, could only detect fairly large mineral crystals in the lava; chemical analysis could often only give the composition of the total mass; the mineral constituents were but guessed at; the mineral texture of the rocks remained a mystery; there was no reliable certainty as to the order in which the elements of the mass had become solidified, or as to the various phases of the crystals, their rough outlines, and primary forms, or the aspect of the rock during its different stages of development. Let us apply the microscope to the examination of a thin slab of lava, rendered transparent by polishing. As we have already seen, lavas may be compared to a glassy mass, but whilst in our artificial glass we endeavour to obtain a homogenous and limpid product, the liquefied matter of the volcanoes already contains at the moment of eruption differentiated substances. The glass which unites them may be regarded as a residue of crystallisation whence numerous individual crystals have extracted their constituents In the volcanic glass, black, brilliant, and opaque, and apparently no longer of a crystalline nature, the microscope discovers a world of mineral forms. It shows us the various periods of their growth, and the cessation of their development caused by the more or less rapid consolidation of the mass. These strangely-formed rudimentary crystals, the first steps of amorphous matter towards a crystalline state, are formed chiefly in those rocks which have retained most of their glassy nature, and which are consequently homogeneous to the naked eye, *e.g.*, obsidian.

Owing to the rapidity with which the glassy paste has solidified, the crystals have been unable to fully develop, and their formation has been brusquely arrested. Hence the embryonic crystals which abound in natural glass, and which receive the name of *crystallites*. Analogous crystals are present in the slag of blast furnaces, bearing close resemblance to those of lava matter. The microscope proves this resemblance, for, on close examination of fine sections of slag, rudimentary crystalline forms are seen closely akin to the crystallites of volcanic glass.

But, as a rule, the crystals do not remain in this embryonic stage. If the lava does not petrify too abruptly, the molecules preserve their freedom of movement, even in a semi-liquid mass, and individual crystals of minute dimensions arise called *microliths*. These microscopical crystals are formed in the heart of the vitreous mass during its gradual solidification. In spite of their infinite minuteness, these little polyhedrons exhibit with marvellous exactitude all the characteristics of their kind, often only fully recognised in far larger specimens of the mineral world, and whose presence in lava would certainly never have been suspected. These microliths in the lava sometimes form a wonderful crystalline network, which gives a special structure to the rock where they are developed, known as the *microlithic structure.*

The dimensions, invariably microscopical, of these microliths, and their disposal in the rocks, clearly prove that they belong to a troubled period, that they were formed at a time when the lava, still in motion, commenced to solidify—originated, indeed, at the actual moment of eruption. Besides these microscopical crystals and these groups of crystallites, which belong to the last stage of consolidation, the lava contains a certain amount of larger and more developed crystals, which can often be detected by the naked eye. These have been formed under calmer conditions, analogous to those presented by a tranquil fluid where crystallisation could take place but slowly. They were formed in the chemical molten bath when it was still hidden in its subterranean reservoirs. This gradual growth is proved by their disposal in concentric zones, and by their dimensions. These large crystals, thrown up in the lava completely formed at the moment of its eruption, are mingled either with the microliths or are contained in a vitreous mass. The upheaval of the mass in which they are held in suspension occurs subsequent to their completed development. The calm is succeeded by a period of agitation, and the violently-ejected lava bruises, corrodes, melts, or crushes the crystals. The microscope shows us distinctly the phenomenon in question—the large dislocated crystals with their fragments dispersed, their edges blunted or worn away, their whole substance penetrated by the paste.

Whilst the physical and chemical agents, started into action by the movements of the lava, thus attack and demolish the ancient crystals, the microliths are gradually forming. The vitreous mass in which the large crystals are suspended, consists of numberless microscopical particles. These are thus connected with a second phase of crystallisation—they are developed in a moving viscous magma,and their ulterior development is arrested by a cooling of the lava so rapid as to cause almost instantaneous solidification.

Moreover, the arrangement of these microliths in the lava clearly proves that this crystalline formation was contemporary with the movements of the lava flow. We notice at once in microscopical preparations that the microliths accumulate round large crystallised sections, and form undulating trails, thus presenting the appearance known among micrographers as *fluid structure.* It is caused by these infinitesimal acicular crystals being arranged in one direction. When these trails of microliths approach an enclosed crystal of large dimensions, they flow round it, stream through the interstices which separate larger sections, and show us the final movement of the mass at the very moment of solidification.

The microscope proves, then, that crystallisation in lava belongs to two periods. During the first, anterior to an eruption, large crystals, already formed, are held in suspension in a mass which we may suppose purely vitreous. In the second, microliths and embryonic crystalline forms appear, which date from the moment of ejection or overflow, and are contemporary with the consolidation of the rock.

Microscopical observations on the crystals of the second period point at once to the conclusion that they were formed purely and simply by igneous process, without taking into consideration either temperatures or hypothetic pressures, two agents hitherto looked upon as chief factors, and without claiming the absolute repose which was one held indispensable for the regular crystallisation of minerals. It is proved that the microliths are formed after the eruption, at barometric pressure, at a temperature by no means so high as was once supposed, and the crystals are even known to form during the actual movements of the lava stream. When the cooling is very abrupt there is no time for microliths to form, and the lava matter only produces crystallites.

But the microscope enable us to determine the chronology of these lava crystals with even greater exactitude. We have just remarked two great periods in their history; let us see how we may, to a certain extent, determine the date at which each of the specimens of the two groups became isolated from the glass.

The particular circumstances which lead to this determination of their relative ages are their enclosures.

A crystal which is developed from a vitreous mass frequently accumulates particles from the medium in which it is embedded. Thus certain sections appear, under the microscope, riddled with vitreous grains imprisoned in the heart of the crystal, and often arranged according to the zones of development. These enclosures sufficiently prove that that the crystals in question are formed from a vitreous matter liquefied by heat. In other cases, there are mineralogical specimens which are found, in the form of microliths, in the interior of a crystal. It is thus evident that these microliths are of earlier origin than the mineral which imprisons them. Finally, in yet other cases, sharply defined crystals are found covered with another specimen which fills up all the interstices between the previously formed mineral, an incontestable proof of the priority of the crystal. With the aid of these convincing facts, chronological lists have been obtained showing the state of crystallisation of each species of the two great periods. We have not space to quote them here, but we get glimpses of the law, discovered by synthetical experiments, which governs the formation and the relative ages of crystals. We have only drawn the outline of the history of lava; but, although we have been unable to do more than sketch in certain of the details of this representation of lithological phenomena, which modern investigations have delineated with such startling fidelity, we have indicated enough to amply and forcibly prove the great capabilities of analysis as a coadjutor of thoughtful reasoning. From this standpoint the study of lava, such as we are endeavouring to interpret, presents surely one of the finest possible examples of the application of inductive methods to natural sciences. We scarcely know what to admire most, the process of analytical operations, the skill of the observers, or the logical chain of thought by which the phenomena are connected. By this powerful mode of investigation, microscopical analysis, we are enabled to trace with minute exactitude the process of crystallisation in a rocky mass where the naked eye fails to detect anything but an indistinct uniformity, to penetrate into this wonderful tissue of volcanic products, which contain millions of polyhedrons in a cubic centimetre, to determine with mathematical precision the nature of each of these infinitesimal bodies, to follow them from their origin through their entire development, and to mark the traces of all their modifications by chemical and physical agents.

(*To be continued.*)

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

A CIRCLE PROBLEM.

As some interest seems to have been manifested in this "catch for the unwary," perhaps I may be permitted to hint to "A. P. T." that a neater way of putting the statement, and one, sounding, too, more astonishing, is to omit altogether the qualifying parenthesis "unless the circles are many thousand miles in diameter,"—and to say (instead of the subsequent sentence): "The difference *will never be greater than* the circumference of a circle 18 feet in diameter." In fact, owing to the rotundity of the earth, the greater the circles, the less will be the difference between them. Their greatest possible circumference would be attained if they were made to encircle the earth exactly at the Equator, and then their difference would entirely vanish, and they would be equal.

M. A. I.

AURORA BOREALIS.

I never saw it recorded that any one had heard this phenomenon, neither have I, although I have seen the entire sky illuminated with the streaks of light, shooting from the northern horizon, with little apparent diminution, to the southern; but a retired ship captain here informs me that he and others with him often heard a crackling noise accompany it, or a sound resembling sheets of tin being rattled together, particularly near the banks of Newfoundland.

North Shields. T. TODD.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

LAMP.—A mineral-spirit lamp has been patented by Mr. W. H. Beck on behalf of Mr. O. Proust. The burner is constructed by means of two combined tubes sliding one in the other to effect the raising and lowering of the wick. A tube perforated throughout its length contains and conducts the wick to the lamp, and thus puts it by means of openings in contact with sponges saturated with the mineral spirit, and leaves it constantly free to be operated on by the regulating apparatus of the burner.

ELECTRIC CLOCK.—An electric clock has been patented by Mr. J. G. Lorrain. The invention consists in the combination of an electromotor capable of being actuated by continuous currents, and rotating at each transmission of the electric current, and a detent serving to arrest the movement of the electromotor when it has travelled through its required distance, and to allow it to make its next movement in the same direction as before, when the next transmission of electric current takes place.

BATTERIES.—An electrical battery has been patented by Mr. C. P. Elieson. The invention consists in the combination of two hollow electrodes of any form, adapted to be placed one within the other. In the case of secondary batteries each electrode is composed of a series of plates of metal superposed, but separated from each other by interposed pieces of suitable porous material, all the plates being secured in position by rods or suitable means. In the case of a primary battery the electrodes are built up in a similar manner, except that the porous material is not required, the plates being kept separate by distance pieces.

ADVERTISING.—An apparatus for exhibiting advertisements has been patented by Mr. F. Schoyer. The apparatus is contained in a box glazed in front, through which the advertisements are seen. The advertisements are made into a continuous sheet and passed round rollers, so that it is held distended where it appears opposite the glass front, but where it is out of sight it is allowed to accumulate in folds. On the periphery of the upper rollers are fixed pegs, which engage in eyelets made at regular distances apart in the advertisement-sheet, so that when the rollers are revolved by means of a handle or other motive power, automatic or not, the advertisements appear in view successively as the sheet is drawn forward.

FILTER.—A pocket filter has been patented by Messrs. S. W. Silver and W. S. Bennett. This filter is so constructed that when not in use it can be folded up and carried in the pocket. It consists of a box with a perforated base, the inner surface of the base being covered by a piece of flannel on which is placed a block of charcoal which has another piece of flannel placed on top of it. This latter piece has a hole in its centre for the block nozzle to project through to enable the suction tube to be attached. A screw cover rests upon the top flannel below the top edge of the box to leave room for receiving the suction tube when coiled, this being kept there by means of an outside cover, and can then be placed in the pocket. The inner cover is perforated, so that when in use the water has access to the block both from top and bottom.

Garment - measuring. — An apparatus for taking measurements for garments has been patented by Mr. J. Couteau. The invention consists of what may be termed a conformator, to be placed upon the body of the person to be measured. It is composed of pieces of cloth arranged exactly in the same manner as those which will constitute the garment to be made; but instead of the different pieces being sewn together, they are attached to each other by slide plates, so that the different parts of the conformator can be drawn together or pulled apart until it is suitably fitted to the person. The slide plates are marked with scales which, after the fitting, are copied on paper patterns, which have numbered lines corresponding with the plates of the conformator. In cutting the patterns according to the marks thus made exact plans of the different parts of the garment are obtained.

Pianofortes.—A repeating action for pianofortes has been patented by Mr. A. Seppe. The mechanism is as follows: The hopper has a swinging lever, one end of which has a cushion to keep the hammer in suspense when the top end of the hopper is driven out by the stop cushion from beneath the hammer. To the *other* end of this lever is fixed a cushion on a regulating screw and a spring. The upper end of this spring is passed through a projection of the hopper, whilst its lower end passes round a pin set in the lever, and bending upwards, bears against the regulating screw. Thus by means of the regulating screw the tension of the spring can be regulated with precision and the hammer balanced to the required degree. The upward stroke of the horizontal end of the lever is limited by a hook on the end of a screw fixed in a horizontal block fixed to the back of the hopper. The downward stroke is limited by the cushion. A third regulating screw secures mathematical precision in the hammer leaving the string at the moment of the stroke.

Alarm Gun.—An alarm gun has been patented by Mr. E. Drinkwater. This gun instead of firing once only, explodes several times in succession, thus more clearly denoting to the person listening from which direction it is fired. It consists of a metal box having at one side a series of chambers at the inner ends of which are holes communicating with the interior of the box. The chambers each contain a charge of gunpowder, which is fired successively by means of a fuse designed to be ignited upon the explosion of a cap. The fuse is mounted on a bar having arms which enter the communicating holes; at the end of each arm the fuse is slit, so that when ignited it will fire each charge. The end of the fuse is placed in a small box upon which is a nipple for carrying a cap. Close to the end of the fuse is a small quantity of powder, so that when the detonator is fired the fire will pass through the nipple, ignite the powder, and then the fuse. The detonator is fired by means of a hammer held up by a plate supported by a catch to which is attached the wire drawn round the part to be protected. When this wire is pulled by any means the hammer falls and the alarm gun fires.

TECHNICAL EDUCATION NOTES.

Proposed Technical and Recreative Institutes for North London.—Last week a deputation of gentlemen interested in the movement of technical and recreative institutes in the boroughs of Finsbury, Hackney, Islington, and St. Pancras, had an interview with Mr. Anstie, Q.C., one of the Charity Commissioners.

Sir A. Rollit, in introducing the deputation, said that in the boroughs of Finsbury, Hackney, Islington, and St. Pancras movements had taken place in favour of the establishment of technical institutions and polytechnics, committees had been formed, and considerable funds had been promised. The parishes now came unitedly before the Commissioners for the purpose of suggesting a scheme which they considered was of a fairly definite character. They thought it was necessary to have at least four institutions on the general lines of the Polytechnic in Regent Street, one for each of the four boroughs.

Mr. R. Chamberlain, M.P., asked whether, after the boroughs had raised as much money as they possibly could, the Commissioners would put a benevolent interpretation upon the pound for pound principle, and would not deny to the different localities the benefit of these technical institutes because they had not been able to raise so much as 20s. for every pound which the Commissioners were prepared to give. If the pound for pound rule were rigidly insisted upon, it would mean that the richer the locality the greater amount of charity would be bestowed upon it.

Mr. Bartley, M.P., said he did not agree with the general view of forming a general committee and a common fund for the whole area. He thought these great boroughs were big enough to have schemes for themselves. If they were boroughs in the country they would be treated separately.

Mr. Anstie said, in reply, that as the deputation did not appear to have absolute unanimity it would perhaps not be very wonderful if the Commissioners found their schemes did not please everybody. He could not answer all the questions that had been put to him, as he was only there to hear their views, but with respect to the pound for pound principle it was a little hard upon the Commissioners that, having in that respect shown themselves open to receive suggestions, they should now have advanced against them the charge that they were imposing some objectionable terms upon the metropolis at large. The principle of pound for pound was suggested by South London, and had been accepted by the Commissioners throughout, as they thought it a very reasonable proposal. Chelsea—not the borough of Chelsea, but the south-western district of London—had also accepted the principle. This mode of dealing with the matter had proved thus far eminently successful. South London was getting on very well, although there was not, he believed, a poorer district in the metropolis. The Victoria Hall had collected its pound for pound, and the Elephant and Castle was getting far on its way; therefore, so far as experience went, he could not see any objection to the very business-like proposal of South London. He did not think it would work at all ill in North London, provided North London did what South London had done and was doing; but if North London was to be split up into a number of hostile camps, then he did not quite see how that district was to be worked. With regard to the position of these institutions it would be impossible to fix them in the poorest quarters, because those were sometimes the most inaccessible parts of the parish, and to place them there would prevent them from being at all successful. He might mention that the Commissioners had before them a proposal of an extremely good kind, which he hoped would facilitate the foundation of some such institute at Clerkenwell, which might be considered as one of the most suitable places in London for such an institute. That proposal had not been made by the poor inhabitants of Clerkenwell. It had been made on behalf of persons who were not resident in Clerkenwell, but who were generous and wealthy. He mentioned that to illustrate the absurdity of the notion that because this business-like proposition of South London had been accepted by the Commissioners as a working basis, therefore it meant that an institution must be established in Grosvenor Square, or in some other of the most wealthy districts. He would like to ask the deputation where the money for four institutes was to come from. A large technical and recreative institute such as that contemplated would cost £100,000. There must be a large and costly apparatus, not only as regards teachers, but also for materials and workshops; in fact, technical education cost about ten times as much as what might be called the common literary education. He would strongly express a hope that North London would establish an executive committee similar to that in South London. It was far better to put down one institution on solid and good foundations than to attempt to put down two or three in an infirm and crippled condition. With regard to the collection of the money, he might tell them that the Polytechnic boys collected £3,000 between them.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Beautiful Model Beam Engine.—½-horse; strong, riveted, copper boiler; constructed for gas; Bunsen burners; water tank; all fittings; splendid order.—Offers to JOHN LOW, 9, Braid Place, Edinburgh.

Wanted, by two experienced Mechanics, Model Work to do at home (Mechanical or Electrical). Specialities and ideas worked out to drawings, scale, or size. Good workmanship guaranteed. Moderate terms.—P. R., 40, Westbury Street, S.W.

Practical Hints on Electro-Plating, etc. One stamp.—Address, HENRIC, 234, Great Colmore Street, Birmingham.

Amalgamating Brushes, Scratch-brushes, Polishing Sand, Calico Mops, Rouge and Crocus Compositions, Nickel Salts and Anodes.—HENRIC, 234, Great Colmore Street, Birmingham.

Fretwork, Carving, Turning, Woods, Tools, and all requisites. Catalogue with 700 illustrations, 6 stamps.—HARGER, BROS., Settle.

Do your own Electro Plating and Gilding. System inexpensive. Particulars one stamp.—PERKS, 47, Alexandra Road, Richmond, Surrey.

Steel Name Stamps, 3d. per letter. Figures (set), 2s. 4d. Post free.—F. BALDWIN, Tuffley, Gloucester.

Meerschaum and Briar Pipes Repaired, Mounted, or Cased, ambers fitted.—W. GEORGE, 324, Essex Road, Islington, London.

Minerals, Fossils, Cretaceous, Liassic, Carboniferous, Silurian. 12 named specimens, 2s. 6d. free—CHAS. WARDINGLEY, Blackwood Crescent, Edinburgh.

Aquarium Plants, Valesneria; 8 dozen Snails, Newts, etc., cheap, post free.—SAMUEL NEWTON, Hollow Stone, Nottingham.

"Precautions on Introducing Electric Light," Fire Risk Rules, Glossary, by KILLINGWORTH HEDGES, Consulting Electrical Engineer; 1s. 2d. post free.—GLOBE ELECTRICAL COMPANY, Carteret Street, S.W.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words.

Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Splendid Solar Microscope, in case, by Nairne, six powers. Exchange photographic apparatus.—RIDOUT, Sunbury Common.

100 Geological Specimens, named. Exchange, 10s. Approval.—HOLDEN, Hoyland Nether, Barnsley.

I offer Lawn Mower, 52-inch Bicycle, Lockstitch Sewing Machine, or Fret-Saw and Lathe, cost £5 5s., in exchange for Lathe.—Wellesley House, Colchester.

SELECTED BOOKS.

Handbook of the Amaryllideæ. Including the Alstrœmerieæ and Agaveæ. By J. G. Baker, F.R.S., F.L.S., First Assistant in the Herbarium of the Royal Gardens, Kew. London: Bell and Co. Price 5s.

Electro-Plating. A Practical Handbook on the Deposition of Copper, Silver, Nickel, Gold, Aluminium, Brass, Platinum, etc., with descriptions of the Chemicals, Materials, Batteries, and Dynamo Machines used in the Art. By J. W. Urquhart, C.E. Second Edition. London: Crosby, Lockwood and Sons. Price 5s.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, July 23rd, 1888. Specially prepared for SCIENTIFIC NEWS from official reports

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	51·2 degs., being 2·8 degs. below average.	8·1 ins., being 1·6 ins. above average.	407 hrs., being 23 hrs. below average.
England, N.E.	52·0 ,, ,, 3·7 ,, ,, ,,	6·7 ,, ,, 1·6 ,, ,, ,,	319 ,, ,, 113 ,, ,, ,,
England, East	55·3 ,, ,, 2·6 ,, ,, ,,	5·9 ,, ,, 0·9 ,, ,, ,,	346 ,, ,, 164 ,, ,, ,,
Midlands ...	54·8 ,, ,, 2·7 ,, ,, ,,	7·1 ,, ,, 1·6 ,, ,, ,,	325 ,, ,, 123 ,, ,, ,,

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

Many still assume, as a matter of course, that all colliery explosions result simply from fire-damp, though Faraday and Lyell, in the *Philosophical Magazine* of 1845, reporting on their examination of a mine in which a great explosion had occurred, told us that "the coal-dust swept by the rush of wind and flame from the floor, roof, and walls of the works would instantly take fire and burn if there were oxygen enough in the air present to support its combustion; and we found the dust adhering to the face of the pillars, props, and walls, and in the direction of and on the side towards, the explosion increasing gradually to a certain distance as we neared the place of ignition. This deposit was in some places half an inch, in others almost an inch thick; it adhered together in a friable coked state."

An examination of this deposit showed that it consisted of partially burned coal-dust, which had been deprived of the greater part of its inflammable bitumen—was in some cases entirely destitute of it. Faraday and Lyell concluded that this coal-dust had been ignited, and the extent of its combustion was limited by the supply of oxygen—that "much of the carbon of this dust remained unburnt only for want of air."

Mr. W. Galloway has more recently and quite independently studied this subject very exhaustively, and has proved that in many mines the dust is more dangerous than the gas. The practical importance of the knowledge which his researches have supplied is very great, even greater than most mining engineers and other experts, who only take into consideration the present operations of coal-mining, suppose.

I base this opinion on the fact that we are rapidly exhausting all the workable coal that exists at moderate depths, and must go on sinking to deeper and deeper seams until we are stopped altogether from further working, not by the exhaustion of the coal, but by the high temperature rendering the operations of workmen, and even the working of coal by machinery, impossible.

When we get below a certain depth, which varies greatly with the locality, the supply of water, which in ordinary pits costs so much to remove, ceases; the roads and workings become dry, and as every stroke of the pick produces a certain amount of coal-dust, the accumulation soon becomes considerable. The danger of such accumulation is increased by the high temperature of the seam itself, of the rock in which it is embedded, and of the atmosphere of the workings.

That an accumulation of dust may produce fearful and fatal explosions without the aid of any fire-damp, or any other explosive gas, has been proved again and again by destructive explosions in flour-mills, although the carbohydrates of the flour are less inflammable than the hydro-carbons of the coal-dust; but, on the other hand, the flour-dust is finer and lighter than ordinary coal-dust. In the "Annales des Mines" for 1875 M. Vital describes very minutely all the particulars of an explosion in the Campagnac Colliery, 2nd November, 1874, where a shot which blew out the tamping produced an explosion that was fatal to three men. No fire-damp had been detected there at any time, but the floor was covered with very fine, dry coal-dust, the shot was fired at the bottom of the face, and would thus raise a cloud of dust from the floor. Other similar cases are recorded.

The negative evidence in these cases is, however, not always reliable. It is usually based on the behaviour of the Davy lamp. The presence of fire-damp is indicated by a "cap," which is a conical blue flame, more transparent than the oil flame, and appearing to rest upon it. The height of this cap varies with the quantity of fire-damp mixed with the air. Mr. Galloway made a series of experiments with measured artificial mixtures of these, using a lamp-flame drawn down to about $\frac{1}{8}$ inch high by $\frac{1}{4}$ inch diameter at the base, and with only a conical speck of yellow in the middle near the top (conditions most favourable for showing a small cap). He found that 1 part of the inflammable gas to 16 of air gave a voluminous, waving, spindle-shaped, pale-blue cap $3\frac{3}{8}$ inches high; with 1 to 18 a similar cap 2 inches high, which burned rather more steadily; 1 to 20 a cap $1\frac{5}{16}$ inch high, with nearly parallel sides to about two-thirds of its height, and drawn out to a point at the top; 1 to 25 a conical cap $\frac{1}{2}$ to $\frac{5}{8}$ of an inch high; 1 to 30 a conical cap $\frac{3}{8}$ of an inch high; 1 to 40 a conical cap $\frac{3}{16}$ to $\frac{1}{4}$ inch high; 1 to 50 an exceedingly faint cap $\frac{1}{8}$ of an inch high, the top having the appearance of being broken off; 1 to 60, hardly possible to distinguish anything above the oil flame. The colliery firemen to which this latter was shown "asserted positively that they would consider an atmosphere in which the small oil flame burned as it did in this mixture to be *perfectly free from gas*."

It is evident from these experiments that, in the ordinary course mines may be reported to be free from fire-damp in which the air is mixed with 1 part in 60 or any smaller proportion.

Mr. Galloway found that ordinary coal-dust mixed with air only is not inflammable at ordinary pressure and temperature, but that if air be mixed with fire-damp in proportions of one in 112 and in greater proportions it becomes inflammable at ordinary pressures and temperatures. From these results, together with those of his experiments on the lamp-flame, it is evident that mines with an atmosphere containing any proportion of fire-damp between $\frac{1}{112}$ and $\frac{1}{60}$ may be reported free from fire-damp, and yet be very dangerous, owing to the combined operation of the coal-dust and the small proportion of hydro-carbon gas. This may have been the condition of the Campagnac Colliery above referred to.

There is a curious fact connected with colliery explosions in dry mines, which at first glance appears mysterious, but which is readily explained when the potency of coal-dust in producing them is understood. It is that they occur most frequently in the winter months when the air is coolest.

This is due to the fact that in coal-mines generally the temperature below is subject to very little variation. It is regulated by the rock temperature, not by that of the atmosphere above ground. I knew an old collier in Flintshire who had saved enough to buy a small freehold and retire, but who worked below in the winter for comfort's sake, or, as he said, for the benefit of his health, just as more luxurious patients winter at Mentone or San Remo. To explain this let us suppose the case of a deep pit at 70 degs. Fah. With the summer air above ground at 70 degs. and saturated with aqueous vapour, it will remain thus saturated below; but in winter the air, say at 40 degs. and also saturated, will when raised to 70 degs. below acquire a proportionately increased capacity for water, and will be very dry and thirsty, taking water from everything it touches that is at all damp. It will thus render the loose dust excessively dry, and thereby increase its inflammability.

It will be further understood from the above-stated facts that thorough ventilation, which is the best safeguard against the accumulation of fire-damp, may contribute to the explosiveness of coal-dust.

It is evident, therefore, that in working the deeper collieries of the future our mining engineers will have to study these modified conditions of danger, and make arrangements accordingly. The watering of mines will become as necessary then as the pumping is now; such watering will be demanded not only for laying the dust, but also for lowering the temperature of the workings.

Volcanic Eruption in the Lipari Islands.—On August 3rd an eruption occurred in these islands, on which the well-known volcano of Stromboli is situated. Immense damage is stated to have been caused by the eruption, but no details have reached here owing to the destruction of the telegraph communicating with the islands.

REPRODUCTION OF ARTICULATE SPEECH AND OTHER SOUNDS.

THE transmission of articulate speech, wonderful and useful as it is, is fully equalled in point of novelty by the instrument for recording, preserving, and producing speech. Without doubt these "speech reproducers" are destined sooner or later to take a large place in business and social transactions. No one who has given the matter a moment's thought will fail to see the utility of a practical machine of this sort. Leon Scott long ago devised a simple and curious instrument known as the phonautograph, in which the vibrations of a diaphragm were recorded by a stylus upon a smoked cylinder, but it is now known that its record was not autographic, although it conveyed a fair idea of the number and variety of air waves necessary to the production of words and sounds. Faber's talking machine is curious and interesting on account of being a mechanical imitation of the vocal organs. It is capable of producing articulate speech by the manipulation of a bellows and key. The first machine to really echo one's own words was the Edison phonograph, which, as originally presented, was not sufficiently effective in its operation to be of any great commercial value, although it contained the germ of the modern talking machine. The graphophone, which is shown in the annexed engravings, is, as its name indicates, a recorder and reproducer of sounds. It is the invention of Mr. Charles Sumner Tainter, and is the result of several years' experimentation and the subject of many patents, several of which were issued in May, 1886. In its construction efficiency has, of course, been the first consideration, after which the matters of simplicity, facility of management, and the practical handling of the records or messages have been disposed of. The machine is an exceedingly simple thing. Fig. 1 shows it as arranged for receiving or recording the message. The frame of the machine consists of end pieces connected by longitudinal rods. In the top of the frame is a fine screw partly enclosed by a tube; the screw is driven through a train of spur wheels attached to the main shaft, which is also provided with a conical chuck. At the opposite end of the frame is a spindle acted on by a spring, which also carries a conical chuck of the same form and size as that on the main shaft. The cylinder upon which the speech is to be received is placed between these chucks in much the same manner as the bobbin is placed in the bobbin winder of the sewing machine, the cylinder being revolved by the frictional contact with the chuck on the main shaft. At the right hand of the instrument is arranged a small rock shaft provided with a cross arm and two keys by which the driving wheel is thrown in and out of connection with the gearing of the machine. On the tube which encloses the feed screw is placed a saddle provided with a follower which enters the slot of the tube, and engages the feed screw. The saddle carries a diaphragm cell, in which is arranged a diaphragm provided with a cutting stylus which engraves the record on the surface of the cylinder. To the diaphragm cell is attached a bar or bridge piece of metal, which extends across the face of the diaphragm, but not in contact with it. This device rests upon the record cylinder a little in advance of the cutting stylus, and supports the weight of the diaphragm cell and its attachments. The depth to which the stylus penetrates the surface of the cylinder is regulated and maintained by this arrangement, and as the bridge-piece bears upon the cylinder near the point of the cutting, the apparatus follows all the irregularities of the recording surface, and perfect accuracy in centering the cylinder is rendered unnecessary. To the diaphragm cell is attached a flexible tube furnished at its free end with a mouthpiece, into which the words to be recorded are spoken. The record cylinder consists of paper wound in cylinder. The machine is driven by connection with any power having a fairly uniform speed: In the engravings the machine is represented as being driven by a small electric motor. The paper cylinders are very light, perfectly portable, and may be transmitted by mai with the same facility as an ordinary letter. The cylinde

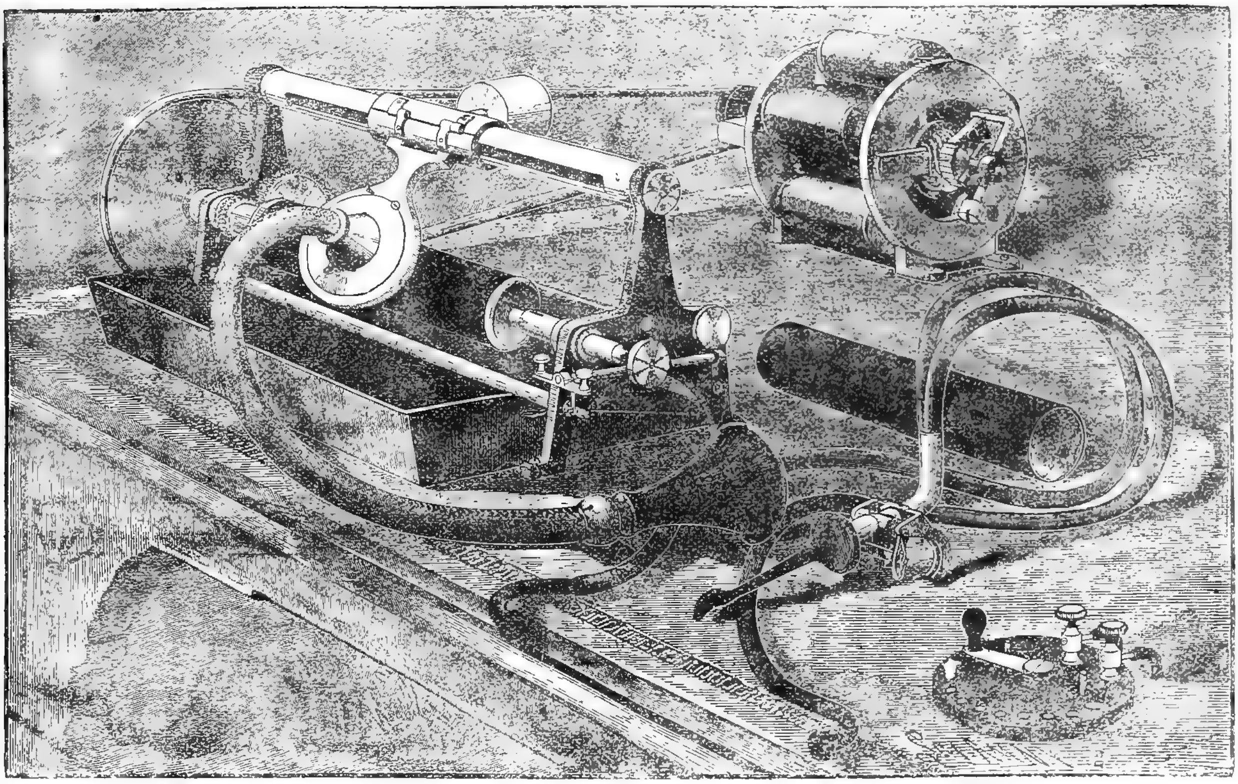

FIG. 1.—TAINTER'S GRAPHOPHONE.

a peculiar way to cause it to maintain its cylindrical form, the outer surface of the paper being coated with a specially prepared wax. Below the cylinder is arranged a pan for receiving the fine shreds of wax cut by the stylus from the cylinder in the operation of recording the message. The groove constituting the record is microscopic in size, it being only three thousandths of an inch wide and about two thousandths deep. One hundred and sixty grooves to the inch are cut on the cylinder. The saddle which holds the diaphragm cell is formed of two parts hinged together to facilitate its removal from the support. After the complete record has been made the cylinder is either removed and placed in another machine or it is allowed to remain, and the recording diaphragm is replaced by the small reproducing diaphragm shown in fig. 2. This diaphragm is connected by a thread with a small rounded finger, pivoted in the end of the arm which supports the diaphragm, adapted to engage the groove and indentations made by the stylus of the recording diaphragm. To the reproducing diaphragm cell is attached a flexible tube which is branched and provided at its extremities with ear pieces similar to those of a stethoscope. The ear pieces are placed in the ears. The rotation of the cylinder containing a message causes vibrations to be set up in the reproducing diaphragm which are similar in character to those of the recording diaphragm which produced the impressions upon the

will fit any graphophone without any adjustment of the instrument. The graphophone has been in practical use for some time past, carrying on correspondence between

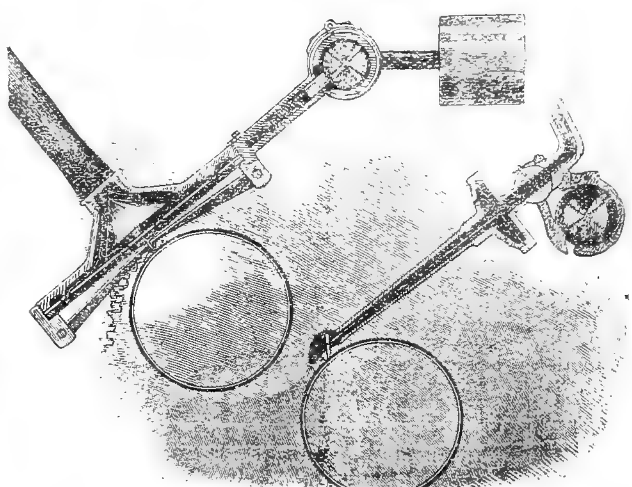

FIG. 2.—RECORDING AND REPRODUCING MECHANISM.

New York and Washington, and in receiving dictation in every-day matters of business the dictations being written out on a type-writer by a copyist who listens to the graphophone. By means of the starting and stopping key, which throws the driving wheel in and out of gear with the recording cylinder, the message can be reproduced sentence by sentence, and reproduction stopped between any two words, or in the middle of a word, if desired. This enables the copyist to take from the graphophone as many words as can be retained in mind, and the machine waits while they are being printed on the type-writer, or written out, as the case may be. Should it be desired to repeat the message, a simple motion of the hand, occupying only a second or two, places the reproducer on any part of the record, and the latter can be repeated a thousand times if desired. The graphophones in general use are provided with treadle motors, which, acting through a very sensitive regulator or governor, gives to the record cylinder a perfectly uniform motion, and as all machines are regulated to run at exactly the same speed, a record made on one machine can be reproduced correctly on any other.

EXTINCT BRITISH BUTTERFLIES,

AND THE CONTINUITY OF EXISTING SPECIES BY MEANS OF MIGRATION CONSIDERED.

THE ordinary observer could not have failed to notice the changes which have taken place in the fauna and flora of the British Isles within, say, the last fifty years.

The plants and animals of any country or district are not absolutely identical for any two successive periods, however brief. Some species are gaining ground, others losing it, while yet others remain practically stationary. These changes are perpetually going on, but very few of them are placed on record.

In the course of a few years the general changes may be inappreciable to the ordinary observer; but locally there are often considerable variations which cannot fail to be detected on close scrutiny. These are links in the great chain of changes whereby the fauna and flora of one geological period are considerably modified, and are gradually converted into the fauna and flora of the succeeding epoch. In the different groups of animals and plants, however, these changes proceed at markedly different rates. Some will change rapidly, while in others the movement is scarcely perceptible.

As a general rule, the change seems to be slowest among the least specialized forms and among those which have been established the longest—the most rapid among the most specialized forms and such as have only recently been introduced.

The *Rhopalocera*, or butterflies of the British Isles, have in particular undergone many great and important changes, even comparatively within the last few years. The lists of only fifty years ago are no longer trustworthy.

We have records of many species occurring in this country which are now extinct. Others, which were very plentiful, are now only occasionally seen. Others, again, which were widely distributed, have become very local, and so reduced in numbers that we may safely venture to predict that within a few years hence they will be entirely extirpated, and the beautiful forms of many which at present adorn our collections will be phantoms of the past.

On the other hand, there are very few species multiplying their numbers or widening their area of distribution to compensate us for such losses. It is the nature and extent of these changes which we are about to consider.

In order, however, to obtain an appreciable estimate of the great changes which have taken place in our *Rhopalocera-fauna* it will be necessary to enter somewhat into details respecting the laws of their distribution.

It is well known that islands are, as a rule, poorer in species than a similar area on adjacent parts of the nearest continent; for instance, the number of species of butterflies indigenous to the British Isles is only sixty, while the number occurring in France is nearly four times that number.

This is brought about by the following means: the isolation consequent on being separated from the continent precludes the possibility of many species passing over from the latter to the island, and thus supplying the place of those forms which may have become extinct, from whatever cause, in the smaller and isolated area.

Now, on a continent, if a certain species become extirpated in any limited district of similar extent the loss would probably be only temporary; for if it belong to any of those species which are ever increasing their area of distribution under favourable conditions, the blank in question would be almost certain to be supplied through migration, and the continuity of the species maintained.

Although the narrow strip of water separating us from the Continent operates as an impassable barrier for many species which would otherwise make their way over here, there are some which possess a powerful flight and are able to overcome the obstacle.

In addition to our isolation, there are other important factors which greatly assist in the reduction of our indigenous butterflies, and are really the primary causes. Of these climate is, perhaps, the principal. Owing to our proximity to the ocean and the gulf-stream, and the excessive humidity consequent thereon, the number of rainy days in the British Isles is greatly in excess of that of any country on the Continent.

Butterflies are entirely dependent on sunshine for their existence; and whereas we get so very little of the requisite in this country, it will be seen that this is tending also to reduce the *Rhopalocera-fauna* of the British Isles out of proportion to the latitude.

The other important factor in the matter is increased drainage and cultivation, thereby causing the extirpation of many indigenous plants which constitute the pabulum of certain butterflies the *larvæ* of which are dependent on them for food.

All these causes operating together are, at the present time, as they have undoubtedly done in the past, bringing about the speedy extinction of our native butterflies. What will be their ultimate fate we can only dimly surmise. Only about a century ago the number of species of butterflies inhabiting this country was probably half as large again as at the present time. Many of the species which have since become extinct have been figured in various Natural Histories, and records of their occurrence have fortunately been preserved for the use of future generations.

The most handsome species of all whose records have been handed down to us is the scarce swallow-tail (*Papilio podalirius*). It is only little more than half a century since the last specimen was seen in this country—namely, at Richmond Park in 1829. Judging from the list of localities it used to frequent, it possessed a wide distribution in this country. The prior recorded dates of its capture are as follows: near Beverley, in Yorkshire, in 1778; near Norwich in 1810; Berkshire, 1826; Shropshire, 1807, and again in 1822; Cambridgeshire, 1818; also in the New Forest, the Isle of Wight, and in Bedfordshire. Though the species is now extinct in the British Isles, it occurs in considerably higher latitudes in adjacent parts of the Continent. Its extirpation over here may probably be attributed to adverse climatic influences, isolation, and increased cultivation combined. It is highly probable that a near relative of the preceding, our only remaining representative of the genus Papilio—namely, *Papilio machaon*—will follow suit not many years from hence; for when *Papilio podalirius* used to occur in this country *Papilio machaon* roamed over the whole of South Britain, being found as far north as Cumberland and Yorkshire, westward as far as Wales, and to the Isle of Wight in the south. There is also a strong probability of its having occurred in the south of Ireland. Now, however, it is entirely restricted to the fenny districts of Cambridgeshire, Huntingdon, and Norfolk, and it is even here much less plentiful than formerly.

It seems very likely that living entomologists will hear

FIG. 5.

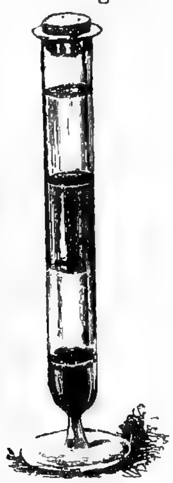

FIG. 6.

of the last swallow-tail being taken in Cambridgeshire and Huntingdon, as both these districts are being rapidly drained and cultivated. Many places where the *Papilio machaon* held its court are now corn-fields. In Norfolk, however, we may hope to have its extirpation retarded. The butterfly in this county has its head-quarters in the neighbourhood of Horning, and the fens hereabouts, owing to tidal influences, are incapable of being drained. Long, we trust, for the sake of entomology, may this be the case.

A more remarkable case than either of the preceding is that of the Black-veined White (*Aporia cratægi*).

This insect only about twenty years ago occurred in great abundance in many localities in the south of England. Dr. Newman speaks of having taken it near Leominster in great numbers at rest on flowers of the ox-eye daisy. Since then, strange to say, it has become entirely extinct in this country, and various have been the speculations respecting its sudden and mysterious disappearance. This, in our opinion, is due principally to a long succession of wet summers which have prevented the insect performing the functions of oviposition.

It is very strange that while this butterfly does not now occur at all in this country, it is to be found in great abundance on the adjacent parts of the Continent, especially in France, where it is said sometimes to cause immense destruction in orchards. In many districts the fate of the fruit crop entirely depends on the abundance or scarcity of *Aporia cratægi*.

The principal districts in our own country which it once frequented were Kent, Surrey, Hampshire, Dorsetshire, and Middlesex in the south; Worcestershire and Herefordshire in the west; and Northamptonshire in the east. In the intermediate localities it was comparatively scarce, It was not found at all in the North of England, Scotland. or Ireland, at least as far as existing records inform us.

(*To be continued.*)

SIMPLE EXPERIMENTS IN PHYSICS.—II.

Cohesion.—A pretty illustration of cohesion. The force which holds the molecules of matter together is shown in fig. 5. In the bottom of a suitable vessel is placed a few drops of olive oil, and into the vessel is carefully poured a mixture of alcohol and water having the same specific gravity as the oil. The oil will be detached from the bottom of the vessel, and will, in consequence of the cohesion of its particles, assume a spherical form. Another method of performing this experiment is to introduce the oil into the centre of the

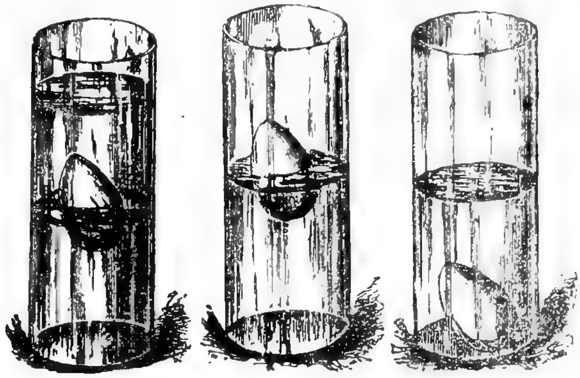

FIG. 7. FIG. 8. FIG. 9.

body of dilute alcohol by means of a pipette. By careful manipulation a large globule of oil may be introduced in this way. Cohesion tends to cause liquids to assume a spheroidal form, but in the case of liquids in large masses, gravity causes them to assume the form of the vessel in which they are contained. The tendency of liquids to assume a spheroidal form is seen in the rain and dewdrops, in liquids dropped from bottles, also in liquids thrown in drops on surfaces which they do not moisten. Water spattered upon a surface covered with lycopodium is an example of this.

Specific Gravity.—The difference in the specific gravity of liquids is illustrated in a striking manner by the "vial of four liquids," shown in fig. 6. A test-tube with a foot makes a convenient receptacle for the liquids. In the bottom of the tube is placed mercury. The second liquid in order is a saturated solution of carbonate of potash. The third is alcohol, coloured with a little aniline red to mark the division of the liquids more clearly. The fourth is kerosene oil. When these liquids are shaken up they mix mechanically, but when the tube is at rest the liquids quickly arrange themselves in their original order. The egg experiment shown in figs. 7, 8, and 9, although without novelty, is interesting on account of its simplicity and effectiveness. Two pint tumblers or similar vessels are necessary for this experiment. Half fill one with water and the other with strong brine. Into the water drop an egg. It goes to the bottom (fig. 7). An egg dropped into the brine floats (fig. 8). By carefully pouring the brine through a long funnel or through a funnel with an attached tube, which will reach to the bottom of the tumbler containing the pure water, the water and the egg will be lifted, and the egg will float in equilibrium at the middle of the tumbler. The first experiment shows that the egg is a little more dense than pure water, the second that brine is more dense than the egg, and the third that the egg can be supported in equilibrium between two liquids of different densities.—*Scientific American.*

THE GLACIAL EPOCH AND THE PRESENT DAY.

ALTHOUGH the former existence of a glacial epoch has passed out of the region of discussion, there are still unsolved questions concerning its origin, its character as single or recurrent, and the possibility of its return. The absolute decision of some of these problems is not to be hoped for to-day or to-morrow. In the meantime every light procurable, be it direct or indirect, is highly welcome. Professor Brückner, in discussing some of these points in *Humboldt*, observes that though the geologist is not in a position to apply any absolute standard of time in measuring the history of the earth he may, by a cautious and critical evaluation of the effects of certain forces, form an estimate of the relative duration of certain geological epochs.

The most recent geological time, the diluvial epoch, is characterised by an enormous development of glaciers. From the Scandinavian Mountains they passed southwards to the foot of the central mountains of Germany and into the heart of European Russia. The Baltic had no existence as a sheet of water, its bed being choked with ice-masses. The glaciers of the Alps filled not merely the mountain valleys, but spread over the sub-alpine territories, both northwards and southwards. A corresponding development of glaciation during the diluvial epoch can be traced in North and South America, in Asia, and Australia. Even within the Tropics our earth did not escape the formation of glaciers, as their traces have been lately recognised in the Sierra de Santa Marta, in South America.

A careful examination of the diluvium leads, in many localities, to the conclusion that the assumption of a single glaciation does not suffice for the explanation of the deposits. There were recognised two glaciations, two icy periods, separated by a milder inter-glacial age. Penck, on examining the region between the Iller and the Inn, was led to the result that there must have occurred a threefold repetition of glaciation, and Professor Brückner, on examining the Salzach region, confirms his inference. Hence we find the following succession of events: First glacial epoch forming glacier deposits, and the oldest "schotter" of the glacier-streams (Brückner applies the term "schotter" to the gravel and other *debris* with which streams originating in glaciers are overloaded, and which they deposit in their beds). First interglacial epoch, erosions by flowing water. Second glacial epoch, repeating the phenomena of the first. Second inter-glacial epoch, with repeated erosion and deposition of the "loess" on the surface of the ground. Third ice-age, with formation of the most recent glacier deposits and stream "schotters." Then follows the post-glacial age, or alluvium, marked by erosion due to flowing water.

From these successive phenomena it is possible to form an approximate conclusion as to the length of the post-glacial age and its proportion to the time elapsed between the third and the second ice-age.

The three "schotter" systems have been piled up by glacier-streams. Upon each period of accumulation there followed a period of erosion which came to an end when the next more recent "schotter" began to be formed. To this alternating accumulation and erosion is due the terrace, or stair-like structure of the three "schotters."

If we compare the destruction which the second "schotter" underwent by erosion before the depositing of the most recent "schotter" with the effects of post-glacial erosion upon the latter, we recognise a noteworthy difference. The erosive work of the post-glacial age (in which we now live) is evidently small in comparison with the erosive work of the second inter-glacial age. Hence it seems that the time which has elapsed since the formation of the most recent "schotter" is shorter than the time which intervened between the formation of the second and of the third, or most recent "schotter." A similar conclusion as to the duration of the first erosion-period may be drawn from the great destruction of the earliest "schotter" effected before the second was deposited. We are in our day probably nearer to the age of formation of the most recent "schotter" than it was to the formation of the intermediate, or than this, again, was to the first. *The post-glacial age is decidedly shorter, so far, than either of the two inter-glacial periods.*

This conclusion drawn from the erosive actions in the times concerned is confirmed by a comparison of the layers of soil, deposited during the post-glacial age and during the inter-glacial age. We see the deposits of the last ice-age covered only by a stratum of brown clay, rarely exceeding a foot in thickness. But to the inter-glacial period belongs the deposition of the strong yellow strata of loess and loess-clay, and though the inter-glacial character of these deposits is still in part contested, yet the affirmative evidence is constantly on the increase. A loess like that formed, according to Professor Brückner's observations, in the second inter-glacial period and completed at its close, is still wanting among the most recent diluvial deposits.

The results thus described are rendered more important by the consideration that they apply to the entire northern sub-alpine country from Switzerland in the west to Enns in the east. Hence the alluvial age is merely the last phase of the diluvial epoch.

That these results throw a certain side-light upon the question of a return of the ice-age can scarcely be denied. As the post-glacial age appears so decidedly shorter than either of the inter-glacial ages, a recurrence of glaciation appears in no wise excluded. But the question can be definitely solved only when the causes of those climatic changes which manifested themselves in the alternation of glacial and inter-glacial epochs shall have been ascertained, and their periodicity accurately determined for the future. No geological evidence speaks against such a recurrence; but if we assume its return, we must expect also a repetition of the "loess" period which would precede the returning ice-age. However, the next attack of glaciation, if it is to be expected at all, belongs to a future which in our way of reckoning must seem infinitely remote.

General Notes.

Deaths from Lightning.—In that part of Europe which comprises Italy, France, Belgium, Rhenish Prussia, and the British Islands about 400 persons are killed each year by lightning. In Belgium alone the storms of June last proved fatal to 11 persons.—*Ciel et Terre.*

Memorial to Charles Darwin.—It is announced that a tablet with an inscription will be shortly inserted in the front wall of the house, No. 11, Lothian Street, Edinburgh, in which Charles Darwin lived in the years 1825-6 whilst studying in the University of that city.

Vulcabeston.—Under this name Mr. R. M. Pratt of Hartford, Connecticut, U.S.A., is introducing a substitute for vulcanised fibre. It can be moulded into any shape, and can be turned and polished. It is said not to soften when exposed to steam, and will not ignite in a gas flame.

Honours Awarded to Pasteur.—M. Pasteur has received no fewer than fifteen orders, of which one only, the Legion of Honour, is French. He is an honorary doctor of all the leading Universities of Europe, and is a member, according to the *Medical Press*, of eighty-three learned societies.

The Fixation of Coal-Tar Colours.—According to a recent discovery, the antimony employed as a mordant can be dissolved, instead of in tartaric acid, in the whey resulting as a waste product in the preparation of cheese. This liquid contains acetic acid, along with a smaller quantity of lactic acid and traces of butyric acid.

The Synthesis of Organic Compounds. — Professor Maumené, in a recent communication to the Paris Chemical Society, maintains that it is possible to effect by means of the electric effluve (silent discharge) the synthesis of all the organic compounds or immediate principles met with in plants or in animals. This can be effected by setting out from principles existing in the atmosphere, such as water, carbonic acid, ammonia, etc.

Predominance of the Polar Atmospheric Current. —This phenomenon, from which we have been suffering during the present season, appears to have been recognised in 1885, and to have persisted to an abnormal extent ever since. Thus in 1887, polar current (that is northerly and easterly winds) is recorded for 202 days, the average being about 120-130. In this year up to August 3rd, the polar current has prevailed for 102 days.

Etching Liquid for Steel.—Take 1 oz. sulphate of copper, ½ oz. alum, and half teaspoonful of salt in a fine powder, and mix with one gill of vinegar and 20 drops of nitric acid. The liquid thus obtained may be used for either cutting deeply into the metal, or for imparting a beautiful frosted appearance to the surface, according to the time it is allowed to act. The parts to be protected from its action should be covered with beeswax or tallow.

The French International Exhibition.—M. E. Sartiaux, chief telegraph engineer to the Northern Railway Company, has been nominated a member of the Organising Committee of the International Congress of Electricians, to be convoked for the Great Exhibition of next year. The other members are—MM. D'Arsonval, G. Berger, Boudet, Bouilhet, Bourdin, Carpentier, A. Cornu, M. Delahaye, H. Fontaine, Gariel, Hillairet, Hospitalier, Joubert, Lemonnier, Lippmann, Mascart, Napoli, de Nerville, Pellat, Picou, Postel-Vinay, Potier, Raymond, Renard, Séligmann-Lui, de la Touanne, Violle, and Vivarez.

Inventors and Lunatics.—Anent the trial of the inventor Raynaud, the *Medical Press* remarks that persons of real or fancied inventive faculties seem peculiarly liable to mental derangement. Our contemporary adds with considerate kindness, that "We would not urge this as a reason for applying restraint to all (!) persons who display inventive tendencies, but lunacy statistics show that the inmates of asylums are drawn largely from their ranks." We think a careful inquiry would show that not a few eminent inventors have been wrongfully treated as lunatics, and have been driven to insanity, not so much by "the constant and unremitting application of the intellectual faculties to one object," as by the treatment which they have undergone.

Manufacture of Wood Oil in Sweden.—This product, along with oil of turpentine, creosote, acetic acid, charcoal, tarry oils, etc., is obtained by the dry distillation of roots, stumps, and other residual parts of trees felled for timber. Wood-oil, as it is produced in Sweden, is not suitable for burning in common lamps, which smoke in consequence of the excess of carbon in the oil. It requires special lamps, which differ, however, little from the ordinary photogen lamps. If wood oil be mixed with photogen in certain proportions, it can be used in ordinary lamps. In its unmixed state it is the cheapest lamp-oil known, costing only 5d. per litre. It is, further, inexplosive, and lasts much longer than the mineral oils. In Sweden there are at present about thirty works, which produce 40,000 litres of this oil.

Production of Wool in the World.—According to *La Nature*, the total yearly crop of wool is about 800 million kilos (1 kilo equals 2⅕ lbs.). Australia and New Zealand contain 75 million sheep, yielding annually 100 million kilos of wool. At the Cape the number of sheep is not ascertained, but the wool exported is 15 million kilos. In La Plata there are at least 100 million sheep, but their produce is only 50 million kilos. The United States contain 50 million sheep, but they do not produce wool enough for home consumption. Europe possesses 200 millions of sheep, which yield 200 million kilos. Here Russia takes the first rank as a wool-producer, followed by Britain, Germany, France, Austria, Italy, and Spain. Forty years ago France had 35 million sheep, but the number has since fallen to 22 millions. India, Central Asia, and China yield 150 million kilos.

A Huge Bridge.—A Bill has been introduced into the American Senate, to obtain the authorisation of Congress for the construction of a bridge across the Hudson River, between the City of New York and the State of New Jersey. The bridge is intended for railway traffic and other purposes. According to the designer, Mr. Gustave Lindelthal, the middle span would be at least 140 ft. above high-water level, and 2,850 ft. in length, and the end spans 1,500 ft. No piers or other obstructions to navigation, either temporary or permanent, would be placed or built between the pier lines. The bridge will be constructed according to regulations for the safety of navigation to be fixed by the Secretary of War, and if the Bill be passed would have to be completed within ten years after the approval of the plans for the bridge had been obtained from the Secretary.

H. Debray.—We regret having to put on record the unexpected death of the distinguished chemist, H. Debray, formerly the pupil and assistant, and subsequently the successor of the illustrious Sainte-Claire Deville. Debray died on the 19th ult. H. Debray was 60 years of age. He was a member of the Institute, an officer of the Legion of Honour, a Professor of the Faculty of Sciences, *Maitre de Conferences* at the Higher Normal School, a Vice-President of the Society for the Encouragement of National Industry, a Member of the Higher Council of Public Instruction, and of the Consultation Committee of Arts and Manufactures.

Exceptional Longevity.—*La Nature* gives the portraits and brief biographical sketches of two natives of France who lived in the last century. Of the former—Jean Causeur, of Ploumogue, a village of lower Bretagne—there exists a portrait painted in 1771 by Charles Caffieri, authorized royal sculptor for the Navy, at Brest, and engraved by Ch. Leverque in 1772. An accompanying inscription states that he was then 130 years of age. There is no confirmatory evidence. The second case is that of M. J. N. de Quersonnières, who was born on February 28th, 1728, at Valenciennes, where his father was royal councillor. He became commissary-general for military requisites in 1789, but fell into disgrace under the Empire and took refuge in London. At 117 years (*i.e.*, A.D. 1845) his portrait was taken and lithographed. His biographer states that at that age his sight and hearing retained "a surprising delicacy of perception." He was still living in 1846, but nothing is said concerning the date of his death.

A Remarkable Hailstorm.—Writing from Lake of Menteith, a correspondent of the *Scotsman* says:—During yesterday forenoon (July 26th) the atmosphere was dull and very sultry, thunder rattling in the distance. Between three and four o'clock in the afternoon, standing with an acquaintance in front of the house discussing your previous day's leader, all at once we were surprised with a most peculiar hissing sound in the direction of the lake, about half a mile distant, bringing out all those living around in real consternation, some suggesting an earthquake. Everything wore a most weird aspect. The sound resembled a great rush of water, and lasted for about ten minutes. A few hours after, taking a walk round the end of the lake, we were surprised to find the woods covered with hailstones, lying in some parts to the depth of 4 ins. My wife carried back with her a sheet 6 ins. by 6 ins. by $3\frac{1}{2}$ ins. thick. Half a mile distant we had nothing but a few large raindrops. Those who have been resident here for the last twenty years say they never heard or saw anything like it. Mr. Walker, of the Lake of Menteith Hotel, informs me that while the shower lasted the lake seemed to be just like a pot of water boiling—not, he thought, affected by the shower, but some underground current. The foliage of the trees has suffered much, the leaves being battered and lying like as if from a shower. A farmer in the vicinity has a field of potatoes laid flat. I don't think the radius of the occurrence was beyond half a mile.

The Tower Bridge.—The following technical description (taken from the *City Press*) of the new bridge, which is rising east of the City under the direction of the Corporation, and comparison with London Bridge, will interest, we believe, a considerable portion of our readers:—Total length of bridge, 940 ft.; total length of bridge and approaches, 2,640 ft.; opening span, width, 200 ft.; opening span, headway, when opened, 135 ft.; opening span, headway, when shut, 29 ft. 6 in.; side spans, width, 270 ft.; side spans, headway, from 20 ft. to 27 ft.; width between parapets, opening span 50 ft.; width between parapets, side spans and approaches, 60 ft.; steepest gradient of approaches, 1 in 40 (steepest gradient of approaches of London Bridge, 1 in 7); depth of foundations, 60 ft. below Trinity high-water mark, 27 ft. below bed of river; sectional area of waterway, 20,040 square feet (London Bridge, 19,300 square feet); depth of water in opening span at high water, 33 ft. 6 in.; depth of water in opening span at low water, 13 ft. 6 in. Estimated quantities of materials in the bridge and approaches:—Bricks, 31,000,000; concrete, 70,500 cubic yards; cement, 19,500 tons; granite and other stone, 235,000 cubic feet; iron and steel, 10,500 tons. Machinery, etc.:—Two steam pumping engines for hydraulic machinery, each 360 horse power, eight large hydraulic engines and six accumulators, four hydraulic lifts in towers for passengers; size of each leaf of opening span, 50 ft. wide by 100 ft. long; weight of each leaf of opening span, including roadway and counterbalance weights, 700 tons; estimated cost, £750,000. The engineer is Mr. J. Wolfe Barry; the contractors are—for foundations, Mr. J. Jackson; for machinery, Sir W. Armstrong, Mitchell and Company (Limited).

The Public Health.—According to the weekly return of the Registrar-General, the deaths registered last week in 28 great towns of England and Wales corresponded to an annual rate of 15·8 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The highest annual death-rates, measured by last week's mortality, were:—From measles, 1·0 in Leeds, 1·1 in Leicester, and 1·3 in Halifax; from scarlet fever, 1·0 in Birkenhead, 1·4 in Bolton, and 1·8 in Blackburn; from whooping-cough, 1·4 in Manchester, and 2·0 in Halifax; from "fever," 0·9 in Salford, and 1·3 in Newcastle-upon-Tyne; and from diarrhœa, 1·3 in Wolverhampton, and 1·5 in Liverpool, in Oldham, and in Sheffield. The 35 deaths from diphtheria in these 28 towns included 21 in London, four in Liverpool, four in Manchester, and two in Sunderland. Small-pox caused three deaths in Preston, but not one in any of the 27 other great towns. In London 2,353 births and 1,308 deaths were registered. The annual death-rate per 1,000 from all causes, which had been 15·7 and 15·8 in the two preceding weeks, further rose last week to 15·9. Different forms of violence caused 63 deaths; 49 were the result of negligence or accident, among which were 25 from fractures and contusions, 11 from drowning, and 6 of infants under one year of age from suffocation. In Greater London 3,062 births and 1,570 deaths were registered, corresponding to annual rates of 28·9 and 14·8 per 1,000 of the estimated population. In the Outer Ring 11 deaths from whooping-cough and 7 from diarrhœa were registered. Whooping-cough caused 3 deaths in Tottenham, diarrhœa 3 in West Ham, and diphtheria 2 in Walthamstow sub-districts.

SUN-DIALS, AND HOW TO MAKE THEM.—I.

A CONSIDERABLE number of books were written during the last century on the art of "dialling," or "dialing," as it was then spelt; but if that word had been used as the title to this paper, it is probable that not one reader in a dozen would have guessed its meaning without a glance at the columns below.

"What an antique air," says Elia in his essay on "The Old Benchers of the Inner Temple," "had the now almost effaced sun-dials, with their moral inscriptions, seeming coevals with that great Time which they measured, and to take their revelations of its flight immediately from heaven, holding correspondence with the fountain of light! What a dead thing is a clock, with its ponderous embowelments of lead and brass, its pert or solemn dulness of communication, compared with the simple altar-like structure, and silent heart-language of the old dial! It stood like a garden god of Christian gardens. Why is it almost everywhere vanished?"

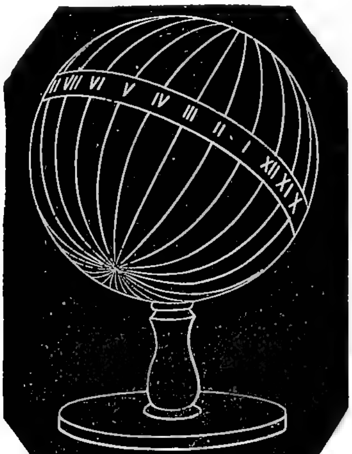

FIG. 1

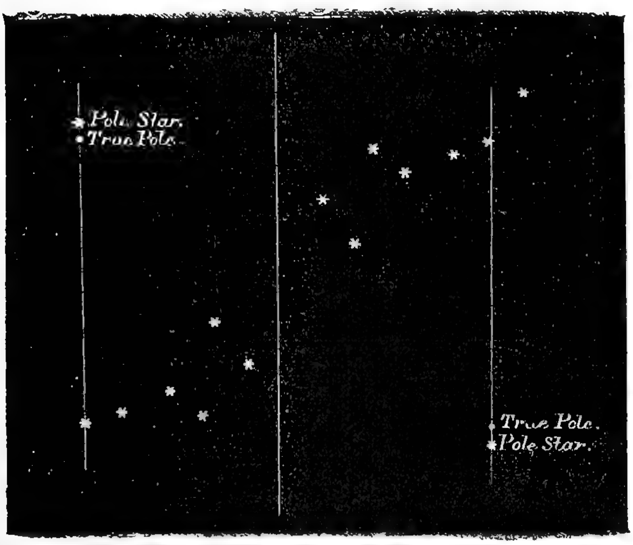

FIG. 2. FIG. 3.

Not only have most of the old dials vanished, but very few new ones are being made. Where a century ago every skilled mason was expected to know something of the art, for a regular art it was, we should now have considerable difficulty in finding anyone but a mathematician who could design the simplest sun-dial. The art was surrounded with no little mystery, and often with a good deal of needlessly involved calculation. The treatises on dialling went, as a rule, into the geometry of the subject, and when this included the consideration of general cases, recourse was had to spherical trigonometry, and the refinements of the art need a certain knowledge of astronomy.

A sun-dial, as a rule, is only adapted for use in the latitude for which it is constructed, and for this reason they cannot be made by the thousand, and the only form in which such a timekeeper can be obtained is that of a small, complicated, and rather expensive "universal" dial at the shop of an optician. Anyone who desires to have a dial painted on the wall of his house, or on the tower or porch of a church, would have a considerable difficulty in finding a workman who could do it.

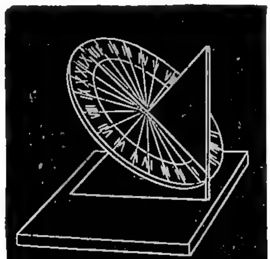

FIG. 4

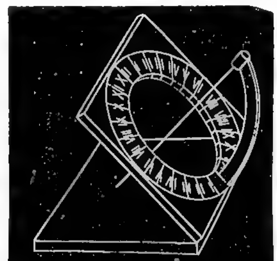

FIG. 5

The following instructions, it is hoped, will render the art of sun-dial making both intelligible and interesting; and a carefully made instrument, which will show the correct time to within two or three minutes, might be both a useful and beautiful object in the humblest garden.

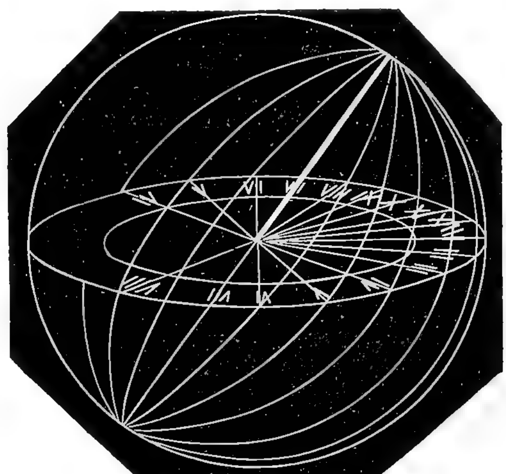

FIG 6

Two motions of the earth have to be considered. First, the perfectly regular revolution of the globe on its axis once in 24 hours. A circle being divided into 360 degrees, the earth moves through 90 degrees or a right angle in 6 hours, and through half a right angle in 3 hours, the motion being uniformly at the rate of 15 degrees an hour. The second motion is that of the earth round the sun. The poles are not at right angles to the path, and, as was explained on p. 373, vol. i., the earth alternately gains and loses part of a revolution, because it does not progress at a uniform speed in its orbit. For this reason the simple sun-dial does not indicate the true time except at the middle of April and June, and at the beginning of September and November. The variation from the true time is given in many almanacks as "sun before," or "sun after the clock." This varies a trifle from year to year, the second year after leap year may be taken as the average. A table of this variation will be given further on in this article.

To an observer on the moon, the earth would form a magnificent timekeeper, hours being marked by the passage of different countries near the Equator into or out of the shadow. Such a dial may be made by setting up a globe so that its axis is parallel to the axis of the earth, as in fig. 1. The north pole of the globe must therefore point to the north pole of the heavens. The Equator being divided into 24 equal parts, the time will be shown by the boundary between the light and the shadow. This line is, however, not well defined, and this renders the method almost useless as a means of determining the time to within a quarter to half an hour, but it is interesting as being the simplest form, as well as that on which all others are based, and in which all others may be said to be contained. Such a globe is sometimes placed on the top of an elaborate dial, and the countries may be represented on it in such a manner that it may be seen at a glance on what part of the globe the sun is shining, and where sunrise and sunset are taking place. The imaginary plane passing perpendicularly through such a globe dial, through its poles, would, if extended, pass also through the poles of the earth. This plane is the meridian of the place, and the line where it cuts the surface of the globe is a line of longitude forming the "great circle" of the place. In setting up any dial it is necessary to find the meridian line. For most purposes this may be done with a good compass, allowance being made for the magnetic variation or declination of the needle from the true north. This is about 17 degrees to the west at Harwich, 17½ at London, 18 at Reading and Peterborough and at places in a line with these towns, 19 at Torquay and Leeds, and 20 at Land's End and Berwick. By drawing these lines on a map, the declination for other places can be found with sufficient accuracy. A large sun-dial can be read to about one minute of time, although one might expect that the edge of the shadow would be too blurred, for the diameter of the sun being about half a degree (see p. 184, first series), and one degree corresponding to four minutes of time, the edge of the shadow is blurred to the extent of about half a degree, or two minutes of time; it is, however, easy to guess the middle of the indistinct part. A fine dial in the gardens of Hampton Court is divided into minutes, and may be read to this degree of accuracy without difficulty. This dial is provided with a table of corrections for "sun before" and "sun after clock" calculated to minutes and seconds, and the same information is given in the form of an interesting diagram in the centre of the dial.

The true north can be found by arranging two fine plumb lines in line with the North Star when the constellation of the Great Bear is in either of the positions shown in fig. 2 or in fig. 3. The middle star of the tail being in a line with the Pole Star and the true Pole. The stars will be as in fig. 2 on the 10th of October at midnight, 10th of November at 10 p.m., 10th of December at 8 p.m., 10th January at 6 p.m., and as in fig. 3 on April 10th at midnight, May 12th at 10 p.m., June 10th at 8 p.m., being 3 min. 56 secs. earlier every day. The Pole Star is about 1 degree 18 seconds distant from the true pole.

The first step towards a practical sun-dial timekeeper is the equatorial or equinoctial dial. This may be supposed to be a thin slice out of a globe dial, the upper and and lower hemispheres being removed, and the axis represented by a thin wire, pointing as before to the North Pole. The circumference of this circle is divided into 24 parts of 15 degrees each, and these may be divided into quarter hours, or into intervals of five minutes, or even minutes, if there be room. As a dial of this kind is very useful in the construction of wall-dials in positions which do not face exactly south, it may be well to remind the reader that it is very easy to divide a circle in twenty-four parts. Draw any circle, and with the same opening of the compasses step round the circumference, thus dividing it into six parts, halve these parts, and then halve again, and these will be the divisions required. The hours may be marked all round so that either side may be used. The XII. line must be set exactly north and south, or in a line with the meridian. The plane of the circle must be set so that it is parallel to the equator of the earth. This is, of course, the case when the axis points to the pole. The angle which the axis makes with the horizon depends on the latitude of the place where the dial is to be used. At the North Pole the dial would be horizontal, and at the Equator it would stand on edge, the axis being horizontal. In either case the VI. line is horizontal, and points east and west.

The latitude of the place where the dial is to be used must be found on a map, and the plane of the dial must be set at this angle of the horizon. The latitude of London is 51½ degs. The angle may be found by a protractor, or by the use of a table of signs or tangents. The angle should be marked on a card, from which a wedge can be cut, and used for adjusting the inclination of the dial with the horizon. Such a dial may be made from a sheet of brass or tin, or even of card, for occasional or indoor use. The axis may be represented by the edge of a piece of metal, as shown in fig. 4. There are in this case really two axes, and two half dials, separated by the thickness of the piece of metal, which is called a style or gnomon. Sometimes a thin wire or thread is used, a support being fixed to hold it, as in fig. 5. In this case, the centre of the shadow must be taken as indicating the time. Many dials are provided with a tolerably thick gnomon, but are divided as though a single axis, such as a fine wire, were used to cast the shadow; their indications will evidently be inaccurate, especially near noon.

The equinoctial dial must be divided on both sides, for the sun will sometimes shine on the upper, and sometimes on the lower side. On and near the days of the spring and autumn equinox, hardly any shadow will be thrown, for the sun will be practically in the same plane as the dial. There are many interesting specimens of equinoctial and other dials among the exhibits of mediæval metal work at the British Museum. These are well worth a visit to any one who is interested in the subject.

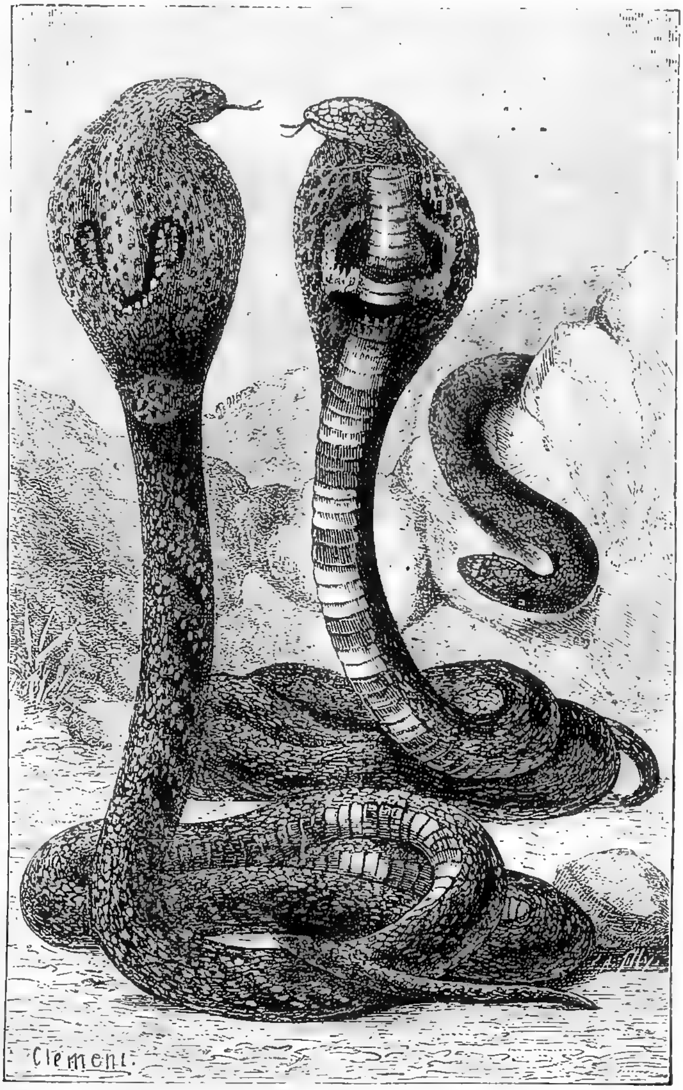
(*To be continued.*)

Natural History.

THE COBRA (NAJA TRIPUDIANS).

Of all the death-snakes the cobra is, beyond all doubt, the most important and the most fatal. Whilst authentic cases of recovery from the bite of the rattle-snake, the jacarandi of Brazil, the lance-head of Martinique, and the tiger-snake of Australia are on record, applied instantly after the introduction of the poison, has proved useless. Perhaps the nearest approach to success has been the maintenance of artificial respiration and the application of electric currents.

The native physicians of India profess to rely upon certain traditional remedies, but when an animal has been really bitten, or, what is always more conclusive, has been inoculated with a minute quantity of the venom, the case has always ended in death.



Cobras.

there is no known instance of the venom of the cobra, if once introduced into the system, proving other than deadly. The only certain exceptions to this sad rule are when immediate amputation of the part bitten has been effected.

We sometimes hear or read of alleged cures, but none of these cases will bear close examination, there being no certain evidence that the bite was really inflicted by a cobra. Numerous experiments have been made upon various animals, in order to test some alleged or supposed remedy, but in all cases the treatment resorted to, though

If the poison, before it is introduced into the blood, be mixed with the chloride of platinum, it is in some unknown manner decomposed, or at least rendered inert. But if the poison is once instilled into the body, it is useless to send the chloride of platinum after it. The supposed remedy cannot overtake the venom, and merely spends its action upon the blood. So far as it is yet known, no animal enjoys any immunity from this poison; all, if bitten, succumb. Nay, if the venom is merely applied to the eye-ball, the lips, or to any mucous membrane, the result is the same. It was formerly supposed that the mungus (*Herpestes griseus*) was proof against all serpent bites. This little animal is indeed wonderfully successful in destroying the cobra and other Indian death-snakes, but it effects its task simply by its wonderful agility, which enables it to tear open the throat of the snake before the latter can plant a bite. But if a mungus is inoculated with cobra-venom it perishes, just as would a rat, a dog, or, for the matter of that, a man.

The body of this formidable serpent is rounded, slightly thickened about the middle, and the head has the same width as the neck, so that it presents, when at rest, very much the same appearance as the ordinary non-poisonous snakes. When excited it erects the anterior part of its body and expands the skin of its neck, so as to form a kind of hood extending behind the neck. The gape of the mouth is wide, which gives greater facility for biting. On each side of the upper jaw there is a poison-fang. The fangs are not, as in some serpents, capable of erection and depression, but are immovable.

In colour this formidable reptile varies. Most commonly its general colour is of a uniform deep brown, sometimes verging on black, and often intersected on the side by white transverse stripes. When the neck is distended, there appear behind two white spots with black centres, connected by a white arch bordered with black, and presenting a rough resemblance to a pair of spectacles.

In length the cobra varies from 2 feet to 2½ yards. It inhabits India, Ceylon, the Eastern peninsula from Burma to Siam and Tonkin, and even the more southern parts of China. It is common in the Western portion of the Malay Archipelago, but it has never yet been found in Celebes, the Moluccas, New Guinea, or Australia. In Persia, Arabia, Egypt, and in the north, east, and south of Africa it is replaced by a kindred species, *Naja Haje*, very similar in its habits and in the intensity of its venom, but for the most part smaller. In India the true cobra is exceedingly numerous; it haunts drains, wells, water-holes, old tree-trunks, ruined walls, stone heaps, etc. Far from shunning man, it frequents by preference towns and villages, and enters houses. It pursues fishes in the streams, climbs palm-trees to capture birds, and hunts for mice, rats, lizards, frogs, etc., in gardens and courtyards. These habits, in addition to its nocturnal character, make it much more dangerous than it would be if it confined itself to the woods and the marshes. It is said that in British India alone more than 10,000 persons perish yearly from its bite, so that its destruction, if possible, becomes an imperial interest.

It seizes and swallows its prey at once, neither strangling its victims by constriction, like the pythons, nor biting and then waiting until the venom has taken effect.

The nature of this serpent's prey raises a very difficult question. Why or how should the cobra elaborate a poison so much more powerful than it apparently needs? The intensity seems a luxury. To a creature feeding on rats and mice, what use is it to be able to kill a dog, a swine, a man, perhaps a tiger or a panther? For defence it can scarcely be, since the wounded animal, though sure to succumb in a couple of hours, has ample time to take its revenge.

The pugnacity of the cobra, and its confidence in its own resources are boundless. It needs very little provocation to act on the offensive. Had Waterton studied the cobra and, indeed, certain other Indian and African serpents, he could not have said that they flee from man and never pursue a retreating enemy. It is on record that a dog, seeing two cobras in a meadow, committed the indiscretion of barking at them. The snakes, instantly uncoiling, gave chase. The dog leaped into a river, but the cobras, overtaking him in the water, bit him so viciously that he died in less than an hour.

It is curious that the snake-charmers of the Far East are fond of exhibiting tamed cobras in their performances. It is sometimes said that the poison-fangs are carefully broken out of the cobra's jaw. But we are inclined to suspect that these serpents are hypnotised—a state to which reptiles have been proved to be susceptible. They are even, it is reported, rendered stiff and inflexible as rods—in other words, thrown into a state of catalepsy—and in that state are handled and flourished about by the jugglers. Here, however, further investigation is wanted.

NOTES ON THE TIGER.

Mr. Inverarity communicated, a short time ago, to the Bombay Natural History Society, a paper on this subject, from which we make some extracts. The size of the animal is apparently often exaggerated. The author thinks that the majority of tigers are under 9½ feet. The measurements taken by sportsmen are, however, invariably deceptive, as they persist in running the tape from the tip of the nose to the end of the tail, instead of to the root. As the tail bears no fixed proportion to the size of the animal, the result is worthless. Tigers are supposed to breed once only in three years, which Mr. Inverarity coolly pronounces "unsatisfactory intelligence for the sportsman."

These animals, it appears, may reach the age of twenty years. The evidence on which this statement rests shows the mischief resulting from the neglect of sportsmen to use poisoned bullets.

In weight the tiger ranges from 350 to 700 lbs.

The author denies that tigers in killing dislocate the neck or sever any important blood-vessel. Large and powerful animals like the bull buffalo and bull bison (a bison in India!!) are attacked from behind. Occasionally the tiger will feed upon the dead bodies of its own species. Mr. Inverarity has never met with any instance of the "sledge-hammer stroke" of the fore-paw of a tiger. Lastly, we notice that this beast is not absolutely unable to climb trees, as it is commonly believed.

Abnormal Habits of Animals.—Correspondents of the *Field* declare that in Britain rabbits have been occasionally known to climb trees, and two cases are given of dogs having performed the same unlikely feat. Hares are also said sometimes to burrow, and rabbits to swim.

Sensitiveness of the Eye.—The sensitiveness of the eye for different colours is not identical. Herr H. Ebert (*Cosmos*) finds that it is greatest for green. Then follow red, greenish-blue, yellow and blue. A spectrum very dimly illuminated appears as a uniform grey band.

THE LOCOMOTION OF CATERPILLARS.

In a communication to the Academy of Sciences M. G. Carlet describes the result of his observations on the locomotion of caterpillars. It has been hitherto supposed that when creeping, the two feet of the same pair are never moved together, a notion which the author fully refutes.

It is well known that the body of caterpillars is composed of twelve rings, exclusive of the head. The three first rings support each a pair of pointed legs, which we may call 1, 2, 3; then follow two footless rings, followed by four rings bearing each a pair of broad, wart-like legs, frequently armed with hooks, and known as *pseudo legs* or *false legs*, because they disappear when the insect assumes its adult condition. We may name them 4, 5, 6, 7. Then come two more rings without legs, and lastly the end ring with two membranous feet, the *anal legs*. Thus, except in some exceptional cases to be mentioned hereafter, a caterpillar has sixteen legs.

If we take a common caterpillar, and let it creep on a flat slip of wood, held on a level with the eye, we see that the two feet of each pair are always lifted together.

Suppose a caterpillar at a standstill, with its body stretched out. Its first movement is to detach the anal pair (8), and bring them up to the pair 7 by contracting the two penultimate footless rings which separate them from 7. The pro-legs (4, 5, 6, 7) are then released *from behind forwards*, in the order 7, 6, 5, 4, and are at the same time pushed forward by slackening the two penultimate footless rings, like a spring set loose. This series of progressive movements of the rings arrives, like an undulation, at the two anterior footless rings. These rings are compressed by the release of the two hinder footless rings, and the pair of legs 4 are thus brought close to the pair 3. This pair is then raised, and in quick succession the pairs 2 and 1.

We thus understand why the false legs are so robust in comparison with the others. They might be called mooring feet, since they really support the caterpillar and govern its movement. They also secure the caterpillar in its situation at the moment of its transformation.

We may now understand why the Cossus and certain other wood-gnawing caterpillars have their false legs membranous, or devoid of hooks. This arrangement is in harmony with their manner of life in the tree trunks in which they excavate their galleries, much as do the larvæ of the wood-eating Coleoptera, which have either very short legs or none at all. In compensation, their masticatory apparatus is developed in proportion to its activity—that is, inversely as the locomotive organs. In both cases the same mode of life has brought about similar arrangements in creatures belonging to different groups. The foregoing considerations explain also why, when caterpillars have only three pairs of false legs, the three last pairs remain. If there are only two pairs of false legs we find the two last only, and then the caterpillar, deprived of all intermediate legs, arches its body into a loop, so as to approximate the true legs to the false legs. It then detaches the true legs from their foot-hold, and advances them in order to fix them again. This kind of locomotion places them at some disadvantage in comparison with other caterpillars having sixteen legs. But they have other means of escaping from their enemies. In fact, the caterpillars which feed upon the bark of trees have a grey or greenish colour, which enables them to pass unperceived. They also remain fixed by their hind feet, with the body stiffened, so as to imitate a twig.

[We can by no means admit that the looper or spanner caterpillars (*Geometræ*) are slow in their movements.—Ed. Scientific News.]

THE ZOOLOGY OF THE BATH DISTRICT.—I.

THE immediate neighbourhood of Bath, although very picturesque and beautiful, is a somewhat disappointing locality for the naturalist, consisting, as it does, mainly of well-cultivated lands, with no wilder portions, no undrained marsh or fenlands, no uncultivated moor, or heath, or wood that has remained for centuries unreclaimed and, untouched. The neatly cropped hedgerows, the regularly mown railway banks, and even the mud periodically scraped out of the canal—the order and neatness everywhere observable are all great drawbacks to the collector of zoological treasures.

The most promising features are the Avon and the Kennet and Avon Canal above Bath, and the valley of the Avon below, towards Bristol, also a few small patches here and there, as on Lansdown, Claverton Down, etc.; better still, but rather out of the district lie the turf moors of Shapwick and Glastonbury. These are happy hunting-grounds for the entomologist or student of other invertebrate branches, mollusca, etc., and will yield rich harvests to those who will work them carefully, and are also the spots most likely to be visited by the migratory birds and other accidental visitors.

To begin with the higher branch—namely, mammalia—of the ordinary feræ, the badger (*Meles taxus*) and the otter (*Lutra vulgaris*) seem commoner than farther east. The stoat, or ermine (*Mustela erminea*), and the weasel (*Mustela vulgaris*) are very abundant; curiously enough, some of the country folk invariably reverse the names of these two species, calling the *smaller* one the stoat, and the *larger* one the weasel.

The polecat (*Mustela putorius*) is getting almost extinct in the district; 1879-80 is the last reliable record of its occurrence; thirty years ago it was quite common, and has been seen in very severe weather, hunting in packs of ten or more individuals.

Of the bats seven species occur. The noctule (*Vespertilio noctula*) is somewhat rare. The pipistrelle (*Vespertilio pipistrellus*) is also rare, although the commonest bat in many parts of England. The whiskered bat (*Vespertilio mystacinus*), "said to be very rare in England," is quite common round Bath in the roofs of old houses. The reddish-grey bat (*Vespertilio nattereri*) also occurs, although rare; two specimens may be seen in the "Duncan Local Museum," at the Bath Literary Institution. The eared bat (*Plecotus auritus*) is fairly common. The great horse-shoe bat (*Rhinolophus ferrum-equinum*) and the lesser horse-shoe bat (*R. hipposideros*) both occur in stone-quarries; the latter is much the rarer of the two.

Mr. Charles Terry, F.R.C.S., in "Wright's Historical Guide to Bath" (1864), gives a list of the fauna within a radius of six miles of Bath. He therein mentions six species of bats, one of which (*Vespertilio emarginatus*), the notch-eared bat, is most likely a mistake; he makes no mention of *V. nattereri*, or *V. mystacinus*.

Of the Insectivora, the mole (*Talpa vulgaris*), the hedgehog (*Erinaceus Europæus*), and the common shrew (*Sorex tetragonurus*) are abundant. The beautiful little water-shrew (*Sorex fodiens*) also occurs, but is rather scarce; this species is easily distinguished from the former by its rather larger size and by the distinct line of demarcation between the dark upper portion and the light (almost white) lower portion. The variety which has been described as *Sorex remifer* is mentioned by Mr. Terry in his list.

Of the Rodentia, the dormouse (*Myoxus avellanarius*) is fairly common, but local, mostly on the margins of woods. The water-vole or water-rat (*Arvicola amphibius*), is somewhat scarce in the banks of the Avon, but gets more abundant lower down, towards Keynsham and Bristol, where the black variety occurs. The short-tailed field-mouse, or field-vole (*Arvicola arvalis*), is fairly common. The bank-vole (*Arvicola pratensis*), although considered a rare and local species, is also fairly common, especially so nearer Bristol, where it abounds in Leigh Woods.

The black rat (*Mus rattus*) is very rare, much more so than in Bristol, where in some warehouses they are plentiful, and are said by the rat-catchers to be fiercer than their bigger and too-abundant rivals, the brown, or Norway rat (*Mus decumanus*). The long-tailed field-mouse (*Mus sylvaticus*) is very abundant, and is the most destructive species in the neighbourhood. The pretty little harvest-mouse (*Mus messorius*) also occurs, but is rare and difficult to obtain.

Of birds, the district can show a good list, at least of inland species. Mr. Charles Terry gives a list of 159 species, of which, however, twenty are only single instances or purely accidental occurrences. Among the Raptores the peregrine falcon (*Falco peregrinus*) is often seen, sometimes hovering over the town on the look out for some unfortunate pigeon; but it is very rarely shot, owing to its extreme wariness. The buzzard (*Buteo vulgaris*) is getting scarcer every year. The honey-buzzard (*Pernis apivorus*), the little owl (*Athene noctua*), and the scops owl (*Scops giu*), although on record, are hardly likely to occur again. The instances on which the record is founded are very doubtful, and date nearly fifty years back

The great grey shrike (*Lanius major*) has occurred several times of late years, although it generally keeps farther west and nearer the coast, as at Clevedon, Weston-super-Mare, etc. The pied fly-catcher (*Muscicapa atricapilla*) will be found to occur occasionally, and even stay to breed, if undisturbed. The dipper (*Cinclus aquaticus*), of which a beautiful nest is in the "Duncan Local Museum," from Wellington, is occasionally seen; its congener, the ring-ouzel (*Turdus torquatus*) is sometimes seen also, though very rarely, preferring the wilder parts of the county, as, for instance, at Dulverton, where it regularly breeds. Our beautiful summer visitor the whinchat (*Pratincola rubetra*), is commoner than the stonechat (*Pratincola rubicola*), though the contrary is the case farther east; it often nests on the G.W.R. embankments. Of the warblers, the sedge-warbler (*Acrocephalus phragmitis*) is very common by the banks of the Avon; and the reed-warbler (*Acrocephalus streperus*) is not uncommon, though much more local than the former; it seems to prefer some quiet, undisturbed pond, overgrown with rushes. Six or seven pairs have been found nesting in such a locality. That rarity the marsh-warbler (*Acrocephalus palustris*) is also very likely to reward a careful study of the local warblers; it has nested farther south, near Taunton, and farther north, near Gloucester, and should occur in the many suitable spots near Bath; it is more than likely to have been overlooked, owing to its resemblance to the reed-warbler. The grasshopper-warbler (*Locustella nœvia*) is often heard, but rarely seen. The garden-warbler (*Sylvia hortensis*) is not uncommon, but very local in its distribution.

The cirl-bunting (*Emberiza cirlus*) some seasons can hardly be called rare; it nests in the district. The snow-bunting (*Plectrophanes nivalis*) is also an irregular visitor, *vide* some good specimens in the local museum. That handsome bird the reed or black-headed bunting (*Emberiza schœniclus*) is very common in the Avon meadows. The siskin (*Chrysomitris spinus*) is captured some autumns in considerable numbers. The lesser redpole (*Linota rufescens*) is also a regular visitor in autumn and winter; sometimes a few pairs breed in the district. The hawfinch (*Coccothraustes vulgaris*) is also an irregular visitor, a nest from Coombe Down is in the local museum. Of woodpeckers, the greater spotted (*Dendrocopus major*) and the lesser spotted (*Dendrocopus minor*) both occur very locally, and are seen year after year in the same wood. Fifteen or twenty years ago the "lesser" was the commoner of the two; of late years the "greater" has occurred most frequently. The rare visitor the hoopoe (*Upupa epops*) has occurred several times, as also the bee-eater (*Merops apiaster*), one at Widcombe, 1850, and three near Bristol, 1870, shot whilst hawking round bee-hives.

Of the doves the ring-dove, or wood-pigeon (*Columba palumbus*) is very abundant. The turtle-dove (*Turtur communis*) is not uncommon in summer; the stock-dove (*Columba œnas*) is rare. That interesting visitor the sand-grouse (*Syrrhaptes paradoxus*), whose incursion this year has caused so much comment, has come near the district, a fine male having been shot in July on Ken Moor.

The sandpipers are poorly represented, with the one exception of the common sandpiper (*Tringoides hypoleucos*), which is numerous in the Avon meadows; the other species only occur as rare stragglers, keeping, as a rule, farther west, nearer the coast. The grey phalarope (*Phalaropus fulicarius*) has been shot on several occasions; five were obtained in 1840, and several others as rare visitors since.

Of the Ardeidæ, the common heron (*Ardea cinerea*) is fairly common, and the bittern (*Botaurus stellaris*), though scarce, and getting much more so of late years, has occurred several times at Bathampton, Kelston, and Lansdown. The spotted crake (*Porzana maruetta*) occurs as a regular visitor, though rarely obtained, owing to its skulking habits. The coot (*Fulica atra*) is often seen on the Avon in the winter, and breeds in other parts of the county. Of the ducks, the peat-moors about Shapwick are regularly visited by some rarities, as, for instance, the beautiful shoveller duck (*Spatula clypeata*). Of the grebes, the little grebe (*Tachybaptes fluviatilis*) is a resident, and the Sclavonian grebe (*Podiceps auritus*) and the great crested grebe (*Podiceps cristatus*) occur now and then as visitors.

Only the commoner gulls come up the Avon, as, for instance, the common gull (*Larus canus*), the black-headed (*L. ridibundus*), and the kittiwake (*L. tridactylus*), this latter somewhat scarcer, and an occasional herring-gull (*L. argentatus*). The common and Arctic terns (*Sterna fluviatilis and S. macroura*) have been seen, though very rarely, over the canal, and once or twice a lesser tern (*Sterna minuta*).

The fork-tailed petrel (*Procellaria leucorrhoa*) and the storm-petrel (*Procellaria pelagica*) have both been picked up in the neigbourhood, evidently driven out of their way by gales.

(To be continued.)

THE NATURALIST AT THE SEA-SIDE.

IV.—THE MARINE AQUARIUM.

BY this name very different things may be understood. There are the homes of pet anemones, built carefully and well tended, and there are the rough adaptations of household vessels, extemporized by the working biologist. These latter may be soon dismissed, though they are for real study far more important than the other and relatively permanent sort of aquarium. Nothing is handier for larvæ, and crustacea, and zoophytes, fresh caught and awaiting examination, than a row of tea-cups. The opaque sides and white inside are exactly what is wanted. A can of sea-water carried up from the beach once or twice a week will suffice to change the effete water, and daily aeration with a glass syringe is the only other necessary means of health. Bits of sea-weed are generally desirable, and certain creatures absolutely require mud or sand.

Though it is true that such hasty provision as we have described is perfectly suited to the collector who has the sea at his doors, the inland naturalist must have his more difficult requirements considered. Everything is now changed by the circumstance that sea-water is hard to procure in large and frequent supplies. With good management, one filling may be made to last for years, and attention must be paid to the only way in which this is possible. The tank should be long, and not very deep or broad. If the ends are square, and the length twice or thrice the depth, the proportions will be found good and convenient. Place the tank in a window. In the bottom fit loosely a number of roofing-slates, each a little longer than the width of the floor, which may form a false bottom, sloping away from the light at an angle of about 25°. Paste a strip of opaque paper on the outside of the glass, so as to darken effectively the space beneath the slates. You have now beneath your aquarium a capacious dark chamber in which life is discouraged. The water, of course, communicates freely with that in the upper chamber, and keeps all cool and fresh. Aerate the tank daily with a glass syringe, and fill up with fresh water as requisite. Two glass bulbs, so weighted that one just floats, while the other just sinks in sea-water, may be bought of the dealers, and these are convenient for indicating the exact amount of water to be added. Failing these, a mark on the side of the tank can be made to do. Rock-work is desirable, but care must be taken to avoid cements which contain red lead or caustic lime. After the tank is complete, but not stocked, it is a good plan to fill it first with fresh water for a fortnight, then with sea-water for another fortnight, and lastly with a second, and, let us hope, final quantity of sea-water.

In the old days, before Lloyd had shown what was possible and what was not, the enthusiast used to plant his aquarium with *Fucus or Laminaria*, and then introduce star-fishes, anemones, crabs, and perhaps a fish or two. In a few days the things began to die, and after a fortnight the aquarium was in the condition of a sewage-settling tank. Long experience has shown the impracticability of these ambitious ventures. Without a good deal of attention and special precautions, nothing can be trusted to thrive except anemones and such vegetation as springs up spontaneously in the tank. The slates and the glass sides soon turn green with confervæ, and this helps materially to sweeten the water. Many species of anemone thrive wonderfully in inland tanks, and some of the most beautiful forms can be kept for many years in this way. Don't feed them at all. They require very little, and that little they find for themselves. One common species (*Tealia crassicornis*) does not survive long in confinement. Its base is very tender, and it is generally fatally injured in removing it from its native rocks. The emission of young anemones is a frequent event, but the young brood hardly ever produces a well-grown individual. In our own experience no single case of the successful rearing of a young anemone has occurred.

The anemone-tank, well managed, may be made as gay as a flower-garden. Varied in colour, and form, and texture, some standing up on the bottom, others projecting from their chosen niches in the rockwork, the polyps delight the eye with their waving tentacles, their gem-like spots, and their discs painted like cathedral glass. It gratifies abundantly that delight in curious and beautiful sights which is a great part of the charm of natural history to glance daily at a richly stocked and well-managed anemone-tank. But there is little to be learnt from it. The creatures whose habits and modes of life are better worth daily observation and study can only be kept alive where a large body of water is mechanically circulated or where loving diligence is spent upon their welfare. It is possible, but not easy, to keep very curious and active marine animals, tube-dwellers, or creatures with strange transformations, alive for months in places far from the sea. The secret lies in isolation of each species and continual supervision. Tiny aquaria of the tea-cup or glass-tube pattern are wanted. If there is a large anemone tank at hand for changing the water daily, so much the better. A neat-handed observer, not afraid of trouble, will find many things possible which the ordinary amateur, enthusiastic but not persevering, cannot be recommended to try.

If mechanical circulation with a limited supply of sea-water is urgently required, the following plan can be recommended: Arrange three or any larger number of glass bowls on shelves, so as to secure slight differences of level. Connect the bowls by bent tubes, which may act as siphons. Start the circulation with the top vessel full and the bottom one empty. A gentle stream will then traverse the whole series, and the current can be renewed at pleasure by emptying the bottom vessel into the top one. If the system is on so large a scale that difficulty is met with in raising the surplus water to the top, some simple mechanical contrivance, such as a bucket and pulley, may be employed. If muslin strainers are attached to the ends of the siphons a great variety of animals may be kept distinct, each set being confined to its own tank.

Reviews.

The Midland Naturalist. Vol. XI., Parts January to July, 1888, inclusive.

Among the many important papers in this journal we may particularly notice that on the function of tannin in the vegetable kingdom, by Mr. W. Hillhouse, F.L.S. The author finds no evidence that it ranks as a food-material analogous to starch, glucose, or oil.

Mr. W. Jerome Harrison expounds the aid which may be rendered to geology—as, indeed, to other branches of science—by photography, and complains justly that "nine out of ten people still think of photography as simply a mechanical way of taking portraits."

Mr. Hillhouse contributes three papers on the "Present and Future of Science-Teaching in England." This able writer asks, "What proportion of an average schoolboy's existence is given to physical or biological science, the knowledge of the world which surrounds him, of the laws which govern his existence, and which will govern him in his struggle for the power to live? Is it one-half? No. One-quarter? No. Doubtful even if it is one-eighth in the best of cases, and from that it sinks away to nothing! And yet we pride ourselves upon being a practical people, when it is doubtful whether one more unpractical, more improvident, exists upon the face of this earth." He concludes his last paper with the weighty remark, "The golden rule of our educational method of the future will, I believe, be not to accumulate information, but to cultivate ability; not to cram the brain, but to train and develop the faculties. Knowledge may indeed be power, but intellectual power is more than knowledge."

Mr. Wragge, the Government Meteorologist of Queensland, gives an account of the climate and resources of this important colony. He considers that the underground water-supply, even in the western parts, where the rainfall is scantier than on the coast, is ample.

An article by Mr. J. G. Baker, F.R.S., F.L.S., on "Kew Gardens and the Botanical Statistics of the British Possessions," is exceedingly interesting. The number of plant species inhabiting the British Empire is estimated at 46,000, or very nearly one-half of those found on the entire earth. The late Sir W. Hooker planned, we learn, a series of works classifying and defining the plants of the empire upon one uniform system. The volumes for Australia, New Zealand, Hong Kong, the West Indies, and Mauritius are finished; that for India is far advanced; those for the Cape and the West Coast possessions are about half finished.

It is not generally known that the Princess Augusta, the mother of George III., was the originator of the Botanical Gardens. The Earl of Bute, the unpopular Premier in the early part of the reign of George III., was an enthusiastic botanist, so much so that he spent £10,000 in printing an elaborate botanical work in nine volumes, of which only twelve copies were struck off. One of the chief objects of Kew Gardens is the horticultural and agricultural benefit of the Colonies. The total number of plants there cultivated is nearly 50,000.

"Passages from Popular Lectures," by Mr. F. T. Mott, F.R.G.S., includes an account of the umbelliferous plants. Here we find a passage to which grave exception may be taken. Says Mr. Mott, "The world will never cease to remember with shame and grief the death of Socrates." If we reflect that he turned away the minds of men from the study of physical and biological science, and that he seems to have originated that antithetical distinction between "Nature" and man, which we are now under the guidance of Darwin beginning to reject, we can only consider the Socratic movement as an apostacy. Though his execution was a judicial murder, it was of little moment as compared with that of Lavoisier.

A Handbook for Steam Users. By M. Powis Bale, M.I.M.E., A.M.I.C.E. London: Longmans, Green, and Co.

A useful, practical little book, that would repay perusal by all users of steam-engines, as a knowledge of its contents would enable them to exercise some check on the frequently incompetent men allowed to have charge of boilers. We suppose it would be too much to expect boiler attendants to read this book themselves until it is made compulsory for them to have a certificate of competency before being allowed to take charge of boilers. We agree with the author that there is little doubt that many disastrous explosions have been clearly traced either to the gross ignorance of the attendants or the criminal carelessness of the owners, and without an adequate system of compulsory inspection and certificates of competency we are likely to hear of many more of these "accidents."

Twelfth Annual Report of Her Majesty's Inspectors of Explosives; being their Annual Report for the Year 1887, presented to both Houses of Parliament by Command of Her Majesty. London: Her Majesty's Stationery Office.

Few persons, we imagine, will question the utility of Governmental inspection and regulation in the manufacture of explosives. Without such interference this industry would constitute a grave danger, not merely to the men employed, but to all persons living in the neighbourhood.

The first point we notice in the report before us is a curious inconsistency in the Explosives Act, which has only just been perceived and amended. Picric acid has long been known to be violently explosive under certain conditions and in certain combinations or mixtures. It is, in fact, supposed to be one of the ingredients of the new French explosive, melinite. Hence its manufacture and storage came very naturally within the scope of the Act. But there was a curious and most illogical proviso—*i.e.*, that it was amenable to control only if made for engineering, military, or pyrotechnical purposes! If manufactured, as was at one time largely the case, for use in dyeing or in the preparation of other colours it was exempt.

An accident which occurred on June 22nd, 1887, at the chemical works of Messrs. Roberts, Dale, and Co., of Cornbrook, Manchester, opened the eyes of the authorities to the very plain fact that the properties of a substance in no manner depend on the purpose or intention with which it is made or sold. They have also doubtless learnt that a manufacturer or merchant does not always know to what use his customers intend to put the articles which they buy. Messrs. Roberts and Dale are, we believe, chiefly, if not exclusively, manufacturers of chemicals for dyers and tissue-printers, and in not placing their works under Government inspection they were acting in a perfectly legal manner. The conclusion arrived at in the inquiry was that the accident originated in a fire at or close to the stove in which picric acid was drying. The fire was caused by one of the workmen, named Heyes, smoking. The main explosion was due to the detonation of a quantity of picric acid or of some self-formed picrate. Only one death resulted, but the damage to property was very considerable.

In consequence of this accident, picric acid, the picrates, and their mixtures, with other substances, now come under the definition of explosives, unless wholly in solution or made and stored in a building exclusively appropriated and adapted for the purpose.

Only eight deaths have occurred in connection with the manufacture of explosives; the annual average for the ten years is 7·5. During the years immediately preceding the operation of the Explosives Act it was 37 per annum.

The Inspectors remark with pleasure that the workmen are very generally beginning to understand that the regulations enforced are for their benefit and protection. Local authorities, however, too often exhibit a lamentable amount of carelessness.

Only two prosecutions for irregularities have taken place. The secret and illegal manufacture of explosives for criminal purposes is by no means at an end, nor will it be until the local authorities are more vigilant, and until the public, whose safety is at stake, call attention to every suspicious circumstance they may observe. Special precautions are required to guard magazines against unlawful entry and abstraction of any portion of their contents. We should beg to suggest, in addition, the introduction of electric alarms, which would at once indicate any entrance after business-hours.

A source of danger to the public is the illegal conveyance of explosives under false names in railway-carriages. One man was found to have left 5 lbs. of dynamite on the rack of a carriage, labelled "Knives and forks." He was fortunately detected and convicted. Carts loaded with dynamite have been sent to mines without even a cover, and with none of the other precautions which the Act enjoins. Perhaps the most glaring case is one which occurred this year on the Thames below London. A fleet of barges, the property of a man who had contracted to convey live shell, gunpowder, etc., for Government, was left moored for some days without any men in charge. It is obvious that the heaviest penalty which the Act enjoins falls sadly short of the exigencies of such a case.

THE FIG TRADE.

THE ordinary edible fig, though in strictness a tropical or at least sub-tropical fruit, is capable of cultivation over a very large part of the temperate zones. The tree thrives in England and resists such winters as that which has just come to a close, whilst many native British plants have been destroyed in the same gardens. It ripens its fruit in the open air, in a fair season, not merely along our south coasts, but in south-western Essex and in sheltered situations, even in the Midlands. The fig tree has the great advantage that it is very rarely molested by vermin. Cats do not sharpen their claws against its trunk, but smell at it and turn away with an air of disgust. As a matter of course, the tree flourishes better and bears more luxuriantly in the south of France, in Spain, Italy, Greece, and Northern Africa. It is still better adapted to the climates of South Africa and Australia, where Baron Müller recommends it for cultivation on account of its power of resisting dry weather.

But whilst figs are thus produced over a very extensive part of the earth the dry fruit of commerce, the "Eleme," is obtained exclusively from one locality in Asia Minor, a slip of land in the fruitful valley of the Mæander, perhaps sixty miles in length by eight miles in breadth, beginning near the site of ancient Ephesus. This valley produces annually about twenty-five million pounds of figs, a great part of which are exported.

Of the many kinds of this fruit known to the horticulturist two only are cultivated on the large scale in the Mæander valley. There is a short kind, plump and pulpy, and of a deep purple colour approaching to black. This kind is preferred for eating whilst fresh, and is hawked about in the East to the well-known cry, "In the name of the prophet, figs!" A larger greenish-yellow kind is preferred for exportation, as it bears the packing and carriage better. The fig season begins about the end of August and finishes early in October. The fruit is not plucked, but allowed to fall when fully ripe. It is not injured by the fall, as the trees are not high, and as the fruit, moreover, grows by preference on the lower branches. But the figs when thus fallen cannot be suffered to lie even a day upon the ground, as they are then apt to turn mouldy and spoil. The whole rural population, men, women, and children, turn out in a body to collect the harvest in baskets. Layers of rushes or flags are laid upon the ground in some part of the gardens, fully open to the sun and not shaded by trees, and upon these the figs are spread out to dry. At first they touch each other but they soon shrink so as to leave intervals. In five days they are sufficiently dry for packing, and the sorting begins. The finest alone were formerly known as "Eleme," which is not the name of a place, but means chosen or selected, just as the finest quality of gum Arabic is termed "elect." Latterly the name has been given to all grades, except the poorest, such as are often sold threaded upon strings or rushes. Each grade is put separately into coarse, porous sacks of goats' hair. These allow a very free passage for the air, even if quite full, so that there is no danger of the fruit becoming mouldy. Each sack when full weighs about two quintals—say 250 lbs.—and in these they are conveyed upon camels to the nearest station on the line to Smyrna.

By one of those curious conventions which we encounter in nearly all countries and in all spheres of human activity, each camel must carry two such sacks. As camels differ among themselves in strength quite as much as do other beasts of burden, it often happens that one is overloaded whilst another could, without inconvenience, carry half as much more. But no one departs from the time-honoured routine.

The fig market at Smyrna consists of two dirty streets, in which the sacks are deposited on the ground so as barely to leave room for the camels to pass between.

To this market come Greek merchants, who act as middlemen, and who generally secure a larger share of the profit than falls to the lot of the cultivator.

These Greeks most commonly sell the fruit to the packers, and these in turn dispose of them to shippers. Sometimes, indeed, the shippers buy at once from the grower, who is represented by the *devegee*, the camel driver who has conveyed the crop to market. The *devegees* are always Turks, and as invariably honest, which can scarcely be said of all the other persons engaged in the traffic.

Next comes the packing—perhaps the most interesting, and certainly the least appetising, stage of the business. The first step is a re-sorting, executed by women. Then follows the "pulling." Each fruit is seized by a man who dips his hand into a can of salt water, flattens the fig between his fingers, gives it a peculiar pull which causes it to split at the stalk end, and lays it neatly in the box. For the cleanliness and the healthiness of these men there is no guarantee. It would be well indeed if these operations could be executed by machinery. The salt water is said to bring out the sugar of the fruit to the surface in about three months' time, and the fruit is then in the best condition for use. The best kind are mostly packed in boxes, and the intermediate qualities in drums, holding from 3 to 9 lbs., or in casks holding more than 1 cwt. Inferior grades are packed in bags, and serve for the manufacture of various concoctions.

We are told that such figs, from their multitude of "seeds," are found useful for mixing with strawberries and raspberries in the production of artificial jams, being boiled up with vegetable marrows, glucose, "fruit essences," and appropriate colouring matters.

Two remarkable facts concerning the fig are not generally known. The fruit is not, like a plum, an orange or an apple, a unitary product, developed from a single blossom. Every fig contains, or has contained, within it a multitude of blossoms, each of which becomes one of those tiny granules found embedded in the pulp, and erroneously called "seeds."

The second memorable point is that, although the fig is perfectly wholesome, the juices of the leaves and the bark are somewhat poisonous, which may account for its general immunity from the ravages of aphides, caterpillars, etc. Some of the near kindred of the common fig tree, such as *Ficus toxicaria* and *Ficus dæmonum*, are well known in India for their venomous character.

Abstracts of Papers, Lectures, etc.

ROYAL SOCIETY.

At the last meeting a paper "On the Electromotive Changes connected with the Beat of the Mammalian Heart, and of the Human Heart in Particular," was read by Augustus D. Waller, M.D. The electromotive properties of various animal tissues (muscles, nerves, glands, retina), and the changes which these properties undergo with activity have occupied a large share of the attention of physiologists during the last hundred years, since the memorable observations of Galvani and of Volta (1786-1798). And in recent years evidence of similar electromotive changes has been sought for and found even in man; two notable experiments are quoted in the physiological literature of this subject, by Du Bois-Reymond and by Hermann, to show that the contraction of human muscle is attended with electromotive changes. It cannot be said, however, that either of these experiments are free from doubt, nor that they furnish anything beyond a problematical illustration of facts which can be analysed only upon isolated tissues. The observations, of which a brief summary was given, deal with an entirely new aspect of the subject; they furnish a demonstration in man of the electromotive changes which accompany each contraction of the heart. The author states that it is possible, by leading off from various parts of the surface of the body to a capillary electrometer to observe upon animals and upon man variations of potential coinciding with and dependent upon the heart's beat, and he showed photographic records of these variations.

ROYAL HORTICULTURAL SOCIETY.

At the meeting of the Scientific Committee on July 24th, Dr. H. Scott in the chair, Mr. Prowright, in acknowledging the letter of thanks addressed to him some time since by the Chairman on behalf of the Committee, made the following remarks:—"It was my hope when I began my cultures that the general outcome would tend to a lessening of the number of the species of the Uredineæ. This, however, is not the case; on the contrary, I feel convinced that physiological investigation will show that these parasitic fungi are much more numerous than we at present imagine. To take one instance only, that of the Uromyces, which occurs upon beans. It is now generally thought that one species is common to most of the Leguminosæ. I have made a number of cultures on this point, and find that when *U. fabæ* from the common bean haulms is placed on young plants of bean, pea, *Vicia cracca*, *V. sativa*, *Lathyrus prætensis*, and *Ervum hirsutum* Æcidia are only produced on the bean and pea; and further, that the Uromyces on *Ervum hirsutum* applied to the same host plants produced Æcidium on Ervum only. In the same way the Puccinia which occurs upon the Compositæ is, I find, not one species, as is generally supposed, but that Uredospores from *Centaurea nigra*, for instance, will not affect *Taraxacum officinale*, neither will the Uredospores of *T. officinale* infect *Apargia autumnalis* nor *Lapsana communis*. Before the true affinities of these species can be satisfactorily determined numerous and long-continued biological investigations will have to be made for the hasty grouping together of the various forms, because they occur on allied host plants, is as liable to error as the opposite plan of making every form a species because it occurs on a different host plant."

Dr. Masters showed diagrams representing the movements in the shoots of firs, not only of the leader shoot of *Abies bifida* (*firma*), but also of the lateral shoots; while the leader shoot gyrates in irregular ellipses, its point being alternately raised or depressed, the lateral shoots not only move from one point of the compass to another, and are elevated or depressed, but are rotated on their own axis, the leaves also being raised or depressed at various angles. These movements of shoots and leaves were very complex, and in all probability dependent on different causes.

THE ARTIFICIAL REPRODUCTION OF VOLCANIC ROCKS.

Translation of a Lecture Delivered by M. Alphonse Renard, LL.D., at the Royal Institution.

(*Concluded from p.* 118.)

According to Sénarmont, one of the essential conditions of a geological synthesis, is that each artificial operation should be compatible with all the circumstances where the natural operation has left characteristic traces. The industrial slags and scoriæ, whose relation to some of the products of nature we have already discussed, are, in reality syntheses, but syntheses of chance, which, in spite of their great scientific interests, cannot be placed on the same level as the intentional syntheses which we will now examine, where the experimentalist, bearing in mind the problem to be resolved, endeavours to realise, in his laboratory, conditions identical with those which surround the formation of the natural products which he wishes to imitate.

In the order of logic, synthetical methods follow to a certain extent the progress of observation and analysis. Nevertheless, it must be admitted that since the earliest days of geology, a few master minds have, with the glance of genius, discerned the light which later experience has brought to bear upon this science. Buffon proved by experiments that granite and the principal crystalline rocks are fusible, and that they are transformed by fusion into a glassy mass. Some years later, Spallanzani worked out a series of experiments on the fusion of lavas, in order to destroy the reigning prejudices on the cause of the heat of the eruptive matter. But the chief honour is due to Sir James Hall, for the inauguration of geological research by means of numerous celebrated experiments, which he generalised and applied in the most masterly way. We can only consider here that portion of Hall's work which concerns the synthesis of rocks. About the time when Spallanzani was studying by laboratory processes the conditions of the formations of lavas, the illustrious Scotch geologist fused some eruptive rocks in a graphite receptacle, and observed that the products of this fusion, if abruptly cooled, gave an amorphous glassy mass, while a more gradual cooling induced the formation of crystals. James Hall had already learnt from experience the principal basis for future syntheses, viz., the fact that to reform crystals in a fused rock, the glass resulting from this fusion must be kept at a high degree of temperature, inferior, however, to that originally required for the fusion of the rock. During this annealing, certain minerals are able to crystallise. These facts can be compared with those furnished by recently ejected lava at the moment when the temperature begins to fall.

Towards the commencement of this century Gregory Watt directed his researches into the same path; he experimented on a mass of basalt 700 lbs. in weight. He fused it and let it cool down for eight days in a furnace, which was allowed to cool slowly. During this prolonged annealing sphærulithic concretions, composed of radiating fibres, about 6 centimetres in diameter, became isolated in the black opaque glass obtained by the fusion of the basalt, and finally this glass passed into a stony stage, becoming granulated and charged with very fine crystalline particles. At the same time its magnetism increased and its density grew from 2·743 to 2·949.

One conclusion arrived at by Watt's research, which resembled in many points that of Hall's, which we referred to above, is that while the molten mass is solidifying crystallisation can take place.

At the time when the path of the synthesis of rocks was thus being prepared, analysis and other means of investigation had not attained to the perfection of the present day; on the other hand, the prejudices which prevailed in the earlier days of geology had accumulated obstacles which were only surmounted at least half a century later. We cannot pause here to survey the brilliant period of mineralogical syntheses which followed closely on the impetus given by chemistry and mineralogy. It suffices to simply quote the names of Ebelmen, Rose, Mitscherlich, Sénarmont, to recall to the remembrance all the remarkable results of the artificial productions of minerals. But the researches of these scientists had reference chiefly to the synthesis of isolated specimens, and not to that of rocks themselves, which are the aggregate of mineral specimens. Generally speaking, these experiments were chiefly of a mineralogical order, and only secondarily lithological. Nevertheless, the efforts of these clever experimentalists solved many a geological problem, and they also proved the steady maintenance and accentuation of the tendency which leads the intelligent to seek, by experimental means, a more complete knowledge of natural phenomena. At last, in 1866, Daubrée reproduced crystalline rocks by simple fusion, and it was his method which was finally adopted and developed by MM. Fouqué and Michel Lévy. The researches of Daubrée to which we here allude, are those which he undertook in order to reproduce by fusion certain meteoric stones characterised by the absence of the feldspathic element. He fused an earthy rock, lherzolite, whose composition resembles that of corresponding meteorites, and succeeded in obtaining results which, in the details of structure and composition, faithfully reproduced those of the cosmic type which he wished to imitate.

At the time when this eminent geologist was thus anticipating the researches which some years after were to throw so brilliant a light upon the geological laboratories of the College of France, the progress of the synthetic method was still much hampered by hypotheses. It was no longer those relating to the influences of mysterious forces that had to be dealt with, but the supposition that the reproduction of geological phenomena in the laboratory was only possible at the expense of an indefinite amount of time, and of temperatures and masses of which, in the present day, we can scarcely form an idea. It was thought then that the mineral combinations in Nature followed other laws than did those produced by chemistry. These prejudices, however, were powerless to arrest Daubrée's progress on the road, on which by his synthesis of meteors he had so valiantly taken the first steps—for he, let us hasten to observe, is one of those whose labours have done most towards the eradication of these hypotheses from the domain of geology. But the methods of analysis in vogue in those days did not render penetration into the depths of the natural rocks and subsequent comparison of their internal structures with those of synthetic products at all possible. The laboratories did not possess the necessary apparatus for obtaining a very high degree of temperature or for maintaining it during lengthy experiments.

The great improvements in the construction of apparatus, and the application of the microscope to lithological work, have however facilitated the reproduction of all contemporary volcanic rocks. Two French scientists, M.M. Fouqué and Michel Lévy, who introduced micrographical lithology into their country, commenced in 1877 a series of synthetic experiments, thenceforth memorable in the history of science. One of them had acquired a well-earned reputation by his remarkable works on volcanic phenomena, which he had studied on the spot in several classic regions; he was familiar with all the secrets of the chemical analysis of minerals, which he carried out in the most ingenious and practical way. The other, well-prepared by his studies in the French colleges, had conducted with striking success an examination of minerals by their optical properties; he had carried on the application of exact methods in micrography further than had ever been done before, and had already made himself known in the scientific world by his researches on eruptive rocks of the ancient series.

In their conjoint labours, MM. Fouqué and Lévy to a certain extent systematised and arranged the facts relating to the chronological succession of crystals in eruptive rocks, and revealed a large number of the details which we have already mentioned among the results of lava analysis. It is to this happy association of talent, this fertile collaboration, that we owe the great discoveries which have rendered the College of France so celebrated, and to which I am proud to render homage here in presence of an audience ever ready to welcome all scientific progress, and at whose tribunal—the first in the world for the diffusion of science—the immortal Faraday has expounded with such generous ardour Ebelmen's wonderful achievements in mineralogical synthesis.

We have already indicated the data furnished by chemical and mineralogical analysis, which these scientists had as foundation for their attempts. One point which we have not yet touched upon, is the base of their general process. Theory would suggest that the most ancient crystals of an igneous rock should be the least fusible, and observation corroborates this theory, the minerals of the first period of crystallisation occupying the lowest place in the scale of fusibility. The constituent specimens of the lavas have appeared at successive times, according to their degree of fusibility, in proportions as the temperature fell. These facts, ascertained in detail by microscopic analysis, served as the point of departure for MM. Fouqué and Lévy's labours. Their process rests also partly on a fact which Sir James Hall had foreseen, viz., that the fusion of a rock produces an artificial rock more easily fusible than are any of its crystalline constituents. Now, if a natural rock be submitted to a very high temperature, and the glass produced by this fusion made to pass through a series of decreasing temperatures, always, however, higher than that of the melting point of the vitreous mass, the minerals which can crystallise in the magma are formed in due succession, the least fusible separating first. These crystals are eventually united and surrounded by those whose fusibility is greater, which appear in their turn as the temperature decreases. Without entering into the technical details of the apparatus, we will content ourselves with remarking that by the aid of the furnaces and tubes which MM. Fouqué and Lévy used for their synthesis, all intermediate stages, from glowing red to dazzling white heat, can be obtained, and a given temperature maintained undeviatingly during an unlimited period. Into a furnace is introduced a platinum crucible, of a capacity of about twenty cubic centimetres, containing the mixture of mineral matters which fusion, and subsequent annealing, are to transform into rocks. The following is the sequence of the operation: first, by the aid of special arrangements the temperature is kept at dazzling white heat, while the mixture is transformed into glass. By regulating the admission of gas and air, and by uncovering the furnace, the temperature of the molten mass is reduced to orange-red heat or about the melting point of steel. The crucible is then raised from the furnace, when the temperature decreases to cherry-red, or the fusion point of copper. Finally, if the crucible be taken quite out of the kiln, its contents can still be maintained at a temperature at which copper would only melt with difficulty.

We have sketched the broad outlines of the operation. It is practically a succession of annealings at diminishing temperatures, which force the crystals to form in a series commencing with the least fusible, and which give the texture and mineralogical composition of volcanic products to the molten matter subjected to this treatment.

We will explain, by a few examples, the mode of operation for lithological syntheses. Let us follow the method of reproduction of one of the rocks, which takes a prominent part in the eruption of Vesuvius, leucotephrite, a rock composed of leucite, labradorite, and augite.

A mixture is formed of silica, alumina, lime, ferrous oxide, potassium, and soda, which corresponds to one part of augite, four of labradorite, eight of leucite. This mixture is placed in the crucible at white heat, and transformed into a homogeneous glass. As soon as the fusion of the chemical compounds has taken place the temperature is lowered, and the vitreous mass is kept for forty-eight hours at the temperature of molten steel. The leucite crystals are formed during this first stage of the proceedings, which evidently corresponds to the first phase of the consolidation of eruptive rocks.

The mass is maintained for another forty-eight hours at the temperature of molten copper, and the whole residue left after the formation of the leucite crystals in the former phase is transformed into microliths of augite and labradorite, and octahedrons of magnetite and picotite. Now let us compare, after this double annealing, the microscopical preparation of the synthesis with natural lava; not only are the same minerals reproduced by this process of fusion of dry materials, but the order of their formation and the proportion of their constituents are identical; this analogy can be traced even in the details of crystallographical forms. Large leucite crystals are present showing all the characteristics of this mineral as found in Vesuvian lava, and grouped around them are the microliths of the second stage, augite and labradorite. Finally, as in the natural rock, the leucite contains enclosures of magnetite and picotite, which are the most ancient minerals.

Let us take for our second example the synthesis of basalt, one of the most widely diffused types of the volcanic series, anent whose origin numerous hypotheses have been advanced. It is well known that basalt is composed of three essential minerals—olivine, augite, and labradorite. The olivine appears in the natural rock as a crystal of the first consolidation.

As in the case of leucotephrite, a mixture of chemical elements or of pulverised minerals is formed, corresponding to the average composition of a basalt rich in olivine. The mixture is composed of three parts of this mineral, two of augite, and three of labradorite. It is first transformed into an almost homogeneous black glass, and maintained at red white heat for forty-eight hours. On examination of a thin section of this glass after this annealing at high temperature, large crystals of olivine are at once detected. These are embedded in a vitreous mass, in which little octahedrons of massicolite and of picotite are discovered, together with a few scarce crystals of augite.

We now have to induce the formation of the microliths of the second consolidation round the olivine crystals formed during the first phase. For this purpose the crucible is kept for forty-eight hours at a cherry-red heat, and after this annealing a paste is obtained composed of microliths of labradorite and augite, of magnetite, and of the glassy residue of this crystallisation. Thus in this second phase we have reproduced the microlithic structure. The basalts obtained by these operations can scarcely be distinguished from the natural rock, and these few grammes of cleverly manipulated substance supply us with a most convincing proof of the purely igneous formation of the rock.

We could mention here whole series of remarkable experiments carried out by MM. Fouqué and Lévy, whence we have obtained these two syntheses. All the contemporary eruptive rocks have been thus reconstituted; andesites, labradorites, basalts, limburgites, nephelinites, tephrites, leucite rocks, peridodites, and labradorites with ophitic structure. We will limit ourselves however to proving, by one last example, how these synthetic processes succeed in throwing a direct light upon the eruptive periods of the past formation of our globe.

Certain ancient crystalline rocks, common in the Pyrenees, were distinguished by the name of ophites. Neither the date of their formation nor their origin was definitely determined, until in 1877 M. Lévy proved that they were eruptive, and that they displayed under the microscope a peculiar structure which he designated by the name of *ophitic structure*, in which the felspar appeared united by very large tablets of augite. It thus appears that these ophitic rocks are igneous rocks in which the cooling down has proceeded much more slowly than in the ordinary products of contemporary eruptions. In endeavouring to reproduce the ophitic type by synthesis, it is necessary to crystallise the augite during a phase distinctly separated from that during which the felspar is produced, and to give ample time during the first period for the formation of the crystals into large spaces. For this purpose, a mixture of anorthite and augite was subjected, after fusion, to a preliminary annealing, during which it was kept for four days at the temperature of melting steel, when some anorthite separated. A second annealing of equal duration at the temperature of melting copper induced the crystallisation of augite in large masses, which formed a mould for the felspar, and attracted little octahedrons of magnetite and picotite to it. The eruptive origin of ophites and the cause of the structure were thus incontestably established by this noteworthy synthesis.

Thus we have convincing proofs of the service rendered by synthesis in enlightening us as to the origin of rocks, and in settling the discussions which, even in the present day, still arise apropos of the principal crystalline types of the modern epoch, as, for example, in the case of the basalts, in which some scientists would fain discover traces of aqueous agency, but in which, in common with all volcanic rocks of contemporary eruptions, these experiments tend to prove a distinctly igneous origin.

But scientists have not always obtained these magnificent successes; many of their attempts have proved utterly fruitless. It is advisable to recall these defects occasionally, as they point out which paths must be avoided if the final truth is to be reached. These failures circumscribe the field of future experiments and trace the limits within which hypotheses must be confined. Moreover, they show that these rocks, whose synthesis the methods employed have failed to gain, must have been formed under conditions differing from those by which actual volcanic products were produced. This conclusion, to which former analyses and observations already pointed, without, however precise certainty as to its causes, is amply confirmed by the failure of the synthesis. If it has succeeded in satisfactorily reproducing the lavas of modern volcanoes, it has completely failed in the imitation of those whose formation no longer occurs in contemporary eruptions. Broadly speaking, one may say that, up to the present, all the acid rocks have evaded synthetic formation, as, for example, all those which include, amongst their mineral constituents, quartz, mica, orthose, or hornblende. The processes of nature are not due to unknown forces; perchance, therefore, by combining those over which we already have control, by modifying their application we might eventually succeed in reproducing those rocks which up to the present have eluded our efforts, a hope which we may surely found upon the results already obtained, since they may be but the precursors of still more remarkable achievements. It is but a repetition of the axiom that the defeats of the past prepare the way for the victories of the future. We have endeavoured, in this rapid review of the progress of lithological synthesis, to show the high scientific importance of the researches instituted at the Geological Laboratory of the College of France. We might have enumerated the no less remarkable synthesis of minerals and meteorites, conducted with such good results by other clever scientists and their pupils, foremost amongst whom stands M. Bourgeois, but space fails us. Still we have at least sufficiently proved how much these methods have enlarged our knowledge in a domain of nature where all access once seemed denied to us.

Hitherto, wherever the torch of experimental methods has penetrated, it has fully and clearly illuminated the most striking phenomena of the science of the earth. To indicate the extent of the field of mineralogical science already explored by experimental science, it is only necessary to mention the name of Daubrée, the direct descendant of many illustrious geologists of the Scotch school. By degrees the processes have been successfully applied to the interpretation of metalliferous deposits, of metamorphic rocks, of the phenomena of trituration, and of the transportation of sedimentary matters, and to the study of the fractures and distortions of the earth's crust, of the schistosity of the rocks, and of certain features of the structure of the mountains.

Thus geology, after having passed through the successive phases of observation and analysis, has entered into the phase of experiments and synthesis, which endeavours to imitate the powerful creations of nature, thus crowning the scientific edifice by processes which facilitate the discovery of the several causes whose complete comprehension is the final aim of physical and natural science. It is this crowning triumph which Leibnitz presaged two centuries ago, when he wrote:—"He who succeeds in carefully comparing the products drawn from the depths of the earth with those of the laboratories, will accomplish a great work, for then at last we shall clearly see the striking similitude which exists between the products of nature and of art. Although the inexhaustible Creator has innumerable methods of carrying out His wishes, yet there is always a certain consistency even in the variety of His works. It is already a great step towards the perfect knowledge of causes and effects to have discovered a means of producing them, for nature is but art in magnified proportions."

WEATHER OF JULY, 1888.

In reference to *St. Swithin* and his mission this year, disappointment is expressed that the subject has not received as much attention from the weather-prophets as is usual at this time.

They have probably been content that the public are fully aware of the *old proverb*, which again has proved substantiated, and that it is known to be not an uncommon thing for July to be wet, as in 1879-80.

A collection of rainfall *observations at sea* in course of formation, and so far summarized, leads one to infer that our present weather is connected with undue prevalence of Atlantic weather.

This is driven to our islands by the numerous *cyclonettes, or minor depressions*, that have crossed them for some weeks at various latitudes, and carried with them clouds full of rain, which have been discharged on our coasts and hills.

In the *North Atlantic Ocean* the wettest months were January, June, and September, and the driest months were February, March, and April, and the wettest seasons were the autumn, and driest were the spring.

The wetness of the *present July* may therefore probably be explained by the rain-clouds of June and July at sea being wafted by the south-west winds from the North Atlantic Ocean over, towards, and across these islands.

These clouds of *aqueous vapour* are now rushing rapidly north-eastward to fill the dry vacancies in the air of the Arctic regions, coincident with the late draughts in northern latitudes, and these will continue to pass onwards until the *saturation* of the summer atmosphere takes place.

This may be accomplished by next month, August, when *finer weather* may be expected, as is usually the case at sea when but little rain falls, and the winds subside, and the sun is less obscured by clouds.

Anti-cyclonic weather will then advance from the south and from the Continent, with south and east winds, and a drier air will follow, as the breezes will then blow from the heated plains of Europe instead of from the warm surface of the Atlantic seas.

In contrast to the wet weather of June in the North Atlantic Ocean, and of July on land in Britain, it may be stated that June is a drier month in *South Atlantic seas*, and July is drier still than in the North Atlantic.

This year there has been exceptional weather at the *Cape*—much as it has been in Britain—and there April, May, and June proved to have been unusually wet, as in this country, on land, they have been unusually dry.

There would therefore appear to have been going on some kind of *reciprocity*, or give and take, between the weathers of the temperate zones of the North and South Atlantic Oceans, whereby the wet of one has been transferred to the other.

Easterly winds this month have been equally wet as the westerly ones, as they are seen to be only segments of the same circle of damp winds that form the other parts of the cyclonettes, or minor depressions, and are then called westerly winds, and both come from the Atlantic regions.

July, 1888. W. V. Black, F.R.M.S.

ALLEGED SHOWER OF FROGS.

A paragraph is going the round of the papers to the effect that, after very heavy and prolonged rain at Leamington, "the Tachbrook-road was covered with thousands of small frogs, which had fallen with the rain." Whilst fully admitting that small living animals have been carried aloft by whirlwinds and deposited elsewhere, I should suggest that the paragraph in question is a case of jumping at a conclusion. It is well known that when the ground is drenched with rain and the air saturated with moisture, frogs—especially young frogs—are apt to leave the ditches and the pools and hop about on what is ordinarily dry land. I should hesitate to admit that they had fallen with the rain, unless they were found on roofs or other localities out of their reach.

"WHENCE COMES MAN?"

In the notice of my book, "Whence Comes Man; from Nature or from God?" in your issue of July 27th, there occurs a strange mistake, which I trust you will do me the justice to correct.

The writer of the notice says:—"For example, he (myself) quotes Spencer as follows: 'Self-existence, therefore, necessarily means existence without a beginning; and to form a conception of self-existence is to form a conception of existence without a beginning. Now by no mental effort can we do this. To conceive existence through infinite past time implies the conception of infinite past time, which is an impossibility.'"

The writer of the notice then quotes a part of my comment upon Mr. Spencer's assertion:—"When Mr. Spencer uses the word 'conception,' he is evidently thinking not of 'conception,' but of '*experience*.' Let us change the word 'conception' to the word 'experience.' To 'experience' existence through un-finite (it is so printed in my book) past time, implies the 'experience' of unfinite past time, which is an impossibility. Of course it is. But a *conception* of unfinite past time is not. It is simply the thought of time *without* limit; and is simply what I call a 'private' idea, the formation of which presents no difficulty."

It is on the last sentence that the mistake I ask to have rectified occurs. Instead of the words "a private idea," which is nonsense, the words in my book are "a *privative* idea," that is, the affirmation of time *without* limits—the "privation," or absence of limits. After having made such a mistake, it is not surprising the writer should have accused me of "rigmarole"!

I may be allowed, I think, to add that when the writer of the notice spoke of what he called the "astounding conclusion—the drift of the book—expressed in the statement of his belief that *space* is *God*," he might have stated at least some of the grounds of that conclusion, or at least the concluding words of my "belief," that *space is the mode in which the Infinite God manifests Himself to us*, and enables us to understand *how* it is that *in* Him we can "*live*," and "*move*," and "*have* our being;" how the Finite can "*co-exist*" with the Infinite, and the Infinite *remain* Infinite; how additions can be made to the sum of things, and the Infinite be Infinite as before. Arthur John Bell.

Easton Court, Chagford, Devon, Aug. 6th, 1888.

METEOROLOGICAL CONUNDRUMS.

Doubtless some of your readers will have noticed that when a season takes up a very decided character all the ordinary signs of a change of weather lose their importance. In 1879, and again in the present year, the indications of fine weather, such as a rising barometer, a rosy sunset, a grey, low dawn, a lofty flight of gnats and of swallows, were merely succeeded by wet and cold. On the contrary, in such seasons as 1868 the ordinary portents of wet and cold had no meaning. Now I should like to ask, what is the cause of a season taking up some special character? How can we ascertain the duration of such a state of things? Again, in Britain a thunderstorm almost invariably "breaks up the weather"—*i.e.*, is followed by northerly winds and a fall of temperature. Is the storm the cause of the cold, or is it an effect of the approach of the latter? Would-be Weather-wise.

NOISES ACCOMPANYING AURORAL DISPLAYS.

In reply to your correspondent, Mr. T. Todd, a number of people believe they have heard sounds accompanying the aurora borealis. The question has been carefully considered by Mr. Sophus Tromholt, who in March, 1885, despatched some thousand circulars to various parts of Norway, containing different queries regarding the aurora, and amongst them the following:—Have you or your acquaintances ever heard any sound during aurora, and, in this case, when and in what manner? He received answers to these queries from 144 persons. Of these, 92 (or 64 per cent.) believed in the existence of the aurora sound, and 53 (36 per cent.) of these again state they heard it themselves, whilst the other 39 cite testimonials from other people; only 21 (15 per cent.) declare they never heard the sound or know anything about it, and the other 31 (22 per cent.) have not noticed the query at all. There are thus 92 affirmations against 12 negations. The sound is described in these answers in the following manner:

Sizzling (3).
Breaking or sizzling.
An intermediate sound between sizzling and whizzling, sometimes as if a piece of paper were torn.
A kind of sound as when you tear silk; sizzling, th—ss.
Soft whizzing, alternative with sizzling.
Hissing and crackling.
Partly hissing, partly as a kind of rushing whiz.
Whispering and glistering.
Strong whiz (3).
Whiz or whipering.
Whiz, or distant, soft, continuous whizzing.

Constant Reader.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

BATTERIES.—Plates for secondary batteries have been patented by Mr. J. S. Stevenson. According to this invention, between the active material and the face of the mould is interposed a material which, whilst capable of withstanding the heat of the casting process, is preferably a comparatively slow conductor of heat and of a yielding character so that when the parts of the mould are forced together the active material is retained in place in the mould without fracturing or disintegrating the said material.

TELEPHONES.—An electrical telephone has been patented by Messrs. J. S. Ross and H. Baines. In this invention sheets of india-rubber are used for coating the surfaces of electrical diaphragms for protection from damp, and the adherence of the diaphragm to the magnet is avoided by arranging an electrical circuit, so that should the diaphragm be drawn on to its magnet the magnetising coil is cut out momentarily. The diaphragm will then keep vibrating, and by making a noise and by the use of an indicator, draw attention to the fact that the telephone requires adjustment.

FIRE-ESCAPE.—A fire-escape has been patented by M. Aug. de Waele. This invention embraces a movable step ladder applied to the front of a house between two windows or their balconies. The two spring-boards of this ladder form, with the hand-rails, a folding frame, in the form of a parallelogram, turning on two fixed pivots with which it is connected by means of rods. This step-ladder, when folded against the wall and fastened thereto, projects but a little way from it; when the fastening is undone it is easily opened out, thus forming a secure and easy exit from the building.

MAKING INCISIONS.—An apparatus for making incisions without pain has been patented by Mr. A. J. Boult on behalf of Mr. J. F. de Silva. Theapparatus consists essentially of a rectangular box which the operator holds with one hand, and containing multiplying gear wheels which he turns by means of a key held in the other hand. These gear wheels actuate by means of rods and cranks, a fly wheel and slide, the latter carrying a working catch which at a determined moment falls into a recess of a slide bar, and imparts to it and the knife a single rapid to and fro movement which makes the incision with such rapidity that no pain is felt as the exciting cause is immediately withdrawn.

CONDUCTING CABLES.—Means for making and insulating the joints of electrical conducting cables have been patented by Mr. C. D. Abel, on behalf of Messrs. Siemens and Halske. This invention consists essentially in the use of a flanged metal sleeve fitted on the cable, between the flange of which sleeve and the flange of a second sleeve the turned-up ends of the conducting wires are clamped so as to be in conducting contact therewith, the flanged sleeves serving for effecting the electrical connection to the second cable or conductor. In combination with this connecting device for the outer conductors of a cable a socket is used, fitted on the centra conducting wires of the cable, and provided with a pinching screw for connecting a conductor thereto.

ELECTRICAL CURRENT METER.—An instrument for measuring electric currents and for regulating electric machines has been patented by Messrs. W. Lowrie, C. J. Hall, and H. W. Kolle. In order to obtain a more sensitive instrument with a moderate length of wire, a wire is used suspended between two rigid supports, and has applied to it, midway between the supports, a weight of such power as to compel the wire, when heated by the current, to form an obtuse angle. The wire on either side of the weight may be considered as the radius of a circle, having one of the supports as a fixed centre, and any variation in length of the wire allows the weight to move along the apex of the angle to the point where two circles struck from the fixed centres with the altered radii would intersect. A maximum of deflection from the straight line is thus obtained, which deflection is caused to act on suitable multiplying and indicating mechanism, or mechanism for regulating electric machines.

ELECTRIC SIGNALLING.—An electrical signalling apparatus for railways has been patented by Mr. A. E. Nicholl. On the permanent way of a railway insulated wires are laid down, in connection with which are projecting bars placed at suitable distances from one another and arranged so as to be normally out of contact when laid down, but can be brought into contact when a locomotive passes over them. Every locomotive is provided with a metal plate for making contact with the bars, which are in connection with a galvanic battery, and also with electro-magnets on the locomotive, to which are attached signals for indicating to the driver that the circuit is completed. The insulated wires are laid down in predetermined lengths, and are so arranged that when a locomotive runs along the metals it will be connected with the laid wire. Should two locomotives come within the certain predetermined distance of one another their proximity will be notified to the driver by the magnetic signals being actuated on the locomotives.

MUSICAL INSTRUMENTS.—A musical instrument has been patented by Mr. E. Parr. The invention relates to musical boxes, but instead of being played by means of a roller with pins projecting from it which strike against vibrating tongues and thus produce the tune as the roller is revolved, it is operated by keys similar to pianos, which sound the vibrating tongues. A keyboard, carrying keys equal to the number of musical tongues, is employed, and opposite each tongue are arranged light levers, consisting of a star-shaped wheel turning on an axis, and having pointed arms the extremities of which, when the wheel is turned, press upon and force back the point of the tongue and then release it, the arm then passing on. In order that the wheel may be turned through a sufficient space by the pressure of the key connected with it, a lever connected with the latter is made to press upon one of the other arms of the wheel when the key is depressed. The end of the key or lever which so operates the wheel is hinged so that when the key is released it passes back and is ready again to sound the tongue when the key is struck by the player. Upon this instrument any tune may be played, and a considerable amount of expression given to it.

SELECTED BOOKS.

Water Engineering. A Practical Treatise on the Measurement, Storage, Conveyance, and Utilisation of Water for the Supply of Towns, for Mill Power and for other purposes. By Charles Slagg, A.M.I.C.E., author of "Sanitary Work in the Smaller Towns," etc. London: Crosby, Lockwood and Sons. Price 7s. 6d.

Forms of Animal Life. A manual of Comparative Anatomy, with Descriptions of Selected Types. By the late George Rolleston, D.M., F.R.S. Revised and enlarged by W. Hatchett Jackson, M.A. Second Edition. London: Clarendon Press. Price 36s.

A Text-Book on Steam and Steam Engines. For the Use of Students Preparing for Competitive Examinations, By A. Jamieson, C.E., F.R.S.E., Prof. of Engineering, Glasgow Technical College. With 200 illustrations and four folding Plates. Third edition. London: Charles Griffin and Co. Price 7s. 6d.

A Manual of the Mollusca. A Treatise on Recent and Fossil Shells. By Dr. S. P. Woodward, A.L.S. With Appendix by Ralph Tate, A.L.S., F.G.S. With numerous Plates and 300 Woodcuts. Fourth edition. London: Crosby, Lockwood and Sons. Price 7s. 6d.

Nature's Hygiene. A Systematic Manual of Natural Hygiene. By C. T. Kingzett, T.I.C., F.C.S., ex-Vice-President of the Society of Public Analysts. Third edition. London: Bailliere, Tindall, and Cox. Price 7s. 6d.

Handbook of the Amaryllideæ. Including the Alstrœmerieæ and Agaveæ. By J. G. Baker, F.R.S., F.L.S., First Assistant in the Herbarium of the Royal Gardens, Kew. London: Bell and Co. Price 5s.

NOTICES.

SCIENTIFIC TABLE TALK.

By W. MATTIEU WILLIAMS, F.R.A.S., F.C.S.

ON page 103 of the number of this magazine for August 3rd is a reference to Dr. Nasmyth's results. The mystery is, I think, explained by unconscious anticipation in my last paper, which was written before I saw the paragraph or the abstract on page 114. The old Welsh collier to whom I referred had learned by experience that he was less liable to lung and bronchial troubles in winter time while working in the pit than if occupied above ground. This was due to the luxurious temperature below, three or four degrees above that of the mean annual temperature of Flintshire, or about the same as that of the Riviera in winter. This uniformity of the temperature of the pits, so pleasantly cool in summer, so mild and genial in winter, is doubtless the cause of the comparative immunity of colliers from phthisis and other lung troubles.

It is well known that horses improve in condition while working in coal pits, and I know cases (one of my own among them) of ponies that after a few months in the pit have materially increased in market value, and have been sold accordingly. The difference is specially shown in the sleek condition of the skin or hair.

Experiments recently made in the Lake of Geneva have shown that the water is much clearer in winter than in summer. White discs submerged at different seasons prove themselves to be visible to a depth of above twenty yards in winter, but in summer disappear at little more than one-fourth of that depth. Corresponding results are obtained by comparing the depths at which photographic action is obtainable at different seasons.

Why is this? Some observations I made about thirty years ago supply an answer to this question. Domestic marine aquaria were then comparatively novel and much in vogue. I was a victim to the mania, and wasted much time upon it, trying in vain to grow the *Delesseria sanguinea*, and other beautiful sea weeds in an artificial rock pool with glass sides, and thereby carry out the theory that ornamental marine vegetation may under such conditions supply the oxygen demanded by the animals. I succeeded in demonstrating the fallacy of this, but discovered that another and very objectionable kind of vegetation was too easily obtainable.

I found that my tanks exposed to the sunlight of a south window, where like many other such amateurs I first placed them, rapidly become turbid, more like green-pea soup than limpid sea-water. The same occurred at about the same time in the first attempt at a public marine aquarium at the Zoological Gardens. The cause of this was the development of minute vegetation. Fresh water aquaria similarly exposed suffered in like manner, but not so severely.

My old friend, J. Alfred Lloyd, was a fellow-sufferer at the same period, but was more persevering, and made the construction and management of aquaria a business; established an emporium in the Portland Road, and afterwards designed and carried out very successfully the public aquaria of Hamburg, the Crystal Palace, etc.

His success mainly depended on his method of overcoming the turbidity due to such vegetation, and his practical abandonment of the theory of balancing animal and vegetable life in artificial aquaria, which Gosse and others, who merely wrote books on the subject, still maintained, and apparently have not yet learned to abandon.

Lloyd built his large aquaria underground, or in places effectively shaded from direct sunlight, *i.e.*, under conditions which checked as much as possible this vegetation that the book-theorists describe as essential. He not only did this, but he further exterminated the vegetation by connecting his tanks with a large reserve of water kept in total darkness, or the nearest possible approach to it. This is the case at the Crystal Palace. He also constructed, and, if I remember rightly, patented, a dark chamber adjunct to small domestic aquaria. Three sides of these were slate, only the front being glass; a sloping false bottom extended upwards from front to back, and contained beneath it more than half of the water in such darkness as to kill all spores and microscopic vegetation in the water, which entered the dark region by convection circulation.

The aeration of such tanks as those at the Crystal Palace is effected partially by a continuous circulation exchanging the dark-chamber water with that in the show tanks, and partly by jets of water carrying down adhering air into the tanks.

I may here remark, by the way, that air may be more effectively injected into an aquarium thus, than by forcing jets of mere air itself. The jet of air forms comparatively large bubbles, but the jet of water carries down with it a cloud of bubbles so minute that they expose a far larger surface, and rise but slowly through the water. The water jet should start from its nozzle at a very short distance above the surface of the water, a distance varying with the size and force of the jet. This can easily be tested by observing the dimensions and character of the cloud of bubbles produced.

Applying these experiences to the case of the Lake of Geneva, the explanation is obvious. In the summer the upper part of the blue water is made turbid by microscopic vegetation, which in the winter has little or no existence.

While Lloyd was making his experiments with shaded tanks and dark reservoirs, I was attacking the same problem chemically, and found that when the sea water thus became turbid it simultaneously became faintly alkaline. This I attributed to the removal of carbonic acid from the sea water, and the precipitation of some of the carbonate of lime that is present in all ordinary sea water, and is dissolved in excess of carbonic acid. This precipitation of course increased the turbidity.

To test this theory, I added, very cautiously and gradually, small quantities of hydrochloric acid. This effectually restored the transparency of the water, but did not meet with the approval of the animals. The actinia closed and became conical, and fishes were seized with fits of coughing, especially when I substituted chlorine-water, or bromine solution (both of which cleared the water) for hydrochloric acid.

A serious trouble arose at the opening, or rather intended opening, of the Crystal Palace aquarium. This was announced for Easter Monday. The tanks and underground reservoir, and duplicate pumping machinery were all punctually ready, and the sea water in its place, but although clear when poured in became quite milky in a very short time, and all the first stock of animals perished. At Mr. Lloyd's suggestion I was consulted by the manager, and soon discovered the cause. The water was alkaline, the alkalinity was due to caustic lime in solution, the caustic lime came from the Portland cement with which the underground reservoir was lined, and by which the rockwork of the tanks was held. Two courses were open for the remedy of this. One was heroic, the other cautious. The heroic remedy was to add sufficient hydrochloric acid to neutralise the dissolved lime, and to dissolve the precipitating carbonate; the prudent course was to go on circulating the water until the carbonic acid of the air gradually did the work. I proved the possibility of clearing at once by an experiment in an isolated single tank, but Lloyd had a dread of mysterious chemicals, and preferred the cautious course, which was carried out, but demanded a long time, and the opening of the aquarium was postponed accordingly. The complete success of this justified Lloyd's selection.

Influence of Trees on the Rainfall. — The reforestation of portions of North-western India is already exerting a beneficial influence by an increasing rainfall in the Southern Punjab, Southern Afghanistan, Northern Beloochistan, and Northern Scinde.

THE NATURALIST AT THE SEA-SIDE.

V.—Some Marine Larvæ.

THE larvæ of which we have to speak are the Ascidian Tadpoles, and the tiny creature long known as Actinotrocha, which turns out to be the immature state of the worm Phoronis. If the reader will forgive the alarming names which these minute and fragile animals bear, he will find that their acquaintance is well worth making. The Ascidian Tadpole is especially noteworthy in this, that while it resembles in nearly all essentials the more familiar tadpole of the frog and toad, it is destined to be transformed into something entirely unlike any amphibian, viz., a fixed and rooted leather-coated sea-squirt. Actinotrocha has something of the same peculiar interest, resembling as it does the larvæ of animals extremely different in the adult condition, such as echinoderms, various worms, and some mollusks. It exhibits a singular mode of transformation adapted to its own special needs, and unexampled in certain respects among other living things.

The Ascidian Tadpole is to be found swimming near the surface of the sea in bright summer weather, and is often taken in the tow-net. It is a small reddish animal easily seen by the naked eye, but requiring a microscope for anatomical examination. When the muslin of the tow-net is washed out in a glass dish, the Ascidian Tadpoles are at once identified by their rapid and peculiar movements. Pick them up with a dipping-tube and transfer them to a preservative fluid, when the details of their organism can be made out.

Like the tadpole of the frog the ascidian larva has a swollen "head" and a long swimming tail. The "head" in each animal is provided with paired slits by which the water taken in by the mouth passes out. The slits do not open directly to the exterior in the ascidian, but lead into a chamber which has its outlet in a spiracle at the back of the head. The tadpole of the frog exhibits precisely the same arrangement after the earliest stages of its free existence are past. Then there is a solid flexible fibre in the young ascidian, which agrees both in structure and position with the very similar notochord of the amphibian tadpole; the nerve-cord is almost identical in the two types, and both have the peculiar "cerebral" eye with rods and cones pointing inwards, and adapted to the reception of the rays of light received through the transparent brain.

The resemblances between the two sorts of tadpole are therefore by no means superficial, but extend to the most characteristic features of vertebrate organisation. The line once drawn so boldly between vertebrates and invertebrates is effaced by the Ascidian Tadpole, and for this reason, if for no other, our restless little larva is worth the most serious attention.

After its short term of activity comes to an end, the larva attaches itself by papillæ (which find their equivalent in the suckers of the amphibian tadpole), the tail is absorbed; some organs degenerate, while others become immensely developed; and what bade fair at one time to become an active, powerful, and intelligent vertebrate, sinks into a motionless sea-quirt with capacious mouth, stomach, and intestine, a stiff and insensitive skin, and a mere ganglion in place of brain and spinal cord*.

Actinotrocha is a very minute creature, just visible as a moving speck in surface collections. A lens or micro-

* A very interesting popular history of the Ascidian Tadpole is given in Lankester's "Degeneration."

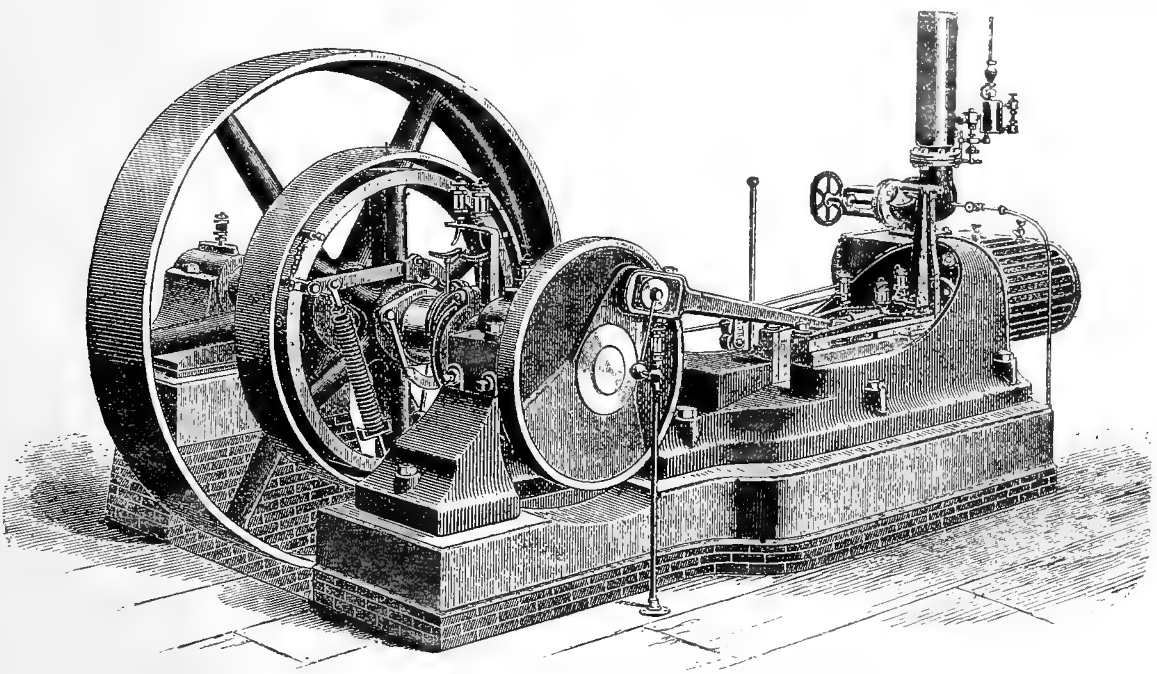
scope is necessary to make out its structure. It has a long transparent body, traversed by a simple alimentary canal, and provided at the head end with a crown of ciliated tentacles. Close to the other end is a ciliated ring. This condition is well suited to dispersal, and some kind of locomotive larva is, as we have more than once pointed out, a very common phase in the life-history of marine animals. But the adult form of our ciliated embryo is a tube-dwelling worm, known as Phoronis. The passage from the Actinotrocha to the Phoronis condition presents certain difficulties, which have been overcome in an interesting way. At first the intestine is straight, as in most worms, but this arrangement does not suit an animal which lives in a tube without outlet below. Accordingly the worm seems to have been led in the first instance to double itself up, so that the intestine ended at the mouth of the tube. In such worms as Sabella this simple resource persists without modification. One serious inconvenience results. The alimentary canal, and the whole body, are reduced by doubling to one-half of their original length—a great disadvantage to any animal which has to reach out of its burrow in search of food. Phoronis has solved the problem in a neater way than Sabella. It prepares beforehand a pouch opening on the side of its body near the head. This pouch gradually lengthens, and the tip, which, of course, is innermost, attaches itself to the slowly elongating intestine, which lies loose in the body cavity. When the moment of transformation comes, the pouch turns itself inside out, like a stocking drawn hastily off the foot, and henceforth constitutes the chief part of the body of the worm. The alimentary canal is at once drawn into it, and thus becomes suddenly bent into a loop, whose two ends are brought together at the mouth of the tube. In a quarter of an-hour the Phoronis is completely adapted to its new conditions.

Some animals, while undergoing transformation, change their bodies and their mode of life by insensible degrees, like a tradesman who gradually alters his shop and fittings, without stopping work for a single day. Others, like many insects, which lie up for a time as motionless pupæ, resemble the shopkeeper, who shuts up for a month in order to clear out his old stock and furniture. But Phoronis must be compared to the man who means to make his shop-door in a new place and add a room or two at the same time. He has all ready; all the new walls, and floors, and passages are complete, down to the door-knobs, and at last there is nothing needed but to shut one door and open another.

THE WILLIAMS SINGLE CYLINDER AUTOMATIC CUT-OFF ENGINE.

THIS engine has achieved such remarkable results as to attract the attention of leading engineers in the United States, so we propose giving a brief description of it.

As will be seen from our illustration, borrowed from the *Illustrated World*, the proportions are graceful, and



all the wearing surfaces very ample and of the best material. The distribution of steam and weight forces upon the bearings has been carefully calculated, so that no unnecessary strains shall be brought on any part.

One of the most valuable features, and one which is quite novel to engineering practice, is a construction of pressure plates which admits steam on their undersides, counteracting in a large part the pressure on their backs. No injury to the valve faces, therefore, can result from letting the plates "down hard" upon the valves, and when so adjusted the "high" portions of the faces will wear gradually away under the light pressures upon them, and the leakage, if there be any, will cease. When the wear has equalled the amount the plates were let down the plates will bear wholly on distance ledges at their ends, and the valves move freely under them. This feature furnishes an easy, safe, and sure means of keeping the valves tight. These pressure-plates do not, therefore, require that refinement of accuracy in fitting and adjusting which has been considered objectionable to other pressure-plate systems. The cut off valves have adjusting screws, easy of access, and the matter of adjustment for wear is simple. Besides, any leakage from these valves is excluded from the cylinder at about $\frac{5}{8}$ stroke by the main valve, and could not, therefore, result in any serious harm. The valves being, in fact, balanced, will wear but slightly, require very little attention, and never want to be replaced by new ones.

Another feature of this valve system is of the highest importance. The port openings are doubled for admission, cut-off, and release. This is one of the reasons for the exceptional economy claimed for these engines. A thorough separation of live steam from exhaust is another essential to economy accomplished by these valves.

Within the casing of the governor is an "inertia wheel," which acts in connection with the ordinary weight and spring forces. This feature is also novel, and produces a very admirable effect upon the action of the engine. The inertia wheel neutralizes the effect of the inertia in the governor weights, and assists the governor in overcoming the resistance of the cut-off valve. The weight and spring forces are made light, and consequently the action is free and rapid.

Messrs. Fairbanks, Morse, and Co., of Chicago, Ill., the makers, are also building compound condensing engines, and their performance justifies the prediction that there will be a large demand for them. The saving in fuel by compounding over single cylinder non-condensing appears to be about 40 per cent.; $2\frac{1}{2}$ pounds of coal per horse-power per hour is about what may be expected as the performance of these compound condensing engines.

THE COLOURS OF FRUITS AND FLOWERS.

SOME of us assert that the colouring principles of fruits and flowers owe their origin to a process of "natural selection." Others say, or at least said in days by-gone, that these pigments have in each case been mechanically determined by a direct creative act. But each of these explanations merely gives a final cause for their appearance, leaving the efficient cause or causes untouched. Yet surely the most interesting part of the question is to know how, when, and where the various colouring-matters have been formed, and by what agency they have been conveyed to and deposited in those particular parts of plants where we find them, leaving the other parts untouched. We almost fear that the popular study of natural selection has withdrawn attention from these questions. Naturalists have come to think that if they can only show how the development of intense colour in a plant attracts insects and promotes cross-fertilisation the matter is mainly explained, and *presto!* the colour must make its appearance.

We may in the first place remark that brilliant colour, alike in plants and animals, is most conspicuous at the epoch of maturity and in the most intensely vitalized portions of the structure. In plants at least, the distinct pigments hitherto recognised are very few. The white and black shades which we encounter—the latter very sparingly—are not due to any especial colouring-matter. White is due merely to the reflection of light through colourless tissues containing air. Blacks are generally due to the dense concentration of violet pigments. If we set aside chlorophyll green, which, though common in fruits, is rarely met with in flowers, we find, according to Dr. A. Hansen, the following three groups:—1, yellows; 2, reds; and 3, blues and violets.

As it was previously demonstrated by Hildebrand the yellows are mostly in combination with the plasmic substance, while the reds, blues, and violets exist mostly in solution in the cell-sap.

The yellow colouring matter of flowers forms an insoluble compound with fatty matters, as discovered by Krukenberg, and is named lipochrome. This fact goes far to explain the general comparative permanence of the yellow colours both of plants and animals. The yellow pigment obtained by Hansen in a crystalline condition agrees in its behaviour with lipochrome. The spectra of the pigments of different yellow flowers agree with each other so closely as to testify to their mutual identity. Between the F and G lines there occur two absorption bands, which do not occupy exactly the same position. The solutions are not fluorescent.

Orange is formed by a denser deposit of the yellow pigment. The colour of the rind of an orange is due to the same yellow pigment as that found in the flowers of *Ranunculus repens*.

The colour of yellow dahlias and lemon-rind is not lipochrome. It is soluble in water, and behaves differently both chemically and spectroscopically, displaying, for instance, no absorption-bands. It is very similar to the colouring-matter of *Aethalium septicum* examined by Krukenberg.

The reds of flowers, in Hansen's opinion, may be reduced to a single pigment, the dye of roses, carnations, peonies, etc. It is soluble in water, and is decolourised by alcohol, probably in consequence of dehydration. On the addition of an acid the colour is restored. The spectrum displays a broad absorption-band between D and F. The varying intensity of the colours of roses, carnations, and peonies depends, perhaps, on the presence of acids. The scarlets and brick-reds of poppies, scarlet lilies, hips and haws are doubtless produced by the joint presence of lipochrome.

The blue and violet pigments also turn pale in alcohol. The solution is reddened by acids, as was noticed by Fremy and Marquardt, who thence concluded that the reds were merely blue pigments modified by acids. Hansen, on the other hand, holds that the blue and the violet colours are modifications of the red. In support of this view he urges the fact that certain blue and violet colours (*Boragineae*) are at first red. On the contrary, we must remember that the corolla of many fuchsias passes from a bluish violet to a red, whilst the flowers of *Erica cinerea* open red and turn more to a violet on fading. Salts of iron, added to the soil, turn the red of peony flowers to a violet. Gardeners can also produce blue Hortensias by the use of iron. Peony red is turned to a violet by the addition of sodium phosphate, whilst larger quantities of the same salt turn it blue. The spectrum of the blue and violet pigments has two absorption-bands between D and *b*. These pigments may be combined with lipochrome yellow, thus producing the colour of the berries of *Ampelopsis*. Hansen assumes, therefore, only four fundamental pigments:—soluble yellow, lipochrome yellow, flower-red, and chlorophyll green. He opposes the view that all colours are derived from chlorophyll green, since the spectra do not agree.

The view that scarlets in flowers and berries are composed of a red pigment superposed upon lipochrome yellow, is strongly confirmed by the instance of bryony.

Its berries are first green, then take a bright yellow, and finally become scarlet. In the blackberry and the bilberry we see the development of blue and violet colours out of red, as both these fruits are red when half ripe.

SUN-DIALS, AND HOW TO MAKE THEM.—II.

THE next pattern to be considered is the ordinary horizontal dial. This may also be considered to be a thin slice of the globe dial, but in a horizontal plane. The axis, as before, points to the North Pole, and it may be either a thin wire or a stout gnomon; in the latter case the dial must be considered as though divided by the thickness of the gnomon.

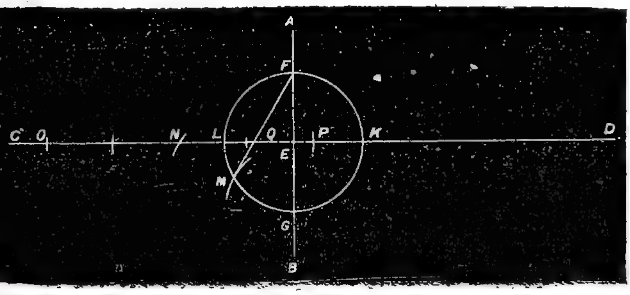


FIG. 7.

Fig. 6 (page 129) shows the horizontal dial as a slice of the globe. It will be seen that the divisions are no longer equal, but decrease in size as they approach XII.

There are a considerable number of methods of setting out the divisions; some of them are well worthy of attention, and those who care for pure geometry will find the subject full of interesting problems, ranging from the simple cases which are given in these chapters to the intricacies of spherical trigonometry, into which we shall not enter.

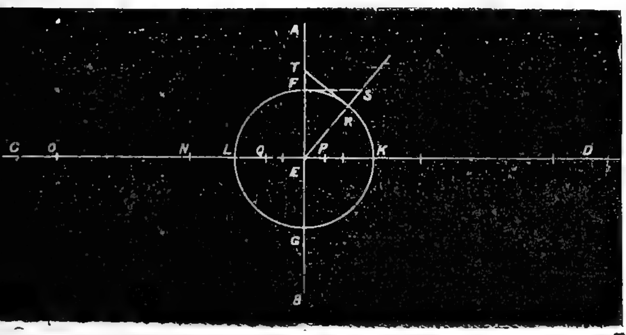

FIG. 8.

The least interesting method is to take the divisions from the following table of angles :—

Lat.	a.m. p.m. I XI	a.m. p.m. II X	a.m. p.m. III XI	a.m. p.m. IV VIII	a.m. p.m. V VII	a.m. p.m. VI VI	Tan. Co.Lat.
50° 0′	11°38′	23°51′	37°27′	53° 0′	70°43′	90°0′	·839
51° 0′	11°46′	24°10′	37°51′	53°24′	70°58′	90°0′	·809
51°30′	11°51′	24°19′	38° 4′	53°36′	71° 6′	90°0′	·795
52° 0′	11°55′	24°27′	38°14′	53°46′	71°13′	90°0′	·781
53° 0′	12° 5′	24°45′	38°37′	54° 8′	71°27′	90°0′	·753
54° 0′	12°14′	25° 2′	38°58′	54°29′	71°40′	90°0′	·720
55° 0′	12°23′	25°19′	39°19′	54°49′	71°53′	90°0′	·700
56° 0′	12°32′	25°35′	39°40′	55° 8′	72° 5′	90°0′	·674
58° 0′	12°48′	26° 5′	40°18′	55°45′	72°27′	90°0′	·625

The XII., or noon line, must be drawn first, and the VI. line at right angles with it; the other hour lines may then be set out with a protractor, but in the geometrical methods which will be given this instrument will not be required.

The last column in the table is the tangent of the co-latitude. This may sound rather alarming to non-mathematical readers, but it will be found useful in setting out the angle of gnomons for those who do not possess a good protractor. At the latitude of York, 54 degrees, to construct a gnomon for a horizontal dial draw a straight line 10 inches long, and at right angles to one end of it draw a line 7·20 inches long. Join the ends of these lines to form a right-angled triangle; this will be the shape of the required gnomon, the 10 inch side being the base and the 7·20 inch side the perpendicular. This side is generally cut in a fancy shape.

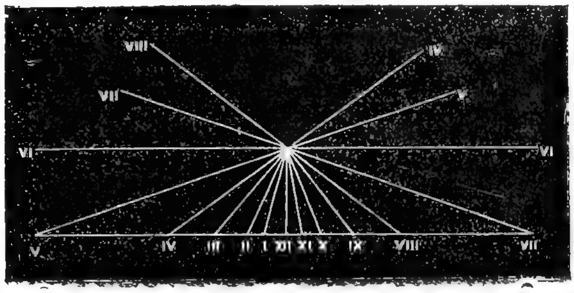

FIG. 9.

The first method which we describe for setting out the angles of the hour lines by simple geometry without the use of a table of angles and a protractor, was held in esteem by the old diallists for a curious reason—it can be produced by "only one opening of the compasses." Old books of geometry often describe figure methods of drawing figures with as few different openings of the compasses as possible; this seems to suggest that in the early days of instrument making the joints of the compasses were either so stiff or so ricketty that the less the legs were moved the better.

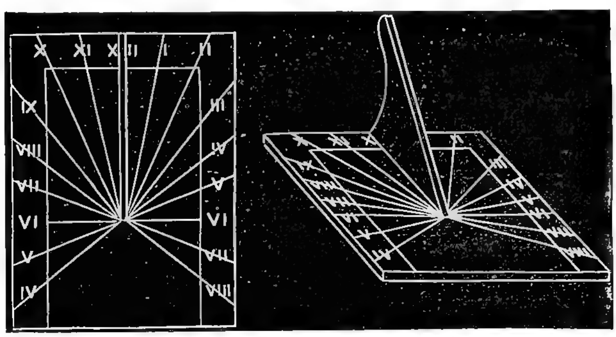

FIG. 10.

Draw two lines AB, CD, Fig. 7, intersecting at right angles at E. From E as a centre, with any convenient radius, draw the circle FKGL, cutting AB at F and G, and cutting CD at K and L. Then, keeping the compasses at the same opening, place one point at G and mark off M. Then turn from M to the point N, then make two steps to O and four steps back to P. Join MF, cutting CD at Q. The points ONLQEP, correspond to the hours V., IV., III., II., XII., and XI. The points found by repeating the process on the other side will give the points for the hours VII., VIII., IX., X., and I.

We have now to find the centre of the dial, or the point from which the hour lines radiate, this being also the point where the style, or the edge of the gnomon meets the plane of the dial. On the circle FKGL, Fig. 8, considering AB as the axis, and CD as the equator of the globe, mark off the point R, corresponding to the latitude of the place, the angle RED being the angle of latitude. This angle may be easily drawn by the aid of the table of tangents of co-latitude. EF being 10 divisions of any scale, and FS 17·95 divisions if the dial is for use in London. Draw RT at right angles to RE, cutting AB at T. T will be the centre of the dial. The triangle FSE represents the gnomon folded down flat. The hour lines may then be drawn through the points already found, as in Fig. 9. The hour lines for IV. and V. in the morning are merely extensions of the IV. and V. lines in the afternoon, and similarly for the VII. and VIII. lines of the afternoon.

A complete horizontal dial is shown in plan and in perspective in Fig. 10.

(To be continued.)

THE MATHEMATICAL ARGUMENT AGAINST ORGANIC EVOLUTION.

WE are about to examine, and we may venture to say, to refute an argument which was first brought forward by Prof. Fleeming Jenkin in the *North British Review* for June, 1867, and which at one time not only created some sensation but seems to have staggered even Charles Darwin.

The argument, strictly speaking, does not tell against evolution in general, but against evolution as effected mainly by Natural selection, or, as it is commonly called, "Darwinism." However, as the two terms are very commonly regarded as synonymous—it is by no means certain that Prof. Fleeming Jenkin understood their difference—it deserves brief notice.

Its author contended that if some advantageous peculiarity made its appearance on any given species it would probably be in the outset confined to one individual. If that favoured individual mated with one of the unmodified original type, its offspring would possess the distinguishing feature of the improved parent only to the extent of one half, and thus in the course of a few generations the improvement will be "bred out," and we have a reversion to the old type.

This argument is, of course, entirely founded upon the assumption that the offspring of any pair of animals will be intermediate, exactly or at least approximately, between their parents. Such an assumption is contrary to general experience. Were it well founded, a "family likeness" could never exist, since any peculiarities of an ancestor in face or figure would not be traced beyond at furthest the third generation. In reality we know that such likenesses are handed down for centuries. The "Bourbon nose" and the "Hapsburg lips" are matters of history. In not a few instances, where a family has been for a long time in a position to accumulate and preserve a series of ancestral portraits, its living members strongly and distinctly embody the features and expression of forefathers who flourished in the days of Queen Anne, or even earlier. Were such collections of portraits more general we should unquestionably find such hereditary likeness as common among the families of peasants as of kings and nobles.

If a momentary digression may be allowed, we should strongly urge the preservation of photographic portraits which are now within the scope of the great mass of the public, and which in course of time will become, from this point of view, valuable scientific documents.

But we may go a step, and a long step further. Any peculiarity, whether it be a new development or a reversion to some long-forgotten ancestral type, so far from necessarily disappearing in its offspring may even be intensified. As an instance, we quote from the *Journal of Science* (October, 1882, p. 623) the following passage, taken originally from *Land and Water*:—

"About twelve months ago, Mr. Peter Low, flesher, High-street, Montrose, bought a ram with four horns from a lady in town, which she had gained at a raffle at a church bazaar in Brechin. Mr. Low put the ram into a park with a black-faced Highland ewe, and the result was that the ewe gave birth to twins, male and female, on July 9th last, the male lamb having five and the female four horns, all well-developed."

We remember a similar case for which unfortunately we can give no details of place and date, but of the main fact of which we are absolutely certain. Every one knows that the domestic fowl has three toes in front, and the so-called spur behind the leg. A farmyard cock was found to have four toes in front, the spurs being developed as usual. This redundancy was transmitted to almost all his descendants, and four-toed fowls became—and are possibly yet—very numerous in the district.

Nor are cases in point wanting in the human species. We know an instance where a man having very dark hair and eyes married a blue-eyed fair-haired girl. One of the sons had eyes and hair darker than those of the father—the hair, in fact, being of the kind which novelists and poets call "purple black"—whilst another had the fair hair and blue eyes of the mother not in the least darkened.

Now, in all the cases which we have mentioned, the peculiarity thus transmitted to descendants has been of a kind not likely to confer any advantage in the struggle for existence. But if such useless abnormalities are transmitted, it is almost certain that advantageous variations are still more likely to be perpetuated.

The advantages gained by even a slight variation from the original type may be almost unlimited. Let us suppose a species of bird hard pressed by some enemy its superior in powers of flight. But if one bird of this species is produced swifter than the enemy, the chances of survival of this exceptional individual will be greater than that of any of the original stock, not by ten or fifty per cent., but, practically speaking, infinitely. If this bird, as we have seen it is possible, transmits its exceptional powers of flight to its descendants unimpaired or still more intensified, the original strain of bird will disappear, and will be replaced by what we may call the improved type.

Prof. Fleeming Jenkin thinks that as variations may take place in all directions, they will be likely to neutralise each other. But, in the instance we have just been taking, any variation in the direction of slower flight would quickly prove fatal to its possessor.

Hence, we see that even allowing—which we do not—natural selection to be the sole or main cause of the variation of organic forms, the contention of the *North British Review* is not of capital moment.

General Notes.

Australian Association for the Advancement of Science.—The first meeting of this Association will be held at Sydney on September 4th.

Alleged Cause of Leprosy.—In Turkey there prevails a notion that leprosy may be occasioned by a stroke of lightning.

Landslip.—There has been another landslip on the Scarborough and Whitby Railway, and traffic is again stopped. A few days ago a large part of the hill round which the line runs, after passing a place called the Peak, fell and blocked the rails. This was cleared, and traffic again resumed, but during Thursday night in last week there was another slip, and the line was again blocked.

Professor Brazier.—This gentleman is retiring from the Chemical Chair at Aberdeen University. Among the probable candidates for the vacancy are Mr. H. J. Jones, recent assistant to Professor Brazier: Dr. Orme Masson, professor of chemistry in the University of Sydney; and Dr. J. Gibson, assistant-professor of chemistry at the University of Edinburgh.

South London Polytechnics.—We understand that the Corporation of London will be asked within a very short time to exercise its well-known liberality in assisting the grand scheme now on foot, and certain of success, for creating in the south of London a series of polytechnic institutes for the education and advancement of the youthful portion (male and female) of our working population.

Registration of Plumbers.—At the City and Guilds Institute, Finsbury, last Saturday week, an examination was held under the auspices of the Company of Plumbers for Certificates of Registration. The practical examination included various branches of lead work, and the theoretical questions relating to the several subjects of plumbers' materials, house fittings and sanitation. Seventy-five per cent. of those attending passed the full examination.

Lightning Conductors.—Arrangements have been made by Mr. Edward Rigg, Recorder of Section G of the British Association, for a joint discussion on "Lightning Conductors," to be held in sections A and G at the Bath meeting in September. Mr. W. H. Preece, F.R.S., the President of Section G, will open the discussion, and Professor Oliver J. Lodge, F.R.S., will defend the position he took up this year before the Society of Arts.

The Preparation of Rhea.—The Board of Trade have received information through the Foreign Office to the effect that the opening of the competition of machinery and apparatus for the preparation of rhea, which was to have taken place at Paris on the 15th of this month, has been postponed till the 25th prox. The period during which applications for permission to compete will be received has also been extended to the 30th of August.

Meteor.—On Thursday morning in last week, at 2.30, a magnificent meteor was seen from Manchester in the south-west. The heavens were suddenly illumined by a splendid burst of light, caused by the explosion of the meteor. For at least three seconds after the white light had disappeared a well-defined train of red light could be seen depending, as it were, from the clouds. It would be interesting to know over what extent of country the flight of the meteor was observed.

Exploration in Morocco.—The following message from Mr. Joseph Thomson and Mr. Harved Crichton-Brown, transmitted by the Eastern Telegraph Company's cable from Tangier, has been sent to the Royal Society, the Royal Geographical Society, and to the friends of the explorers:—"City of Morocco, July 28th.—We returned to Amsmiz across mountains, safe and well, July 24th; many interesting geographical and geological notes; so far successful beyond our expectations. We were prevented going direct from Glamoa to Gundaffy by tribal revolt. We shall start on August 6th for third trip across the Atlas, further S.W. this time."

The Greenland Expedition.—The captain of a whaler which arrived at Sandefjord on August 4th reports that he fell in on July 10th with the ship *Jason*, having on board Dr. Nansen, of Bergen, and his companions in the journey on snowshoes across Greenland. The *Jason* was to have landed them at the east coast, but the first attempt had been a failure, owing to heavy weather and fogs. In order not to lose the seal-hunting season, the *Jason* had turned southward again; but it was the intention to shape a northerly course soon after July 10th, when another effort would be made to land Dr. Nansen and his party of explorers. Heavy masses of ice were reported along the coast.

Suicide Contagious.—Most of our readers will have heard of the sentry-box at Paris in which a number of sentinels hanged themselves in succession, until it was destroyed by the order of the Emperor. Every one is aware how persons came sometimes from a distance to fling themselves over the Highgate Archway, to the grievous peril of passengers on the road below, until a lofty iron fencing rendered this mode of self-destruction impossible. The same curious trait of human nature is now being manifested at the Clifton Suspension-bridge, which is about to be caged in with iron trellis-work from end to end. A similar fascination attaches in Paris to the Vendôme column and that of the Bastille, which are about to be caged in a similar manner, for the protection not merely of the madmen in question, but of those passing below.

Crystal Palace School of Practical Engineering.—On Saturday afternoon Mr. Arthur T. Walmisley, C.E., President of the Society of Engineers, awarded the certificates gained by the students of the Crystal Palace Company's School of Practical Engineering, the distribution taking place in the south tower of the Palace. Mr. F. K. J. Shenton read the report, which stated that out of thirty-two students who had attended the lectures on "Railways, their construction and appliances," twenty-two proved eligible for examination, and eighteen satisfactorily passed. The result of the examinations in the various sections was of a most satisfactory nature. Mr. Walmisley, in addressing the students, said that the report showed that good work was being done in the school. He could speak with a practical knowledge, having examined in the civil engineering section two years ago. Civil engineering was world-wide in its work, and could claim to have done a good deal towards the civilisation of the globe. Engineers must go before the missionaries to make the roads and provide water for them. The work of the students then on view displayed great aptitude on their part and reflected credit on the teachers. Mr. J. W. Wilson, the principal, said the school had been established sixteen years and that was the forty-seventh occasion upon which certificates had been awarded. Between 700 and 800 students had passed through the school, many of whom were doing well. He mentioned that seven or eight of their old pupils were now engaged as engineers in the construction of the Manchester Ship Canal.

National Co-operative Exhibition.—On August 18th an exhibition of the skill of workmen in their own trades will be opened at the Crystal Palace in connection with the National Co-operative Festival. The competition will be amongst working-men members of the Industrial Co-operative Societies throughout the kingdom, and the special facilities offered to them to compete, by their respective societies agreeing to pay carriage on all exhibits, should open the door to a very large and representative display of individual work. The prize list is a good one, and the Council of the Society of Arts—who have promised to appoint the judges—will also award one of their bronze medals in eighteen of the principal classes. The Secretary, Mr. W. Broomhall, 1, Norfolk Street, Strand, will supply any further particulars.

Earthquakes in Norway.—Dr. Hans Reusch, of the Norwegian Meteorological Institute, who is engaged in collecting particulars of the earthquakes which occur in Norway yearly, has issued his report for 1887, from which it appears that earthquakes are far more frequent in Norway than has hitherto been imagined. Reports were received of twenty-three, all of which were faint except three. One occurred on the night of May 7th, in the Bommel Islands, on the west coast, and was accompanied by subterranean detonations; another in the islands of Værö and Röst, at the extreme point of the Lofodden group, where doors and windows clattered, and the slates on the roofs were pitched off. Again, on November 5th, a severe shock of earthquake was felt at Bodö, on the north-west coast. Of the minor shocks those which frequently occurred on the Ytterö are particularly remarkable, as this island lies far out in the ocean, off the coast of Söndfjord.

The Public Health.—The Registrar-General reports that the deaths registered last week in twenty-eight great towns of England and Wales corresponded to an annual rate of 16·0 per 1,000 of their aggregate population. In London 2,530 births and 1,309 deaths were registered. In allowing for increase of population, the births were 87, and the deaths 473, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 15·7, 15·8, and 15·9 in the three preceding weeks, was again 15·9 last week. During the first five weeks of the current quarter the death-rate averaged 15·6 per 1,000, and was 6·0 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,309 deaths included 29 from measles, 18 from scarlet fever, 19 from diphtheria, 25 from whooping cough, 9 from enteric fever, 121 from diarrhœa and dysentery, 4 from cholera and choleraic diarrhœa, and not one from small-pox, typhus, or ill-defined forms of continued fever; thus, 225 deaths were referred to these diseases, being 278 below the corrected average weekly number. The deaths referred to diseases of the respiratory organs, which had been 166 and 160 in the two preceding weeks, rose last week to 167, but were 25 below the corrected average. Different forms of violence caused 49 deaths; 42 were the result of negligence or accident, among which were 17 from fractures and contusions, 5 from burns and scalds, 5 from drowning, and 9 of infants under one year of age from suffocation. In Greater London 3,318 births and 1,593 deaths were registered, corresponding to annual rates of 31·3 and 15·0 per 1,000 of the estimated population.

Archæological Congress.—The annual congress of the Archæological Institute was opened on Thursday in last week, in the New Municipal Buildings at Leamington. In the Architectural Section Chancellor Ferguson read a paper on the "Castles in the District." This was followed by one on "The Great Wall of China," prepared by Mr. E. T. C. Werner, of H.B.M. Legation, Pekin. In the afternoon the members of the Institute paid a visit to Warwick. At St. Mary's Church the Rev. J. Case read an interesting paper on the building itself; and Mr. A. Hartshorne, F.S.A., commented upon the monuments in the Beauchamp Chapel. From there the party proceeded to the Museum, and subsequently visited Leycester's Hospital and the Castle, where Mr. Hartshorne read a second paper, and Professor E. C. Clark described the famous "Warwick Vase."

On Friday a visit was made to Baginton Church, where Mr. W. G. Fretton acted as guide over the church and the site of the ancient castle. From Baginton the party made their way on to Stoneleigh, where the ruins and remains of the ancient abbey were explained and commented upon by Mr. Fretton. They then inspected the modern mansion of Lord Leigh, and the pictures and other treasures belonging to the family. They also were shown the interior of Stoneleigh Church, with its fine Norman doorway, chancel arch, and curious font, and other decorations and monuments, including that to the Duchess of Dudley, who was a daughter of the noble House of Leigh. Their next halt was at Kenilworth, where Mr. Hartshorne acted as their guide and interpreter, showing them the ground plan of the castle as it was in the days of Elizabeth, almost surrounded by the lake, now dry. Leaving Kenilworth, they went on to Guy's Cliff, and were conducted through the little chapel and hermitage by Mr. Hartshorne.

On Saturday the ancient city of Coventry, so rich in mediæval buildings and events, was visited. Mr. W. G. Fretton, F.S.A., acted as guide. Among the places specially examined were St. Mary's Hall, St. Michael's and Trinity Churches, the Benedictine Priory and the site of the ancient Cathedral Church of Coventry and the Hospitium adjoining. The remains of the ancient walls and gates of the city were next inspected, and then St. John's Hospital, so long used as a free grammar school, the Collegiate Church of St. John, and the Bablake Hospital. After lunch Mr. Fretton conducted the members over the Palace Yard, the buildings of the White Friars or Carmelites (now used as the Coventry Union), St. Anne's (formerly the Carthusian Monastery), the Park Walls, the Manor House of Cheylesmore, the Grey Friars (now Christ Church), and Ford's Hospital.

WHIRLWINDS AND WATER-SPOUTS.—II.

(Continued from p. 78.)

THE whirlwinds which I observed on the ridges of our high mountains (where the snow is generally agglomerated in a manner more or less compact) so that the whirlwind can only raise up a sort of very dry rime, of a very slight density, present, on a reduced scale (2—6 yards in height) the same form as the dust-whirlwinds seen on dusty roads, *i.e.*, that of an inverted cone. On the contrary, the snow whirlwinds seen on the great tablelands, where the snow is plentiful and powdery, exhibit the aspects of the terrible sand-pillars of the deserts (Fig. 3). Hence it seems to me that the density of the materials lifted up modifies decidedly the general form of the whirlwind, beginning even with its *base of suction*, being acute in the one case and wide in the other. Evidently the existence of conical whirlwinds raising up snow and sand indicates a very considerable intensity.

In conclusion, R. Duhamel records his conclusions as follows :—

Everything conspires to demonstrate that the whirlwind itself presents an ascending force, so that in its whole mass the current sets from below upwards.

In mountainous regions whirlwinds occur by preference in certain places, rounded ridges, large open hills, enclosed ravines (forming in a manner chimney-shafts), high plateaus and points in valleys situated below currents of air coming from passes which open above them.

M. D. Colladon, of Geneva, forwards to *La Nature* some further observations on the same subject :—

"I have read with much interest M. H. Gilbert's note on the whirlwind which he studied at Vincennes. The most important matters are the formation of the point of the whirlwind and the direction of the rotation, which is that of the hands of a watch."

In 1879 I noted down the following particulars on a whirlwind which I watched for some minutes :—

"On a fine day in July, and in very calm weather, between 11 a.m. and noon, I was passing along the Boulevard de la Coulouvrenière at Geneva, near a stony place, where a great quantity of linen articles of different sizes had been laid out in the sun to dry. All at once a whirlwind with a perpendicular axis, and two or three yards in diameter, rendered distinctly visible by the rotation of a wave of dust, passed over this piece of ground spread with linen, and turned a part of them over, carrying them up at a dizzy speed above the roofs of the town, where all these articles continued to whirl about describing divergent cycles. Finally, at a height of at least 600 to 700 yards these articles were scattered in in different directions. This was evidently a whirlwind with an ascending rotatory movement. The column appeared, at the outset, to have the form of an inverted cone. All the objects lifted up were drawn into the interior, and then transported by the impulse of the air. Such momentary whirlwinds sometimes occur in calm and hot days in spring and summer, but they are visible only if there are at their place of origin light bodies or abundance of dust, and hence they often escape observation."

If the whirlwind just described had not carried away with it the linen, it would have ceased to be visible at the height of thirty or forty yards.

Whirlwinds in which the air ascends spirally have been seen in various countries, in dusty plains, and generally in calm weather. Their form has been compared by Humboldt to a funnel, the point of which rests on the ground. In his "Pictures of Nature" he speaks of whirlwinds of this kind observed in the Llanos of Venezuela.

Mr. Stephenson has observed similar phenomena in the province of Behar on certain dusty plains near the Ganges. He describes at the confluence of the Ganges and the Sone two enormous dust columns of more than four yards in diameter, the summit of which was lost in the atmosphere.

M. Adrien Arcelin, of Saint Sabin, sends to *La Nature* a notice of a similar phenomenon recorded in 1873, near Solutre. "A quire of so-called straw-paper which I used for wrapping up objects collected in the excavations, and which was lying on the ground at our feet, was whirled into space. All the leaves parted company, and began to rise turning over along helicoid trajectories which became gradually larger. It was curious to see these twenty-four sheets of paper whirling in the air like a flock of birds. They went far beyond the summit of the rock which rises 90 yards above the place where we were standing, and they lost themselves in the sky in the direction of Vergisson. The whirlwind was, therefore, moving in a

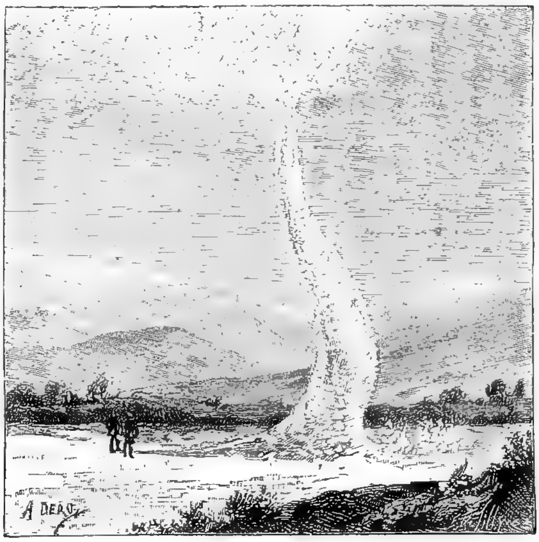

FIG. 3.

north-westerly direction. The time was 4 p.m. The weather was delightful, the sky clear, and the air calm both before and after the event.

Our party of ten labourers who were sitting on the ground, eating, at the distance of about 20 yards, felt nothing. There was no cloud of dust, as the ground was overgrown with grass, and had it not been for the paper the phenomenon would have quite escaped observation.

FAYE'S COMET.—Faye's periodic comet was seen near the calculated position by an observer at Nice Observatory at twenty minutes after three on Friday morning. The position was—right ascension 5h. omin. 28sec.; North Polar distance 69deg. 59min. 18sec. Comet Brooks was in right ascension 10h. 22min., and North Polar distance 45deg. 11min. at ten p.m. on the 9th inst., and the daily motion was $7\frac{1}{2}$ minutes decreasing right ascension and 9 minutes increasing Polar distance.

OUR KNOWLEDGE OF THE BACTERIA.

(*Continued from p.* 109)

THE forms which bacteria assume have been known for a couple of centuries. Van Leeuwenhoek, of Delft, an observer to whom we are indebted for an abundance of microscopic discoveries, saw in the year 1683, merely with single lenses of his own grinding, the now well-known bacilli, micrococci, and spirilli. Further observations showed the frequent and plentiful occurrence of these beings in the most different localities and under varied conditions. This circumstance, as well as the apparent impossibility of preventing their appearance and multiplication, gave rise to the thought that they were a product of *generatio aequivoca*. The first protest against this view was raised by Spallanzani, in 1769. He found that in infusions of plants contained in vessels which had been closed and were then heated for a long time the development of these micro-organisms—or as they were then called animalcules—did not take place. But on the free access of air which had not been heated they promptly made their appearance. Hence he argued that these microbia were not a product of spontaneous generation, but were developed from pre-existing germs. His opinion, long contested, was at last definitely and victoriously established by the researches of Pasteur.

The reason why these microbia were at first ranked among animals was their swarming motion. Not until the middle of the present century they were removed from the animal kingdom by Perty, Cohn and Nageli in accordance with their physiological properties and grouped along with the fungi, under the name Schizomycetes. It appeared that in certain essential points they present the same vital relations as do fungi. By reason of their want of chlorophyll they are not able to decompose the carbonic acid of the atmosphere and thus to obtain their supply of carbon. They are therefore restricted to a nutrient medium containing organic substances, animal or vegetable, *i.e.*, higher compounds of carbon. Without such a medium they cannot exist.

This is the case with the bacteria, which are never able to decompose carbonic acid. Both ordinary fungi and bacteria require a large proportion of nitrogen, and are therefore limited to a nutrient medium rich in that element. But not all bacteria and other fungi require organic compounds of nitrogen; many of them are able to assimilate even the simplest, such as nitric acid and ammonia.

Germs of bacteria susceptible of development may be found everywhere in the air around us, in the water, and in the superficial layers of the soil. Being suspended in the air or adhering to particles of dust they are driven by the wind against the surfaces of our walls, our furniture, and our clothing, and are always to be found there. Only on the loftiest peaks of snowy mountains and far out upon the ocean, remote from the land, is the air found free from such germs. The surface of our bodies, in health, is covered with bacterial germs, and not merely the external surface. With every breath of air they find their way into the mouth, the nostrils, and the respiratory organs. With every morsel we eat, and with every drop we drink, bacterial germs enter the mouth, the throat, the stomach, and the bowels. The secretion of the mucous membranes, and the other organic masses, which they here encounter, supply them with scope for multiplication. We must not, however, suppose that each and every kind of bacteria can prosper in any nutrient medium suited for bacteria in general. On the contrary, bacteria have their likes and dislikes, and every species requires particular kinds of nourishment.

In the growth and the multiplication of bacteria there occur a great series of phenomena all reducible to the circumstance that the complicated compounds of which their nutrient medium is composed are reduced to simpler ones by their vital process. There are thus produced the simplest chemical bodies, such as carbonic acid, hydrogen, hydrocarbons, sulphuretted hydrogen, and ammonia. During this decomposition of the nutrient medium we meet with the formation of the most varied ferments. Thus there are bacteria which generate ferments capable of converting saccharose into glucose, and also starch into glucose, which dissolve (peptonise) coagulated albumen and congealed gelatine, and which coagulate milk. Other bacteria effect the most manifold fermentations, and others, again, occasion the different phases of putrefaction, *i.e.*, decompositions of nitrogenous organic masses—with liberation of evil-smelling products. These latter processes have been for the first time closely studied by Pasteur. This able inquirer discovered the important general part which the bacteria play in the household of nature, reducing the complicated organic compound (formed by the life of plants and animals from inorganic substances) to the simplest states, and thus completing the circulation of matter. Among the chemical compounds produced in the vital process of bacteria, a prominent place is due to the so-called *ptomaines*, nitrogenous compounds of a basic character, some of which, known as *toxines*, are intensely poisonous.

We may lastly mention that many bacteria can elaborate from the substance of their nutrient medium colours, some of which are wonderfully beautiful. Others develop in their transparent nutrient medium a splendid fluorescence, whilst others give out in the dark a phosphorescent light.

HONOURS AT THE LONDON UNIVERSITY.—The honours list of the London University Intermediate Examination in Medicine, in July, shows a remarkable performance on the part of the candidates sent up by the London School of Medicine for Women. The total number of places obtained in honours by men and women was twenty-one, and of these the men took eleven, and the women ten. Owens College, Manchester, Middlesex Hospital, King's College Hospital, St. Bartholomew's Hospital, each obtained one place. From University College four successful candidates obtained seven places, but from the London School of Medicine for Women seven candidates obtained ten places. It should be noted also that only five out of the large number of men's schools have succeeded in getting a place in the honours list, while a small and comparatively new school, such as the one for women, has secured ten places.

THE NEW RECTOR OF LEIPZIG UNIVERSITY.—Dr. Franz Hofmann, Professor of Experimental Hygiene and Director of the Hygienic Institute in Leipzig University, has just been chosen Rector of that seat of learning. There is no higher name in Continental state medicine than that of Professor Hofmann, as all who remember the greeting accorded to him at the great Vienna Congress of last year will understand; and the German journals, professional and lay, are hailing his election as proof that public sanitation is becoming daily more prized in the great centres of scientific education.

Natural History.

THE RATEL (MELLIVORA RATEL).

Among the distinctive peculiarities of animal, or at least of mammalian species, one of the most curious, and at the same time most generally overlooked, is the comparative tightness or slackness of their skins. In ourselves, and in our nearest "poor relations," the apes and monkeys, the skin fits very tightly over the body. On some parts of our frame only, such as the knuckles, the elbows, and the knees, there is a loose fold of skin to allow of the free play of the joint. In some of the lower mammalian forms, those especially which coil themselves up into a kind of ball when asleep, the skin is of necessity very loose, like a coat too large for the wearer. This arrangement occurs more or less in the porcupines, the hedgehogs, but perhaps most of all in the uncouth-looking animal whose portrait we borrow from *La Nature*. So loosely clad is this creature that, familiarly speaking, it can turn round in its skin; and if seized almost by any part, it can thus contrive to inflict a bite upon the hand, or paw, or head of the aggressor. In the ratel, or beejoo, the skin is, in addition, very thick, and the fur dense and compact. If we inquire into its habits and its way of earning a livelihood, we may easily see that the structural features just mentioned are exactly such as are likely to have been developed by natural selection. It lives in Africa and India; it is a nocturnal, burrowing animal, and its favourite food is the comb of the wild bee, full of honey and young brood. Had the ratel, therefore, such a skin as men or monkeys, it would be infallibly destroyed by the stings of the insects whom it seeks to plunder. Even in England a hive of bees, when thoroughly enraged, is a formidable antagonist, but in tropical climates,

The Ratel.

where the swarms multiply all the year round, and may amount to hundreds of thousands, the only safety lies in a speedy retreat. But the coat of the ratel is practically impenetrable to the stings of bees, wasps, and hornets. The ratel cannot climb, and hence, if a swarm of bees have made their nest in the hollow top or branches of some huge tree, they are safe from their greedy assailant. But too often they make their home in a forsaken nest of termites, or in the burrow of some mining beast, such as the aard-vark, and then they are defenceless, the short, trenchant claws of the ratel enabling him to break through the compactest earthworks, and the industrious insects are then at his mercy.

But the peculiar nature of the ratel's skin secures him from the attacks of far more formidable enemies. As a nightly rover and as given to burrowing, he may often come in collision with the deadly serpents of his native country. Now though the snakes of Europe and, according to Charles Waterton, those of South America never take the offensive, those of Africa and India are exceedingly touchy, and are very apt to dart at any intruder who disturbs their meditations. But there is a very trifling probability of a puff-adder, a cobra, or even a hamadryad being able to introduce its venom into the blood of the ratel. What with the thick, compact coating of hair and the looseness of the skin, the poison is expended on non-vital parts. As for scorpions, centipedes, and tarantulas they are to the ratel perfectly harmless. We may here note that when in districts infested with poisonous vermin we wear loose clothing we imitate the defence with which this animal is provided by nature, and if we are foolish enough to range about in viper-covers clad in knickerbockers we deserve what we may possibly get.

From the attacks of wolves, jackals, wild dogs, and leopards the ratel often escapes by burrowing, but if there is not time for this expedient, he falls on his back and defends himself bravely, and often successfully, with teeth and claws. In such cases, again, the thickness and looseness of his skin serves him in good stead, and he is moreover exceedingly tenacious of life.

The ratel is black upon the snout, legs, and all the lower portions of the body, whilst the top of the head, neck, back, and tail are clothed with long, ash-grey hair. This is the same exceptional arrangement of colour which we meet with in the badger, and which has hitherto not met with any explanation. An additional peculiarity is that there runs along each side a bright grey stripe, forming a boundary between the dark and the light-coloured portions of the fur. The ratel in walking applies the entire sole of its foot to the ground, and hence belongs to the *plantigrade* (sole-walking) section of the Carnivora, of which the bears are the type. It displays, indeed, such an analogy to the bears, that it has been called the "honey-bear," a misleading name, since the true bears are all fond of honey. It belongs, however, to the family of the badgers (*Melidæ*).

If taken young, the ratel is capable of domestication, and in captivity it affords much amusement from its grotesque performances. It is exceedingly fond of throwing somersaults, as it is shown in our illustration.

The ratel of South Africa is about a yard in length, of which nine inches go to the tail. It is a very unpopular animal, as horses often tread in its holes and break their legs, or at least throw their riders. In India it is, if anything, still more disliked, from its propensity for digging into newly-made graves to feast upon the bodies. It is thus, in its way, a silent but effective advocate for cremation.

A New Evidence of Organic Evolution.—M. Bordier has recently found among microbia actual instances of transformation. These beings have so brief a life, and multiply with such rapidity, that the observer may witness changes accumulating from generation to generation. During the year there may occur 24,000 generations of bacteria, or as many as could occur in the human race in 600,000 years. One and the same microbion—that of "blue pus"—has been seen under the action of different substances to take the form of a *bacterium*, then that of long filaments, then that of comma-bacilli and that of spirilli.

The Poison of Eels.—From a communication made to the Royal Linceian Academy at Rome (*Cosmos*), it appears that eels and muraenas secrete a venom similar to that of the viper. It is not localised in the mouth, and they are not provided with any organ for instilling it into their enemies. Hence it has no effect upon man, since in cooked eels the poison has been destroyed by the heat applied in cooking. It has further no action unless introduced into the blood.

Prescription for Mosquitoes.—"F. B.," writing in the *Field*, recommends a mixture which he has found efficient in Manitoba and the North-Western Territory. It is made by mixing 1 pint Stockholm tar, 2 pints olive oil, 3 teaspoonfuls Calvert's carbolic acid. The hands, face, and neck are to be anointed with this mixture, when, says "F. B.," no mosquito, sand-fly or "bull-dog" will cause annoyance. He adds:—"The bull-dog seems like a cross between a horse-fly and a hornet." Such a cross, we need scarcely say, cannot be admitted as possible, but we should like to know the real name of this offensive fly. We should also be happy to learn whether "F. B.'s" mixture is better than tincture of *Ledum palustre?*

The Flora of the British Empire.—According to Mr. J. G. Baker, F.R.S., 46,000 species of plants, or nearly half the number existing on the entire globe, grow naturally in the British Empire. One third part of the number belong to India.

Influence of Sewage Farms upon Fish.—A portion of the river Kent, extending for a couple of miles above and below Kendal, and once abounding in trout, is said to have become barren in fish since the establishment of a sewage farm which drains into the river.

Shoals of Fishes.—A marine officer, writing in the *Revue de la Marine Marchande*, states that in 50 degs. N. lat., and 25 degs. W. long. (probably from the meridian of Paris), the steamer in which he travelled sailed for two consecutive hours among fishes; it was night, the weather was fine, and all the fishes had the appearance of sardines. The previous night the same vessel had encountered numerous shoals of fish. According to the estimate of this officer, the shoals covered a space of 700 nautical miles. The point in question was in the full current of the Gulf Stream. The *Bulletin de la Société d'Acclimatation*, suggests that it would be useful to draw up fish-charts, marking the spots where fishes are found in numbers at different seasons, and noting their periodicity or its default.

Organic Poisons.—It is gene ally supposed that all the poisonous principles found in plants contain nitrogen, and are alkaloidal or basic compounds. This is a mistake: two poisonous compounds, which have latterly attracted some attention, strophantine (from *Strophantus hispidus*), and ouabaïne (obtained from the Ouabaio, the arrow-poison of the Somalis), are both free from nitrogen. Both are powerful poisons, acting especially upon the heart. Though not identical they are very similar in composition, strophantine being what is technically called a "higher homologue" of ouabaïne.

The Speed of Carrier Pigeons. — A number of pigeons thrown up experimentally at the Railway Station of Roche-sur-Yon (Vendée) at 5 a.m. reached Beauvais, a distance of 500 kilometres, at 9¾ a m., and had consequently travelled at the rate of 80 kilometres (equal to 50 miles) per hour.—*La Nature.*

Acclimatisation of Wild Turkeys in Europe.—This attempt, which has little interest for the naturalist, has been made with success by Count Breuner on his estate of Graffeneck, in Austria. The three male and four female birds originally introduced have multiplied to a flock of 580 head, in addition to 150 strays which have been shot on adjacent estates. Some of the birds have reached the weight of 19 lbs.

Strange Action of a Beetle.—The other day we saw in a lane near Aylesbury a small beetle (*Platysma niger*) running round in a circle of about 6 inches in diameter. There was no apparent inducement for it to keep in this one track, and no obstacle to prevent it from going elsewhere. After watching the insect for at least ten minutes we left it, still revolving.

An Enemy of Silpha Ophaca.—Like many other of the less formidable agricultural pests, this Silpha, which has turned vegetarian, is being decimated by a parasitical fly, the exact name and nature of which have not been determined, though it is probably a *Tachinus.* At Fournes, ninety-six of the larvae of the Silpha have eggs of this parasite attached to their bodies. Would that some parasite would rid the world of the vine, the coffee, and the potato diseases!

Changes of Colour in Flowers.—The flowers of *Lantana camara,* which are of a deep golden yellow, change before fading into orange and scarlet. *L. nivea* opens white, but turns blue; *L. mixta* is also white on opening, but becomes successively yellow, orange, and red.

Sensitiveness of the Eye to Colours.—The *American Journal of Science* notices the experiments of Mr. E. L. Nichols, on the sensitiveness of the eye for low degrees of saturation of colours. Among his results is that in the male sex the eye is relatively more sensitive to red, yellow, and green, and in the female to blue.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The fifty-eighth meeting of this Association will be held this year at Bath, commencing on the 5th, and concluding on the 12th of September, under the presidency of Sir Frederick Bramwell, D.C.L., F.R.S., M.Inst.C.E.

It may first be pointed out that Bath has in its geographical position great advantage for such a purpose, and that the railway facilities in connection are fairly good. From London, Bath may be reached in 2¼ hours, from Exeter in 2, from Cardiff in 1½, from Birmingham in 2½, and from Manchester in 5½. The usual cheap-rate arrangements have been made with the various railway companies.

There being no reception room large enough available, the local executive committee is erecting a large temporary building adjoining the Assembly Rooms, where the business of the Association will be transacted. In this, most valuable aid has been and is being ungrudgingly and gratuitously rendered by one of the local secretaries, Mr. J. L. Stothert, M.Inst.C.E., who prepared the plans and is really "engineering" the whole matter.

The first general meeting will be held on Wednesday, 5th September, at 8 p.m. precisely, in the Drill Hall, when Sir Henry Roscoe will resign the chair, and Sir Frederick Bramwell will assume the presidency and deliver an address. On Thursday evening the Mayor of Bath (Anthony Hammond, Esq., J.P.) will give a *soirée* in the Assembly Rooms. On Friday evening Professor W. E. Ayrton will deliver in the Drill Hall a discourse on "The Electrical Transmission of Power." On Monday evening, September 10th, Professor Bonney will give a discourse on "The Foundation Stones of the Earth's Crust." On Tuesday evening there will be a *soirée* of a microscopical and natural history character in the Assembly Rooms; and on Wednesday the concluding general meeting will be held in the council chamber of the Guildhall.

It is anticipated that the Bath meeting will be one of much scientific interest. The eminence of the President, in a profession of great practical importance to the country, would alone attract many visitors. Nor will the names of the Presidents and Vice-Presidents of the sections fail to ensure a good attendance at their meetings.

The sections are the following:—

Mathematical and Physical Science: President, Professor G. F. Fitzgerald, M.A., F.R S.; Vice-Presidents, Captain Abney, R.E., C.B., F.R.S., F.R.A.S., F.C.S., William Esson, M.A., F.R.S., F.R.A.S., F.C.S.

Chemical Science: President, Professor W. A. Tilden, D.Sc., F.R.S., V.P.C.S.; Vice-Presidents, Professor Odling, M.B., F.R S., V.P.C.S., W. H. Perkin, Ph.D., F.R.S., V.P.C.S.

Geology: President, Professor W. Boyd Dawkins, M.A., F.R.S., F.G.S., F.S.A.; Vice-Presidents, W. Whitaker, B.A., F.R.S., F.G.S., Rev. H. H. Winwood, M.A., F.G.S.

Biology: President, W. T. Thiselton-Dyer, C.M.G., M.A., B.Sc., F.R.S., F.L.S.; Vice-Presidents, Professor E. A. Schäfer, F.R.S., P. L. Sclater, M.A., Ph.D. F.R.S., F.L.S., F.G.S., F.R.G.S., Sec. Z.S.

Geography: President, Colonel Sir C. W. Wilson R.E., K.C.B., K.C.M.G., D.C.L., F.R.S., F.R.G.S.; Vice-Presidents, the Right Hon. Lord Aberdare, G.C.B., F.R.S., V.P.R.G.S., E. Delmar Morgan, F.R.G.S.

Economic Science and Statistics: President, the Right Hon. Lord Bramwell, F.R.S., F.S.S.; Vice-Presidents, J. B. Martin, M.A., F.S.S., R. H. Inglis Palgrave, F.R.S., F.S.S.

Mechanical Science: President, W. H. Preece, F.R.S., M.Inst.C.E.; Vice-Presidents, W. Anderson, M.Inst.C.E., W. Shelford, M.Inst.C.E.

Anthropology: President, Lieut.-General Pitt-Rivers, D.C.L., F.R.S., F.G.S., F.S.A.; Vice-Presidents, J. Beddoe, M.D., F.R.S., J. Evans, D.C.L., LL.D., Treas.R.S., F.S.A., F.L.S., F.G.S.

This year there will also be the additional feature of an International Congress of the leading geologists of the world, to whom the unique geological features in the neighbourhood of Bath will be of especial interest; and, further, the first public appearance, so to speak, of Edison's phonograph.

All the chief objects in Bath will be easily accessible. The old Roman bath and its adjuncts, lately uncovered, with other remains, will be of prominent interest; as also the new buildings erected by the Corporation to meet the increasing demand for the Bath waters, and furnished with the newest appliances. The Literary and Scientific Institution, with its reading-room, library, and museum, will all be open. Botanists will be invited to visit the Botanic Garden in the Bath Park, and members generally to see an exhibition of flowers, fruits, and plants, at the Autumn Show of the Bath Horticultural Society.

It is known that the neighbourhood abounds in much that is interesting. On all sides the country is remarkable for variety and beauty. The Somersetshire coal fields and the West of England cloth factories are within easy distance. Bristol and Clifton in one direction; Gloucester and Cheltenham in another; Salisbury, Stonehenge, and Southampton in a third—all present strong attractions. The beautiful cathedral and quaint old city of Wells may be reached by a short journey along the Cheddar Valley.

The following excursions to these and other places have been organised by a special committee,—

On Saturday, September 8th, to Stanton Bury, Stanton Drew, Maes Knoll: Bannerdown, Sodbury Camp, Dyrham, Lansdown: Box Quarries, Corsham, Lacock Abbey: Bradford, Farleigh Castle, Wraxall: Cirencester, Museum and College: Tytherington and Thornbury: Swindon G.W. Works: Berkeley Castle: Wells, *via* Maesbury and Shepton Mallet, Ebbor, Wookey Hole: Barry Docks and Cardiff.

On Thursday, September 13th.—To Stonehenge, Salisbury, Wilton: Silbury, Avebury, Bowood, Wansdyke, Beckhampton: Stourton, Pen Pits, White Sheet, Longleat: Frome Valley, Nunney Whateley: Maesbury, Wells, Glastonbury, Street: Sandford and Banwell, Churchill, Dolbury, Rowberrow, Burrington, the two Charterhouses, Mendip Gorge, Cheddar Cliffs: Severn Tunnel, Chepstow, Tintern, Wyndcliffe: Radstock, Wellow, Littleton.

Another committee is preparing to meet the wants of the members with regard to hotel and lodging accommodation. It is believed that ample accommodation will be found. The Committee will be happy to give any aid in their power to those who may desire it.

The Right Worshipful Anthony Hammond, J.P., Mayor of Bath, invites the members and associates to a *conversazione* in the Assembly Rooms on Thursday, September 6th, at 8.30 p.m.; and the chairman and members of the Local Executive Committee invite the members and associates to a *conversazione* at the Assembly Rooms, on Tuesday, September 11th, at 8.30 p.m. On this occasion the Bath Microscopical Society, assisted by the Bristol Microscopical Society, have arranged for a display of objects in the various departments of natural history, etc.

On Wednesday and Thursday, the 5th and 6th of September, there will be an exhibition of fruits, flowers, etc., in the Sydney Gardens; to this exhibition all members and associates will be admitted on presentation of their tickets. On the 12th and 13th September there will be a horse show.

The places of meetings, etc., are—

In the Assembly Rooms	Reception Room. Conversaziones.
In the Drill Hall . .	President's address. Evening discourses.
In the Guildhall . .	Council meetings. Committee of Recommendations. General Committee. Concluding general meeting.

The Secretaries of the sections will be lodged at the White Lion Hotel.

The following are the section-rooms:—

A, Mathematics, St. James's Hall; B, Chemistry, Friends' Meeting House; C, Geology, Mineral Water Hospital; D, Biology, Mineral Water Hospital; E, Geography, Guildhall; F, Statistics, Christ Church Hall; G, Mechanics, Masonic Hall; H, Anthropology, Grammar School; Sub-sections C, and D, Blue-coat School.

The reception-room at Bath will be opened on Monday, September 3rd, at 1 p.m., and on the following days at 8 a.m., for the issue of tickets to members, associates, and ladies, and for supplying lists and prices of lodgings, and other information, to strangers on their arrival. In the reception-room there will be offices for supplying information regarding the proceedings of the meeting. The published volumes of the British Association can be ordered in this room, for members and associates only, at the reduced prices appointed by the Council. The tickets will contain a map of Bath, and particulars as to the rooms appointed for Sectional and other meetings. For the convenience of members and associates a branch post and telegraph office (which will be available also for communication between members attending the meeting) will be opened in the reception room.

By the courtesy and liberality of the Directors of the Western Counties and South Wales Telephone Company, the whole of the section-rooms will be telephonically connected with the reception-room and, through the Telephone Exchange, with all important places in the neighbourhood, free of any expense to the Local Executive Committee, or members and associates, for the meeting.

THE COLUMBUS COMMEMORATION.—On account of the four hundred years' anniversary of the discovery of America, to be celebrated in 1892, the Italian Government, as we learn from *Cosmos*, has decided to publish all documents and maps relating to Columbus. The execution of this project is committed to the Senator Correnti, with the assistance of a commission of *savants*.

THE ZOOLOGY OF THE BATH DISTRICT.—II.

(Concluded from p. 134.)

THE list of local reptiles is necessarily a very short one, the whole number of British species, including the amphibia, being only twelve; of them the Bath district yields nine species. Mr. Charles Terry mentions ten species, but one of these, the sand-lizard (*Lacerta agilis*), is evidently an error. The viviparous lizard (*Zootoca vivipara*) and the blind-worm, or slow-worm (*Anguis fragilis*), are both common in suitable localities.

The common or grass snake (*Tropidonotus natrix*) is rather scarce; much more so than its dangerous relative the viper or adder (*Pelias berus*); a fine specimen of the latter may be seen in the Duncan collection.

Of the Amphibia, the toad (*Bufo vulgaris*) and the frog (*Rana temporaria*) are both very common. The crested newt (*Triton cristatus*) and the smooth newt (*Lissotriton punctatus*) also are abundant. The palmated newt (*Lissotriton palmipes*), marked as "rare" in Mr. Terry's list, is very abundant in some localities. This species seems to have become much commoner of late years, in many ponds even exceeding the smooth newt in numbers.

Of the Fishes Mr. Terry enumerates fifteen species curiously enough omitting the perch (*Perca fluviatilis*) and the carp (*Cyprinus carpio*), both of which are plentiful in the Avon and canal. There are two distinct species of eels; the sharp-nosed eel (*Anguilla acutirostris*), which is sometimes taken at the weirs in immense numbers; and the broad-nosed eel (*Anguilla latirostris*) which seems more resident in the Avon, not migrating *en masse* like the former species.

A somewhat local species is the bearded loach (*Cobitis barbatula*), to be found hiding under stones in some of the small streams which flow into the Avon. The flounder or dab (*Platessa flessus*) comes up the Avon as far as Bath, which seems to be its limit, as it is not found above. Of the sticklebacks, only one species is recorded—the smooth-tailed stickleback (*Gasterosteus leiurus*), which swarms in brooks and ditches. Careful study of these fishes should yield one or two more species. For the present the total number of species of fish recorded in the district is eighteen.

Turning to the Invertebrata, of the Mollusca the neighbourhood of Bath yields a good number of species; the Avon and canal contain most of the aquatic species, and of those which live on the land, "Helices," "Bulimi," etc., there is also a long list. Dr. Bird, in Vol. I. of the Proceedings of the Bath Natural History and Antiquarian Field Club, gives a list of sixty-five species of local mollusca. The subject has been more fully treated still by Mr. J. E. Daniel in his paper on the mollusca of Bath, read before the Zoological section of the British Association in 1864, *vide* report of last meeting at Bath. Mr. Daniel enumerates ninety species, belonging to twenty-eight genera. Attention is also drawn in the same paper to the parasites of Anodonta; as these shells abound in the canal they afford ample material for the study of those curious Entozoa. The Duncan Museum also contains a very nice collection of local shells, among which the specimens of "Anodon Anatina" are remarkable for size and beauty. There are also specimens of that curious slug *Testacella maugei* from Batheaston and Bitton.

Turning, lastly, to the most popular branch of natural history, namely, entomology, a science that owes its popularity to the extreme beauty of some species, and to the facility with which specimens may be captured and kept for future observation; and lastly, also, to the enormous number of species which it contains, 200,000 species being known, and this (according to Dr. Sharp) is not more than one-tenth of the number actually existing. What a field for research? That venerable local scientist, the Rev. Leonard Blomefield, without a reference to whose labours for the past 30 years in the study of local phenomena no sketch of the natural history of Bath would be complete has drawn attention to the fact of the comparative scarcity of insect life in the district, as compared with other districts in the Eastern counties. Mr. A. E. Hudd, also, in his carefully worked out list of the *Lepidoptera* of the Bristol district, says, "Collecting in this district is disappointing to those accustomed to other parts of England;" that is, in the number of good things that would fall to any one seeking local rarities. Mr. Terry gives a list of 541 species of *Lepidoptera* for a radius of six miles around Bath, but his list is evidently imperfect, and there seems no reason why the number of species should not be much nearer to the number recorded for the adjoining district of Bristol, by Mr. Hudd, viz., 1,310. Some of the species enumerated by Mr. Terry have quite vanished from the district, such as *Papilio machaon, Colias hyale, Pieris daplidice,* and *Limenitis sibylla. Apatura iris,* that "blue ribbon" of the lepidopterist, has been seen several times. *Lycœna Adonis* has not been found nearer than Bristol. *Lycœna Acis,* though very rare, has occurred near Bath, and also the beautiful *Lycœna arion* has been recorded from "Hills near Bath." Of the *Nocturni,* the following are some of the most noteworthy: *Chaerocampa elpenor,* one specimen taken at Sugar, by Mr. J. G. Ross, near Bath; *Arctia fuliginosa,* same recorder, from Bathampton. The following scarce *Geometrœ* have also been recorded by Mr. Ross: *Emomos tiliaria* and *E. fuscantaria, Ephyra trilinearia, Lobophora lobulata, Scotosia certata,* etc. The unique *Platypteryx sicula* has not been recorded nearer than Leigh Woods, near Bristol. Many rarities have been reported from near Bath, such as *Neuria saponaria, Rusina tenebrosa, Cerastis erythrocephala, Euperia fulvago.* That grand insect *Catocala fraxini,* is recorded from Leigh Woods, near Bristol, in 1880; and the rare *Aventia flexula,* from near Bath, by Mr. Ross. It is to be hoped that the members of the Bath Natural History and Antiquarian Field Club will thoroughly work out their local *Lepidoptera,* and also the much-neglected *Coleoptera,* and other branches of entomology, such as *Neuroptera, Diptera,* etc. An excellent paper, on the *Hemiptera-Heteroptera* of the district will be found in the proceedings of this Society, vol. vi., No. 3, by Lieut.-Colonel Blathwayt, F.L.S., F.E.S.; over 40 species are there referred to.

Many other branches of natural history have not yet found exponents among local students; for instance, the *Arachnida,* which would doubtless afford material for as substantial a monument of industry as the Rev. O. P. Cambridge's splendid monograph of the "Spiders of Dorset." The curious little *Cheliferœ,* or pseudo-scorpions, are not uncommon under dead leaves, or beneath bushes and hedges. Those singular worms, the *Land Planaria* were found by Dr. Bird under stones and rotten wood, in woods on Lansdowne. This rapid and imperfect sketch of the zoology of Bath cannot be concluded better than by these words of the Rev. Leonard Blomefield:—

"There is enough in any one of these inquiries to employ the leisure hours of a man's life if he will give his mind to it. Results of value, however, can only be obtained after many years of close observation, carried on for the most part in the same locality."

EXTINCT BRITISH BUTTERFLIES,

And the Continuity of Existing Species by Means of Migration Considered.

(*Continued from p.* 125.)

A FEW years ago the common large white butterfly (*Pieris brassicæ*) became remarkably scarce throughout the country, so that entomologists were afraid that it had followed in the wake of the black-veined white (*Aporia cratægi*). In the summer of 1884, however (as recorded in the *Entomologist*), our gardens were visited by an innumerable horde of this species, and since then it has occurred in tolerable abundance in every locality we have visited. Whether the continuity of this species was maintained by migration from the continent, we are not in a position at present to determine.

Now migration possesses a far wider influence upon the present distribution of the *Rhopalocera* in the British Isles than is generally entertained. Many species would undoubtedly die off in the course of a very few years if it were not for the continual stream pouring over here from the continent to take the place of those species which succumb to the adverse influences of our climate. Let us take the Painted Lady Butterfly (*Vanessa cardui*) as a good instance.

This insect possesses a wide area of distribution, being found in nearly every country in the globe. It is one of those insects in which a strong migratory instinct appears to be developed. Gathering together in enormous clouds, they quit the place of their birth, and depart in search of "fresh fields and pastures new."

The Painted Lady produces two broods in the year, and hibernates in the perfect state. When one of these large migratory hordes reaches this country, it generally appears to be composed of those insects that have hibernated; such hordes reach our shores in or about June.

If the swarm is a large one, the butterflies spread over the island; if, on the other hand, the swarm is a small one, the range is more restricted. The butterflies then breed and die. The first brood is produced in August, when the imagines again in their turn deposit ova on the thistles and die. In our British climate thistles and kindred plants die early in the autumn, and before the *larvæ* can feed on them the chilly nights have withered the food plants. Starved with cold and hunger, the *larvæ* fall victims to our climate, so that the second brood, which ought to live over the winter to continue the race over another year, never reaches maturity, and the species disappears.

It may happen, however, sometimes that a few of the first brood emerge so late that they hibernate or emerge so early that the progeny passes through the various stages and does the same. Either of these occurrences would carry the race on for another season, but it does not seem possible for this to last more than a year or two. The species is then lost until a fresh migration causes it to be abundant once more.

The year 1879 will long be remembered for the great numbers of this butterfly which were seen in this country. It occurred all over the British Isles, as far north even as the Orkneys and the Shetlands. Since that date, however, it has not been seen in abundance in any locality known to us.

Several species of butterflies which occur in this country are *entirely* dependent on migration for their appearance. These are the Bath white (*Pieris daplidice*), the two clouded yellows (*Colias hyale* and *C. edusa*), the queen of Spain fritillary (*Argynnis lathonia*), the Camberwell beauty (*Vanessa antiopa*), the pea-pod Argus (*Lampides boetica*), and the great American butterfly (*Danais archippus*).

In the case of *Vanessa antiopa* it was formerly believed that the fact of all the specimens taken in this country possessing white borders to their wings, while those on the Continent have yellow borders, was sufficient proof that the former were indigenous to the British Isles. Subsequent investigation and observation, however, have proved beyond doubt that those insects with white borders to their wings are old specimens, being generally those which have hibernated. They moreover also occur on the Continent in spring, whereas it was thought that they were peculiar to this country. In our opinion, therefore, the occasional appearances of this grand insect in the British Isles may be referable to the same theory of continuity by migration as in the case of *Vanessa cardui*.

The two clouded yellow butterflies (*Colias edusa* and *C. hyale*) have both a great predilection for wandering, and on account of the number which have of late years made their way over from the Continent both species seem to be apparently becoming more plentiful and widening their area of distribution in the British Islands. About fifty years ago both these insects were looked upon as great rarities. They are now however, to be met with somewhere in the country every season.

The year 1877 will long be remembered as the great "Colias year," when they occurred in this country in immense swarms.

Their increase may be attributed in some measure to the same cause which is operating just the reverse with such a number of other species, namely, cultivation—the extended cultivation of various tracts of clover by agriculturists, this plant constituting the pabulum of both species.

In this country *Colias edusa* occurs much more commonly than *C. hyale*, the reverse being singularly the case on the Continent.

Danais archippus is a species which has the last few years occurred in this country in considerable numbers —chiefly on the south coast. It is decidedly cosmopolitan in its distribution, being found over a great part of the globe. In America it is found from the Arctic Circle to the Tropic of Capricorn. Its occurrence in our own country is due, of course, to migration. It is a species that possesses a very powerful flight and is capable of withstanding great vicissitudes of climate, and in addition two species of plants, *Vinca major* and *V. minor*, very closely allied to one of its *pabula*, occur abundantly on rocky places in the south of England; so that it is not at all unlikely to establish itself over here at some future date, as it has already done in Australia and New Zealand, etc.

(To be continued.)

Injurious Action of Noise.—Dr. W. B. Platt *(Popular Science Monthly)* formally recognises noise as one of the chief injurious influences of city life, and makes suggestions for its limitation, such as the abolition of church bells.

Reviews.

Alkali Works Regulation Act, 1881. *Twenty-fourth Annual Report on Alkali, etc., Works, by the Chief Inspector. Proceedings during the year* 1887, *presented to the Local Government Board and to the Secretary for Scotland.* (London : Printed for Her Majesty's Stationery Office.)

There still exist educated and intelligent persons not a few to whom the nature and the necessity for the so-called *Alkali Act* are perfectly unknown. The case is this : in the manufacture of alkali from common salt by the Leblanc process, the salt is converted into sulphate of soda, or salt-cake, by heating with sulphuric acid. During this process all the chlorine of the salt, which is more than half its entire weight, is given off in the state of hydrochloric acid gas. In the earlier days of this important manufacture this acid was allowed to escape freely into the atmosphere, when it became the cause of abundant mischief to all kinds of vegetation in the districts. An Act was therefore passed, compelling manufacturers of alkali to condense the acid vapours given off. Similar enactments were made to control the escape of other acid and corrosive fumes, and the working of this Act was placed in the hands of a Chief Inspector and a number of assistants. It was feared at first that this legislative interference would gravely compromise the position of an industry of great national importance. But, thanks to the scientific resources, the practical judgment and the tact of the first Inspector, the late Dr. R. Angus Smith, the end desired—the protection of the public—was attained without any injury to the trade. It may even be said that the vapours which were once simply a nuisance have now become the main source of profit of the alkali manufacturer.

The total number of works registered under the Act was, in 1887, in England and Ireland 927, and in Scotland 198.

It is a very gratifying feature, brought out in the report before us, that the escape of acid gases is considerably less than what the law stipulates. Thus the maximum amount of hydrochloric acid tolerated by the Act is one-fifth of a grain per cubic foot of chimney-gases. The quantity actually escaping is only half that limit. The escape of sulphurous acid from the lead chambers is very little more than one-third of the limit laid down. An additional ground for congratulation is the fact that this improvement has been effected not by a system of prosecutions, but by an investigation of the causes of any irregularity complained of and by suggestions as to its removal. Only four prosecutions under the Act have taken place during the year, three of them for neglecting to register works liable to inspection under the Act, and the fourth at a manure-works, for neglecting to use the best practicable means of arresting noxious gases.

The report duly notices the struggle now taking place between the process of Leblanc and the so-called ammonia-soda process of Solvay. About three millions of money are supposed to be invested in the Leblanc process in this country, which will be to a great extent wasted if that process has to be abandoned.

The total quantity of salt used in the United Kingdom in the Leblanc process is 649,867 tons yearly, whilst 158,636 tons are consumed in the ammonia-soda process.

A fearful nuisance connected with the Leblanc process is the production of so-called "vat-waste," a material which on contact with any acid, even the carbonic acid of the atmosphere, gives off sulphuretted hydrogen, whilst an offensive liquid drains away from the mounds of this refuse, often finding its way into water-courses.

Of this offensive material there are now 1,500,000 tons produced annually. At Widnes, in Lancashire, these deposits cover 450 acres of ground, and contain above 8,000,000 tons, to which 1,000 tons are added daily. Such being the condition of things, it is very satisfactory to learn that two processes are being elaborated, each of which bids fair to extract the sulphur from these mounds, thus rendering what is now a nuisance to all parties, harmless to the public and profitable to the manufacturer.

The present Chief Inspector, Mr. Fletcher, points out a number of inconsistencies in the provisions of the Act. Thus any escape during the manufacture of sulphuric, nitric, or hydrochloric acid (above the proportion legally fixed) renders the proprietors liable to a penalty. But an escape of these acids to any extent whilst being used—not made—falls outside the provisions of the Act, and the inspector cannot interfere. But suppose the manufacturer, in order to abate the nuisance, attempts to condense the fumes, he then becomes a "maker" of the respective acid concerned; the works must be duly inspected, and if the method of condensation adopted is insufficient, he is liable to prosecution.

It appears that the production of sulphurous acid is regulated by the Act only when it is generated in order to be ultimately converted into sulphuric acid. If it is made for any other purpose, or with any other result, it is exempt from inspection. Thus the production of acid fumes from the combustion of fuel rich in sulphur is the cause of a frightful nuisance, but it completely escapes control. The inspectors, therefore, suggest that the present Alkali Act should be superseded by a general Noxious Vapours' Act—a very desirable step.

Model Engine-making. By J. Pocock. London : Swan Sonnenschein, and Co.

A book intended to help ingenious boys to make unmechanical model steam-engines with the least possible apparatus. We confess to a horror of those hissing little monstrosities called "model" steam-engines ; the manufacture of them serves no useful purpose, unless it be to keep idle hands from mischief, as their educational effect on the manufacturer must be *nil*, the builder's efforts appearing to be chiefly directed towards making something as unlike any engine that was ever made, since the days of Newcomen and Trevithick, as possible.

The model engines illustrated and described in this little book are just what amateurs have kept on making for the last thirty years, neither better nor worse, faulty in construction, crude in design, and "sloppy" in workmanship.

Cannot the amateur be instructed how to make something a little more modern than oscillating cylinder locomotives and table-engines ?

The Navigable Balloon in War and Peace. By General W. N. Hutchinson. Eastbourne : Farncombe and Co.

There exists a very general belief that every invention, if only practicable and successful, should be greeted as a boon without sufficient regard to the character of its possible results. This belief will, on careful consideration be found to be a grave mistake. There are, of course, inventions—it would be invidious to point out instances—which are unmixed benefits to mankind.

There are others, such as the lucifer match, where the good does little more than turn the scale; and there are, lastly, a class where the apparent evil results are likely to counterbalance, if not to overbalance the good.

It is a strange and painful fact that in the present day the attention of inventors is more than ever turned to devices for the wholesale destruction of human life and of property. This is obviously a subject so largely mixed up with moral and political considerations as to fall very barely within our legitimate scope. But we may point out that recognised governments may, perhaps, refrain from the employment in war of "high" explosives, of aerostats, submarine boats, etc.; but will treasonable societies be so scrupulous? We fear not. It is, indeed, noteworthy that the chief use of the "high" explosives hitherto made for the destruction of human life has been in the so-called "private war" waged by such bodies against governments.

It must also be considered that the "navigable balloon" will be of immense advantage to the ordinary criminal. He can come in the night, sailing unseen over the heads of policemen or soldiers, and break into banks, warehouses, mansions, etc., at upper windows or skylights. In the morning no trace of him will be left, and there will be no clue to suspect any one of the inhabitants of the globe more than any other. For murder or other outrage the facilities will be as much increased as for robbery.

Hitherto, and especially of late, the criminal classes have shown themselves fully alive to any inventions which promise to subserve their objects. Why, then, should they hesitate to use the "navigable balloon"?

Of course the utter proscription of such inventions would be practicable only if all nations would agree. But, unless we are wrongly informed, the Austrian Government has shown a good example by suppressing an invention which would doubtless have been useful to its possessors in war, which would have given man complete safety in dealing with wild beasts, but which would have opened the door for robbery and murder on the vastest scale.

Geology for All. By J. Logan Lobley, F.G.S. London: Roper and Drowley, 29, Ludgate Hill.

This little book contains the substance of a course of lectures delivered at the City of London College in 1887, which appeared in a series of articles written for the *Industrial Review* by the author.

It was a happy thought to have these articles republished in book form, as they make a concise introduction to the study of geology as a science, and can be recommended to any one who desires to gain a general knowledge of the composition and classification of the rocks forming the earth's crust, without taking the science of geology as a regular study.

We think that the author has been very successful in writing a small, comprehensive book on geology that is interesting and attractive to those requiring only a general knowledge of the subject, and at the same time has produced a work that will serve as a good introduction to a more complete study of the science.

Causes of Mental Phenomena. — According to an American contemporary, Dr. S. V. Clevenger is endeavouring to work out the proposition that "mental phenomena are modes of chemical energy."

BRITISH MEDICAL ASSOCIATION.

Abstract of the Presidential Address by William T. Gairdner, M.D., LL.D.

In seeking about for a topic on which I might occupy your attention this evening, I have been led to make some special reflections on the curious survival among us of an ancient way of thinking that is presented to the mind by the designation in English of the *physician*, or, as Chaucer has it in his well-known Prologue to the "Canterbury Tales," the "Doctour of Physike." I do not know if it has occurred to many of you to observe that in no other language than our own has this survival occurred. The surgeon—*chirurgus*—has, indeed, kept from a very remote antiquity the title which was given to him in the days of his subjection as the *handworker* or *operator* under the direction of the physician. But the most remarkable thing about this last, and conventionally the higher, title is that while it seems to recall a time when the medical art was distinctively associated in the minds of men with the study of φύσις, and when the healer of the sick was regarded as in a very special, if not exclusive sense, a *student of nature*, it is very hard to discover from the traditions of language, either our own or any other, when this idea first took shape—how and when the notion began to be entertained that the most fitting title for the most highly honoured representative of the medical art was to call him, distinctively, a *naturalist*, or, if you will, a natural philosopher or *physicist*. It has occurred to me that it may not be an altogether unprofitable task for one who holds a chair in this University popularly designated as one of *Physic*, to inquire how the idea represented in this word *physic* came first into existence, and how it got floated into such a degree of popularity as not only to have practically displaced to a considerable extent in our own language the much older one of *medicine*—that is, healing—as applied to the art itself, but to have got itself into currency as applied to the very tools of the art, the drugs with which the physician, so called, was supposed mainly to work his cures. I hope to be able to show you that these words *physician* and *physic* have relations with some of the very best and highest traditions of antiquity, and that it may be possible for us even now to make an application of them which will repay and at the same time justify their retention in the English language, although, it may be, tending also to discover certain deficiencies which still unhappily exist in our systems, both of medical and general education.

My argument, in other words, will be this:—For a series of indeterminable ages, from the time, very probably, of Hippocrates downwards to what we call the dark or middle ages, the tradition has continuously existed that the healer or physician of the highest class ought also to be, in a very real sense of the word, a naturalist or perhaps a man of science (physical science being, of course, understood); that it is his prerogative to be trained and exercised after the best manner and according to the most thorough discipline of the science of his age; and that he ought to be (or, at least, that he has been in very remote times) regarded as being admirable and trustworthy as a healer or physician chiefly in proportion to the confidence reposed in him as a naturalist, that is, a humble, reverent, and exact follower and student of nature.

You are all familiar, no doubt, with the magnificent opening of the "Novum Organum,"* which ascribes to man as the "minister (or servant) and interpreter of Nature" only so much either of power or of knowledge as he has gained by observing the order of nature, outside of which he neither knows nor can do anything. Now, it is a curious fact, which has not escaped the editors of Bacon in recent times,† but which may require, nevertheless, to be brought to your notice, that the very word or phrase here used to designate the limitations imposed upon the *power* of man in reference to Nature is the one which, in a very remote age, had suggested itself to Hippocrates as specially indicating the function of the healer. He is, he must be (according to Hippocrates), "the servant of Nature"—ὑπηρέτης φύσεως. Nor is this a mere accidental expression, which might be passed over as a coincidence not extending below the surface. On the contrary, the expression is taken up and specially commended by Galen (surely the best of all authorities on such a point) as being of the very essence—the key-note, as it were—of the Hippocratic teaching, with which all the later authorities (Aristotle and the Peripatetics), as he tells us, were essentially in accord.

But to return to Hippocrates and his remarkable declaration, that the ἰάτρος, or healer, is the servant of Nature (φύσις). This expression, as I have already said, is no merely casual one in the writings of Hippocrates; for Galen remarks upon it, and (in the full knowledge, therefore, of all that could be said for or against the expression by rival sectaries) he does not hesitate to declare that Hippocrates was "*the first* to observe the works of Nature:" and that he "is always admiring and insisting upon the sufficiency of Nature, whereby what is necessary for the life of all animals is done ἀδίδακτος—that is, spontaneously, and without apparently conscious effort." He thus places Hippocrates distinctly in advance of, if not above, Aristotle and the Peripatetics, in respect of originality in the study of φύσις; and he further maintains that Erasistratus, the Alexandrian anatomist, had adopted an inconsistent attitude towards Nature, and that his followers had exposed themselves to ridicule by their unintelligent criticism on what was simply a development by the Peritetics of the physiology—that is, Nature-teaching—of Hippocrates. It is not necessary to go into this old controversy now further than to show that, by the very fact of its having become a controversy at all, the position of the ἰάτρος, or healer, as the "servant of Nature," must have been very well known not only to Galen, but probably also to Aristotle: and through these to the Arabian physicians and to the whole of the middle ages, of which they were the teachers and lawgivers.

Nor did Hippocrates, the father of medicine, escape the reproach which it has been so easy and so profitable in many ways to fling at those who, in a later day, have proceeded in accordance with his precept, if not his example. We hear chiefly from Pliny and Cælius Aurelianus of a certain Asclepiades of Bithynia, a contemporary of Cicero, whose true character it seems rather difficult to decipher, but who at least may be said to have been a fashionable physician in Rome, with a brand-new system of his own. Asclepiades, whose *rôle* in the treatment of disease seems to have been one of constant interference, or, as we should say, of meddlesome physic, only (it is believed) using as a rule and in a temporising kind of way, the mildest and most agreeable of medicines,* had, of course, no appreciation at all of anyone who, in his character of a healer, professed to be a "servant of Nature." He said, in fact, that, in speaking of nature as a kind of intelligent principle, Hippocrates was (not to put too fine a point upon it) talking nonsense. Nature is too often bent, not upon healing the man, but (as a witty member of this Association once said in my hearing) on putting him into his coffin! Hippocrates, as the servant of Nature, is simply a *waiter upon death* (θανάτου μελέτην). The true business of a physician is to "make himself master of the occasion"—that is, to shove old Dame Nature out of the way, perform the cure *tuto, cito, et jucunde,* and claim all the credit, which, no doubt, he did in Rome, as the quacks in all ages have done everywhere, with great comfort and advantage to himself, and (let us hope) with the minimum of injury to his patients.

The truth and the falsehood that underlie this old-world argument I will not attempt to discuss this evening, having done so already on more than one occasion. I am alluding to it now mainly to show that the position of him whom we now call the physician, in reference to φύσις, was a well-recognised one long before the origin of the term *physicus,* as applied to him in the Latin of the Middle Ages and the French of the thirteenth century—from which, in all probability, we have derived our English word. What I have now to do is to inquire how far we are maintaining, in this nineteenth century of ours, the position assigned to Hippocrates by Galen (and, I have no doubt, rightly assigned) of being prominent among the seekers into φύσις, or, at all events, capable workers in this field, in accordance with the methods and advances of modern physical science.

It may be not unimportant for this purpose to remark that, so far as we can judge of him from literature, the physician of the middle ages, though retaining the name, was in a very small degree, if at all, cultivated according to the type. Chaucer's Doctour of Physike, though very far indeed from being a pedant, was assuredly much more of a *learned* than of a *scientific* physician. The fate of Roger Bacon in the century before Chaucer was an amply sufficient warning to the good-natured and easy-going doctors of his time that anything like original research into φύσις was dangerous—nay, liable to be proscribed and punished with imprisonment, perhaps with the faggot, unless it proceeded exactly on the lines of St. Thomas Aquinas, the "angelic doctor." It was very much easier and more comfortable, in every way, to stick to Hippocrates and his "humours," where everything was sure and safe; and to add a little astrology, which at least was permitted, if not encouraged,† and

* "Homo, Naturæ minister et interpres, tantum facit et intelligit quantum de Naturæ ordine re vel mente observaverit, nec amplius scit aut potest."—Aph. i.

† See note at p. 157 of Ellis and Spedding's edition of Lord Bacon's works, vol. i., 1870.

* He is reported to have been the inventor of the phrase, "Tuto, cito, et jucunde," as applied to medical treatment in general. But he also employed, according to Pliny, magical remedies to a great extent. (See Le Clerc: Histoire de la Médecine, 2nd partie, l. 3, cc. 4-7.)

† Judicial astrology, however, which (according to Naudé) was "l'enfant supposé de l'astronomie," was (he says) very properly condemned by the Church, "non point comme suspect de magie, mais comme une science vaine et chimérique, *quæ stellis ea quæ geruntur in terrâ consecret;* qui veut pénétrer dans nos destinées, et qui par la témérité qu'elle a de vouloir s'égaler à la Providence, en fouillant dans l'avenir, combat directement la religion." So that Chaucer's Doctour of Physike was, perhaps, a heretic after all!

could get no one into trouble. And when we come down more than a century and a half to Rabelais, two centuries to Montaigne, three centuries to Molière and Guy Patin, we find the position still much the same, or rather, in all probability, worse as respects the *physician*, although surgery and anatomy may have been making some steps in advance. I apprehend that the doctor of medicine in the middle of the seventeenth century in France, unless he has been caricatured out of all recognition by Molière, must have been altogether the most stupid, pompous, brainless formalist that ever in any age of the world practised the art under a learned title. The satirical portrait of Thomas Diafoirus, and the magnificent installation of Argan in the "Malade Imaginaire," remain for us and for our remotest successors, to show how the art of healing may degenerate under the influence of scholasticism, and how base a creature it was at least *possible* to represent a "physician" as having become in the days of Louis XIV., in the midst of a most brilliant outburst of literature and art, at the very time when Harvey's great discovery was slowly making its way against prejudices derived from the darkest of the middle ages, and the still overpowering authority of Aristotle and of Galen.

But at this time the Faculty of Medicine in Paris was probably the last retreat of obscurantism in all Europe, at least within the domain of the physician. In Italy, in England, in Switzerland, in Germany, and in the Low Countries, the spirit of observation and experiment was awakening from a long sleep; and in many departments —anatomy, botany, physiology, surgery—things were moving on apace; but the physician was almost everywhere belated in the race. Even down to the last century, the man of *learning* (of the type of Linacre and Caius) in the Royal College of Physicians of London greatly predominated over the man of *science*, as exemplified in William Harvey; while Oxford and Cambridge, which alone could open the portals of the College, were absolutely *nowhere* as schools either of science or of medicine; and neither taught, nor professed to teach, anything but a mostly mediæval curriculum. And thus it came about, so late even as the year 1815, that the curious anomaly of the "double qualification" obtained a legislative sanction in English medical education. For, while in most European countries, the State and the universities co-operated in arranging and controlling the issue of a single qualifying diploma for the general practitioner, the Royal College of Physicians of London was still too much the college of a learned *caste* to allow of their exclusive privileges being shared by any but university graduates; while the two great English universities were altogether too helpless, as regards the necessary discipline of a medical career, to make it even possible for them to afford the slightest assistance. The Royal College of Surgeons, on the other hand, which had for ages concerned itself only with anatomy and surgery, to the exclusion of physic, continued on the even tenour of its way, including in its membership men ignorant of Latin, but instructed as regards fractures, dislocations, and surgical procedures generally; while the Worshipful Company of Apothecaries, cleverly perceiving and taking advantage of the enormous gap which was at once apparent between the technical discipline of the pure surgeon and that required for the all-round practice of the medical profession, marched into a position of legal independence through this gap, and, from being the humble servants of the physician, obtained for their licentiates not only the exclusive right to dispense medicines, but the status of prescribing them also, and thus a perfectly just and well-earned rivalry with the physician all over England.

What I am chiefly concerned to bring under your attention, however, in this connexion is that, according to the historical development, or evolution, of medical education in this country, and especially in England, the physician, in the sense of *Naturæ studiosus*, the devotee of φύσις, as aforesaid, stood a very fair chance of being altogether, and finally, suppressed and wiped out of existence.

From the earliest days of my experience as a teacher it has been customary with me to use expressions and to act in a spirit, of which you may readily judge for yourselves from the following brief paragraph, taken from an address to students of medicine, delivered more than twenty years ago: "The first lesson to be learned in order to make all other lessons possible is, in my opinion, this—to deal very largely with things and not with mere words; to realise as much as you can all your instruction by making it your own through personal observation; to suffer nothing, if it can possibly be avoided, to lie in the mind as a dead weight of vocables, oppressing the memory and dwarfing the intellect; but to bring everything into the living light of fact and of nature, and thereby at once to assure to yourself the truth and exactness of your knowledge, while at the same time you are stamping it down upon the memory by the most sure and lasting of all technical methods." *

No one can be more ready than I am to admit that there are—nay, that there must be—limitations in the very nature of the case to the too absolute recognition of this ideal. It is said by some that the spirit of modern science is ungenial and hard, even pitiless, and therefore not at all fitted for the ministrations of humanity; that it tends to make the suffering man, the *patient* (as we call him), into a mere case—a thing to be observed and noted rather than a man of like passions with ourselves, and therefore to be treated with consideration and sympathy. There may be just a grain of truth in this; and to whatever extent it is true, we of this medical school claim to be aware of the fact, and to be ever on our guard against the tendency. But none the less it may be affirmed with entire truth, and with cumulative evidence if need be, that all the evils inflicted on poor suffering humanity by the physician as scientist have been but a drop in the bucket as compared with those which have sprung from the too slavish adoption of traditions, in which there never was any trace of the scientific spirit at all.

I shall venture to anticipate—because I am well assured that anything I can say here will only give expression to what will still more clearly emerge from the forthcoming address in physiology by my esteemed colleague Professor McKendrick—some of the discouragements to which I referred a moment ago, the difficulties we experience in training our students adequately on the lines we have laid down from them. These difficulties are manifold, and they are not of our making, nor are they peculiar to Scotland. I have only time now to refer to two of them.

The first of these difficulties belongs to the medical curriculum, in which, although chemistry, botany, and natural history have long been with us a necessary part, and, so far as they go, a well-conceived and valuable scientific basis for the more technical part of our teaching, nevertheless physics proper—or, as we call it

* "Medical Education, Character and Conduct," etc., p. 70.

natural philosophy—the very first step in the study of the laws of matter, is still but very imperfectly recognised. This great omission has arisen, no doubt, from the fact that these laws were supposed to be taught, and in a measure were taught, in connection with chemistry, which, from its old hereditary relations with pharmacy and the pursuit of the philosopher's stone and the elixir of life, had from time immemorial a claim on the physician. But when we consider how completely modern science has demonstrated the subordination of living bodies and physiological processes, not to a wholly detached set of laws termed vital, but to all the most elementary laws of matter; and, further, the correlation of all the physical forces throughout the universe, so that the living body and its environment act and react on each other throughout infinite space and time, it will be readily admitted, I think, that some kind of systematised instruction in physics, and not a mere elementary examination in mechanics, should be an essential part of an education with a view to the medical profession.

But this leads me directly to the other difficulty, or disadvantage, under which the Scottish universities have hitherto laboured in endeavouring to restore to the healing art its ancient association with the study of Nature. And this is by far the graver difficulty of the two, inasmuch as its rectification depends in no degree upon us or upon any possible change in the medical curriculum, but upon what amounts to a practical readjustment of the entire edifice of general education.

The evil to which I now refer, as some of you have already no doubt perceived, is the extremely unprepared state in which the minds of most boys and young men are found at the time of their leaving school as regards the most elementary truths and methods of physical science, and of the observation of Nature. It is now more than a quarter of a century since this great defect in the English public schools attracted the attention of a Royal Commission appointed in 1861, and there is no reason to suppose that in Scotland, at the time in question, the state of school education was in this respect much better than in England. Evidence of the most convincing kind was given in 1872 before another Royal Commission to the effect that "the limitation of the examinations (under this revised code) to the subjects of reading, writing, and arithmetic unfortunately narrowed the instruction given in the elementary schools; and that this change, together with the lower standard adopted in the training and examination of pupil teachers and the curtailment of the syllabus of the training colleges, exercised a prejudicial effect on the education of the country." I am well aware, indeed, that in Scotland, and even in our own city of Glasgow, there are schools which have already made some considerable advances in the direction here indicated, and that in the old High School of Glasgow, in particular there exists now a chemical laboratory such as would do no discredit to any university. But as regards the schools throughout the country, the advance has been so slow that for a long time to come our boys will leave their schools, and our young men will continue to enter the universities, in a state of great mental unfitness to grasp even the most elementary ideas of physical science, and therefore requiring more than ordinary care to ensure, at the very commencemeut of a medical education, the preparation in *physics* which will shortly become all-in-all to the true *physician*.

I have now to ask your attention, for a very few minutes only, to a concluding topic, which I approach, indeed, not without fear and trembling, but which is of too much prominence and importance in itself, in connexion with the subject of this address, to allow of my passing it by without some reference.

Probably there may be some of you here present who have been led to take note of a proverb, which I am bound to say I have not been able to trace to its source, but which I suspect to have been the growth of that mediæval period to which allusion has already been made in the course of this address: "Ubi tres medici, duo athei." I am not concerned in tracing out for you, even if I were able to do so, the most probable origin of this defamatory saying, nor shall I spend many words in venting my honest indignation upon it as a calumny and a reproach. It will be wiser and more profitable in every way to take it as it stands—as an example of what the late Earl Russell said of proverbs in general—"the wisdom (or in some cases the foolishness) of many," accentuated and condensed into a telling phrase by "the wit of one." From this point of view it may be that there is something more or less worthy of careful reflection in this proverb, even if we should disown it in its literal acceptation. But I need scarcely say to those who are at all conversant with philosophical studies, that to have been accused of atheism in the middle ages may be quite the reverse of a real reproach to any man or set of men. From the time of Socrates downwards, indeed, this reproach has been a part of the stock-in-trade of vindictive, even if sincere, ignorance and bigotry all over the world; and to have been tabooed with atheism is often, almost without qualification, a passport into the ranks of those who have kept alive the flame of the human spirit, tending, and often vainly struggling upwards, to escape from the jargon of scholastic controversies and the mephitic vapours of ecclesiastical strife. From this point of view it was inevitable—nay, it was essential—that the physician or naturalist, in so far as he really was or aimed at becoming such, should incur this reproach. The marvel rather is, to us of this nineteenth century, that those who incurred it should have done so little to deserve it. The reproach from a philosophical point of view, inconsistent with atheism, but not seldom conjoined with it, of tampering in an evil sense with magic was sure to be launched in those days at men who professed to be successfully investigating the *secreta naturæ* by other than the most orthodox methods. And the prosecution and imprisonment of Roger Bacon on the one side and of Galileo on the other, not to speak of the numerous "martyrs of science" both before and after these, will remain as an imperishable record of the blind and impracticable spirit of mediæval dogmatism, which, covering itself with the mantle of religion, stood athwart the path of the physician for hundreds of years. But although the condemnation on the side of godlessness came most easily and naturally out of the mouths of ecclesiastics, it is not by any means to be inferred that, either in ancient or modern times, it has been confined to them. Even in the kindly and thoroughly human word-picture drawn for us by Chaucer, of the typical "Doctour of Physike," in the Prologue to the "Canterbury Tales," line 440, it comes out that while—

"Wel knew he the old Esculapius,
And Dioscorides and eke Rufus,
Old Hippocras, Hali, and Gallien,
Serapion, Rasis, and Avicen,

Averrois, Damascene, and Constantin,
Bernard, and Gatisden, and Gilbertin"—

yet, alas! as a sad balance in the way of defect to all this learning of ancient, and also of then quite modern date, it is quaintly and humorously added, in a single line, without even an attempt at amplification or excuse, that—

"His studie was but little on the Bible."

This, then, is the position and stigma that we have to deal with as physicians or students of Nature and science in the present, as in all former ages, in proof of which you will allow me simply to refer (without at all dwelling upon it) to an article in the actually current number of the *Contemporary Review.** I will, therefore, close this address with a very few thoughts of my own on the subject, not at all in the way of controversy or of recrimination, but as expressing the matured convictions of a lifetime on a theme which must needs come home to every man's conscience in the exercise of our profession, and on which I should despise myself if either the desire of saying smooth things or the fear of saying the opposite were to move me in the least degree in addressing an assembly like this.

That the active ministry of the healer, if fitly and diligently pursued in a serious and not a sordid spirit, cannot possibly tend to irreverence or to what I would call essential atheism or godlessness, is, I think, so obvious that it is only wonderful that any doubt should ever have arisen on the subject. That ministry is the ministry of the body, no doubt; physical, therefore, in its aim; physical also, to a certain extent, in its limitations; and I am not one of those who would argue that, because it is so, the physician is thereby degraded and straitened unless he is also constantly invading the province of the religious teacher. But when we consider how closely the one province trenches on the other, and, further, that in all the greater and graver crises of the lot of man on this earth—birth and death, sickness and health, moral contamination producing disease, and, on the other hand, physical disease inducing moral aberrations, and, with or without these, positive insanity—we must acknowledge that the spiritual element in man is brought necessarily into the sphere of the physician's daily work. I am confident there is not a man in this room who will not emphatically agree with me in saying that a physician who even inclines towards irreverence as his habitual attitude of mind is thereby disqualified from performing aright the greatest of all the services that at times he can render to the sick.

The physician of the future will, I believe, be much more, instead of less, inclined to study the Bible than hitherto, and in this respect will differ greatly from the representative and typical "Doctour of Physike" of the "Canterbury Tales." But he will study it in the spirit of modern scientific freedom and of historical research, not under the influence of mere tradition and ecclesiastical authority. And thus only, as it seems to me, can the reconciliation of science and religion ever be brought about.

The physician of the future will do well if he remembers always the pernicious despotism which has been exercised over his own art (though in a minor degree) by the fetters of these dead orthodoxies, and will therefore be very slow to acknowledge their claims upon him to any more than a historical regard, even in the realm of theology. He will say of them, in the noble words of the Westminster Confession, which (but for the formula connected with it in our Scottish churches) might almost be taken as the Magna Charta of Christian liberty in all such documents, "All synods and councils since the Apostles' times, whether general or particular, may err, and many have erred; therefore they are not to be made the rule of faith or practice, but to be used as an help in both."* But I desire you very specially to remark, as my own personal anticipation, shared, I have no doubt, by many of those now present, that the physician, in his character of student of Nature, will make, and in the end will establish, this claim to emancipation, not in virtue of any irreverent, much less atheistic tendencies, but for the very reason that he has access to a revelation of God distinct from the written revelation, and requiring a wholly distinct method of investigation. In obedience to this call he will, sooner or later, absolutely decline to walk in the leading-strings of ecclesiastical tradition. And in so doing he will (far from fulfilling old Dan Chaucer's satirical description) studiously insist upon the Bible, and especially the New Testament, and, above all, the recorded life, words, and works of our Lord Himself, as containing by implication the charter of his emancipation, and the only perfectly free religious atmosphere as yet opened to human thought and inquiry.—*Lancet.*

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

"WHENCE COMES MAN?"

Mr. Bell, the author of the above-named book, writes to complain of "a strange mistake" in the notice of it which appeared in your issue of July 27th. The "strange mistake" is the substitution of the word "private" for "privative," in a quotation from his book, and Mr. Bell finds therein reason sufficient for the expression "rigmarole" as applied to his remarks. I hasten to assure him that the mistake is due wholly to the printer, and that my critical comments are in no way connected with or influenced by it, as I perfectly appreciated his use of the word "privative," although I made no special allusion to it. As a matter of personal opinion I may perhaps be allowed to say that, with a little more care, Mr. Bell might easily have seen that no part of my criticism depended in any way on the "strange mistake."

THE WRITER OF THE REVIEW.

SHOWERS OF FROGS.

I read in the papers various accounts of "showers of frogs" of recent or former occurrence. But I do not see that any one, except "Korax," in the *Evening News*, alleges having actually seen the frogs falling. It may even be doubted whether he can be regarded as an eye-witness, since he merely speaks of people putting up their umbrellas "to ward off the living shower." Where the little amphibians are not seen in the act of falling, the probability is that they have come, not from cloud-land, but from some sheet of water. That whirlwinds may occasionally carry frogs up aloft along with other "unconsidered trifles" cannot be questioned, but such cases are doubtless rare.

S. D.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

DRINK.—A method of converting sea-water into a palatable drink has been patented by Mr. G. S. Hazlehurst. To accomplish this an effervescent such as lemon kali and a corrective such as bismuth are mixed with sea-water, the result being a refreshing saline beverage that may be drunk during effervescence without causing after-thirst. The bismuth is used to counteract the purgative effect of the sea-water, and it also acts as a sedative.

PRESERVING FISH.—A method of preserving fish has been patented by Mr. A. R. Roosen. Instead of covering the fish when packed, first with an antiseptic powder, and then with ice, as is usually done, they are packed with an antiseptic, in a frozen state, which more effectually preserves them. To prepare this antiseptic ice, the water is first sterilized by boiling it with steam; the desired antiseptic is then added, and the solution frozen as quickly as possible. The strength of the solution may be varied.

FOOTBALL INFLATER.—A football inflater has been patented by Mr. W. Fraser. The invention relates to a portable apparatus, and consists essentially of a combined plunger and air-chamber, working telescopically within an open-ended cylinder, with a coiled spring disposed between the bottom of the latter and a recess formed within the inner end of the former. The combined plunger, air-chamber, and cylinder are provided with valves respectively, the cylinder valve being at the entrance of the pipe of an outlet nozzle. The return movement of the piston is effected by a coiled spring placed between the underside of a cap on the end of a piston-rod and a bridge carried across the open mouth of the cylinder.

CAMERAS.—A shutter for photographic cameras has been patented by Mr. A. S. Newman. This shutter is made in two parts, which open inwardly on upright hinges at each side of the shutters, being arranged somewhat after the manner of a double casement window, and where the edges of same meet in the middle they are formed so that in shutting they overlap one another so as to make a light-tight joint, and in addition are padded at such joint, and also at the top and bottom, so as to ensure a light-tight fitting all round, the hinges being placed behind projecting flanges all round the opening. This shutter is actuated by a pneumatic cylinder and loose piston therein, actuated by the operator with a compression-ball and tube.

BICYCLES.—A rear-driving safety bicycle has been patented by Mr. C. Grant. This machine is so constructed that it can be ridden by females in ordinary dress. The backbone proper is kept on a level with a horizontal line through the centre of the back wheel, so as to keep it as low as possible, except near the front wheel, where it curves upwardly and is jointed to the front wheel standard. The seat standard is secured to the backbone close to the back wheel, and the treadle shaft is situated immediately beneath this standard. No stay is placed between the seat standard and the steering standard, and the portion of the backbone between the latter and the seat standard must be of sufficient length to afford ample room for a lady to enter between the same.

ELECTRIC SWITCH.—An appliance for making and breaking an electric circuit has been patented by Mr. H. K. Read. The switch employed in this invention consists of a centre spindle carrying a pair of cross-arms arranged so that one is immediately above another, and such that the extremities thereof are capable of embracing the contact pieces, the grip being capable of regulation by means of bolts and nuts near the extremities. To ensure a very quick "break," the handle is made independent in movement from the arms; its motion is conveyed to the arms through the intermediate action of a V-shaped spring, the two forks being pressed upon by pins on the collar, and the other end screwed down to the blade. Thus when the friction of the "contact" is absent the arm flies round very rapidly, the spring having been compressed before forcing the arms from the contacts.

MUSICAL INSTRUMENT.—A musical instrument has been patented by Mr. S. J. Talbot. The instrument is played by strings, and the resonant chamber is constructed of wood. To the back-board of the chamber is glued the curved front and the top and bottom pieces. The front board is provided with sound openings, and strings are stretched from top to bottom along the curved upper surface of the chamber, firmly secured at the bottom in any manner, and at the top attached to pins adapted to be turned by a key, so as to tune each string to the required pitch. The top of the front board is provided with a raised portion, on which is laid a curved upper bridge of metallic wire. A lower bridge is placed diagonally across the face of the instrument, and also consists of metallic wire. Below the lower bridge each string is secured by a small staple. Fifteen strings are usually employed, and the curve of the front board is such that a bow may be drawn easily across any string without touching the next. The instrument is made tapering, and in playing the bow is drawn across the strings between the two bridges.

PHOTOGRAPHIC FILM.—Mr. J. Brown has patented a photographic film. The invention relates to the preparation of gelatine on a temporary flexible support, which is finally removed after the photographic image is obtained either in its monochromatic state or after colours have been applied. The film is formed as follows:—A sheet of paper is taken and coated with gelatine rendered insoluble, when this is dry another coating of indiarubber is laid upon it, to which is added a mineral oil, and when this is dry it is coated with a solution of cotton wool prepared with acid and dissolved in ether and alcohol. After this has dried it is again coated with a solution of gelatine, and on this surface is placed a layer of bromide of silver emulsion. This bromide emulsion surface is ready to receive the monochromatic photographic image; for the polychromatic image colours are placed at the surface of the monochromatic image before the film of gelatine and gums is removed from its flexible support. After the colours are dry the film is transferred to a rigid support and the flexible one removed.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

The recently published report of Dr. Hans Reusch, of the Norwegian Meteorological Institute, on the earthquakes that occur annually in Norway, appears to have surprised some of us who reside farther to the south, but a little reflection on the subject must show that Norway is one of those countries in which *à priori* considerations should lead us to expect a frequent occurrence of earthquakes.

It is well known that the regions surrounding our existing and active volcanic centres are specially liable to earthquakes. A glance at a map will show that the coast of Norway is just that part of the continent of Europe which is the nearest to the most active European volcanic region, viz., that of Iceland. The places specially named in Dr. Reusch's report are those nearest to Iceland.

The islands of Vaerö and Röst, where "doors and windows clattered and the slates of roofs were pitched off," are the outermost and southernmost of the Lofoddens those which stretch out the nearest towards Iceland. Bodö, also mentioned, is on the coast just opposite to them. Ytterö, another place specially named, is an island standing off the coast just opposite the southernmost extremity of Iceland, as Bodö, Röst, and Vaerö are opposite its northernmost extension, which just touches the Arctic circle. (See page 152 of this volume.) At and between these the maximum of shaking occurs.

It is further to be noted that a very remarkable physiographical feature of Scandinavia attains its maximum thereabouts. I refer to the terraces of till and alluvium which run up all the valleys opening on the west coast, whether those valleys be sea-paved and thus constitute the fjords, or whether they form the troughs of rivers or torrents in which all the fjords terminate.

Before knowing anything about the earthquakes of this region (1877) I wrote as follows of the valley which opens out in a fjord nearly opposite to Ytterö: "The valley of the Nid, like all the greater valleys of this region, is a gigantic staircase of two, three, or more, up to a dozen steps, the steps varying from 8 ft. or 10 ft. to about 100 ft. high, and with all breadths, from half a yard to a mile or two. The top of each of these steps, *i.e.*, of the terraces in this part of this valley, are beautifully flat—ready-made croquet-lawns if merely rolled and mowed."

The upper terrace in all these valleys is about 600 feet above present sea-level, but is less in the southern valleys. About half-way between Ytterö ("Hitteren" on many maps) and the arctic circle is a very curious island, Torghatten, which is perforated from east to west with a tunnel 530 feet long, 66 feet high from floor to roof at its eastern entrance, and 250 feet high at its western or oceanward entrance. The roof of the tunnel varies from 650 feet above sea-level on its west side to 530 on the east. It thus corresponds very closely to that of the 600 feet of the upper terraces of the valleys.

Many curious traditions concerning the origin of this tunnel are extant, in spite of which I ventured to suggest the following, in the first edition of "Through Norway with a Knapsack," published in 1859: "When the whole of the northern coast of Scandinavia was some 600 feet below its present level Torghatten was of course similarly lower, and the floor of this tunnel was washed by the low-tide waves. The waves of previous centuries had, aided by other agencies, such as frost and the gravitation of overhanging masses, formed this tunnel as an ordinary sea cavern, and the great upheaval had raised it to its present place."

Since the above was written the tunnel has been carefully examined by a Geological Commission of the University of Christiania, and their report confirms my general explanation, but shows that "frost and the gravitation of overhanging masses" have done more than I at first anticipated. The amount of *débris* on the floor is very great, and fully accounts for the additional 50 ft. of height at the end exposed to the full sweep of the ocean. The original solid rock floor is correspondingly lower than the present rubble floor, indicating, if the general explanation be correct, a gradual or step-by-step upheaval, corresponding to that displayed by the inland terraces.

I have seen "the Parallel Roads" of Glen Roy and Glen Spean, but interesting as they are, they are not comparable to the terracing of these Norwegian valleys. The causes materially differ. The shores of Glen Roy are those of an ancient lake formerly dammed by glaciers, first to a height of 1,140 feet above sea-level, then reduced by a breaking down of the dam to 1,059, then to 847 feet. The Norwegian terraces are ancient sea-shores, are in every valley there, and incomparably more distinct. One may walk above forty miles along some of them, as on an artificial esplanade, or sea-wall, which only terminates when the height of the bottom of the valley reaches its level.

On my visit to Norway in 1856 I walked from Christiania to Trondhjem, and first observed them in the Gula Valley, by which the road descends towards the sea. I struck into this valley on descending from the Dovrefjeld, near to where the upper terrace spreads out to form the bottom of the valley—*i.e.*, where the bottom of the valley is 600 feet above sea-level. Here was a fertile plain, such as may be found at a corresponding elevation in most of these valleys. Viewed thus from above, the terraces were very puzzling, but their true nature was fully revealed lower down.

The tourist of the present day will run over this ground by rail as I have subsequently, and in doing so will behold a magnificent panorama of these terraces, extending for miles not only along the main valley, but up the many branches of the tributaries to the Gula, each terrace winding about at its respective level in an unbroken curve. Referring to my diary, I find that I counted five in the main valley, at fifteen to twenty miles' distance from its mouth. These of course correspond to so many variations of relative land and sea level. Assuming that the differences were due to upheaval of the land, there must have been a series of great upheavals, with comparative rest between, during which periods of rest the material of these shores was deposited. The mode of deposition I must not discuss. It opens a wide field of interesting study, both of river deposition and glacier deposition. I will only add that at the present moment similar plains are to be seen on the sea-shore (as at Bodö, for example), which if upheaved would be cut down by the river, and thus form another and a lower terrace.

The present period represents one of quiescence between the upheavals, a period when there may be earthquakes amounting to such tremblings as are now occurring, but not sufficiently violent to cause a measurable variation of sea-level and convert a sea-shore plain into an estuary or valley terrace.

THE NATURALIST AT THE SEA-SIDE.

VI. Petrified Seaweeds.

At low-water mark on a rocky English coast begins a zone of bladder-wrack and tangle, which stretches down into considerable depths. Where these seaweeds fail, because the darkness grows too great for those peculiar chemical operations on which their nutrition depends, we find patches, sometimes miles in extent, covered with branching and often jointed organisms of stony texture and white, greenish, or purple in colour. The old naturalists considered these to be allied to the true corals, which indeed they resemble superficially, and named them *corallines*, or sometimes *nullipores*, from the absence of such pores as in most true corals lodge the polyps. They are now ascertained to possess no animal characters at all. Neither in nor around the stony skeleton is anything of polyp-kind to be discovered. The so-called skeleton is itself the living tissue—a mass of minute cells impregnated with carbonate of lime; and these cells are vegetable, and not animal.

The corallines (*e.g.*, *Corallina officinalis*) are small branched and jointed plants, consisting of many flattened fronds attached together by narrower articulations. If placed in weak hydrochloric acid (1:10) they become soft and flexible. Thin sections may then be cut and examined in glycerine. The fronds will be found to consist of crowded cells of rounded shape, which at the articulations pass into much elongated cells, or fibres. The cells are filled with granular protoplasm, and send very delicate fibres of communication from one to another; the cell walls consist of cellulose, and after the lime-salts are removed are very thin and fragile. The whole frond is covered by a sort of epidermis of flattened and rounded cells, which secretes a tender investing membrane. Reproductive organs, lodged in little hollow capsules, are borne at the ends of the branches. These are essentially similar to those of other algæ of the order Florideæ.

Nullipores (*e.g.*, *Melobesia*) have unjointed branching stems. They often encrust stones or other algæ, but some of the species have a tree-like mode of growth. Even at low-water mark or in deep shore-pools, which are never uncovered by the tide, claret-coloured crusts of nullipores may be found.

The colouring-matter of these curious plants is believed to be the same red pigment which tinges so many flexible sea-weeds. It is soluble in cold water, and may be removed readily from crushed and powdered nullipores. A green colour, previously masked by the red pigment, then shows itself, and this turns out to be chlorophyll, the ordinary colouring-matter of green plants.

The calcareous matter enormously preponderates over the rest of the tissues. It is no doubt obtained from sea-water in a state of solution, and precipitated in the cells. To this ingredient the corallines owe their rigidity and a certain degree of immunity from the attacks of browsing animals. The sea-snails, which devour ordinary seaweeds in vast quantities, cannot touch the corallines. Some fishes, however, have strengthened the armature of their jaws to such a point as to be able to grind up even this hard provender. But it is indirectly, not as food, but as a means of shelter, that the stony seaweeds are chiefly serviceable to the crowd of animals which throng the coralline zone. A bivalve (*Lima*) gathers their broken branches, and weaves them with threads of its own into a nest. Here many fishes lay their spawn in safety, colonies of hydroid zoophytes spread their feathery branches, and spider-crabs creep about what is to them a petrified forest. When the naturalist's dredge crashes through the spires and pinnacles of these submarine cities many a shy recluse, never washed ashore by winter gales, is dragged forth to the unaccustomed light of day.

The brittleness of the corallines determines their vertical range. In shallow waters which are swept by storms no slender and rigid architecture is possible. The tough and flexible seaweeds are here in place. Where corallines are found they give proof that the sea-bottom is vexed by no waves, and that no currents bring sand and mud to choke the rooted plants.

Diamonds in Meteorite.—According to the *American Naturalist*, at a meeting of the Philadelphia Academy of Natural Sciences, a fragment of a meteorite containing diamonds was exhibited by Professor H. C. Lewis.

SUN-DIALS, AND HOW TO MAKE THEM.—III.

A VERTICAL wall dial facing due south may be drawn in the same way, but in finding the centre the angle REA, Fig. 8, must be made equal to the latitude of the place. Fig. 11 shows a wall dial and a horizontal dial

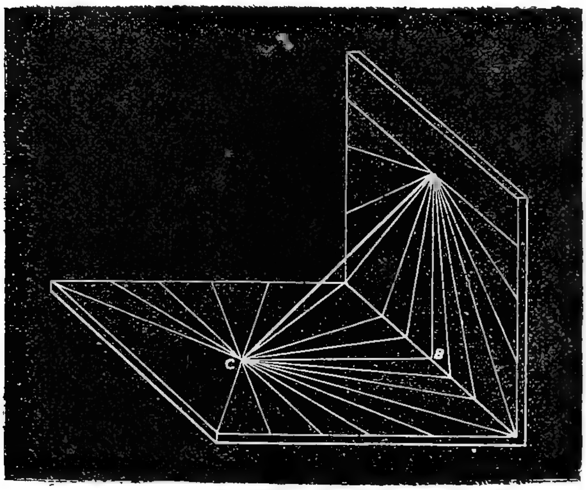

FIG. 11.

arranged with one style in common to both. It will be noticed that the corresponding hour lines meet at the line where the dials meet. At latitude 45° a wall dial and a horizontal dial would be exactly alike.

The geometrical construction of a wall-dial which does not face exactly to the south, is rather complicated for those who are not familiar with the art of projection,

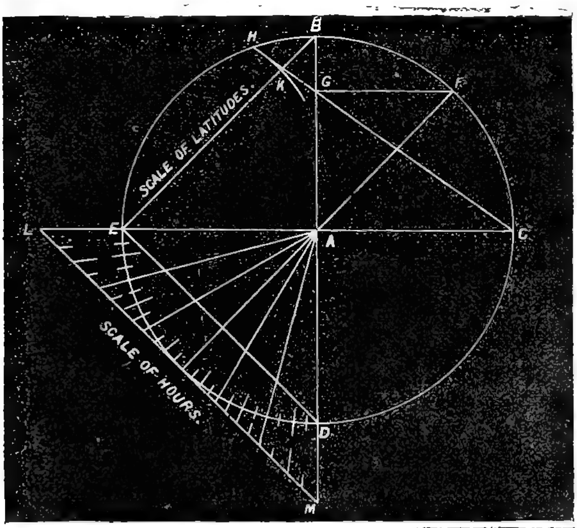

FIG. 12.

but the hour lines can be readily set out with the aid of an equinoctial dial by the following method :—

Ascertain the true north, and mark the direction on the ground, or on a temporary support beneath the proposed dial. This may be done with a compass, making the necessary correction for deviation, and taking care that there is no iron water-pipe near, since this might affect the compass. This line will be the meridian of the place, and is represented in Fig. 11 (which is a south dial) by the line CB. Draw a perpendicular line AB. Suppose the place to be near Manchester : we find

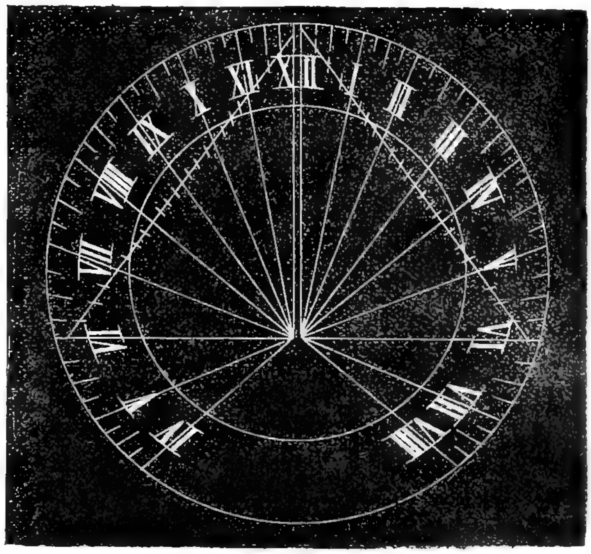

FIG. 13.

on a map that the latitude is about $53\frac{1}{2}$, and in the table of tangents of co-latitude we find the tangent would be ·738. Divide the line CB into 100 parts; this is easily done by making it $12\frac{1}{2}$ inches long; an eighth of an inch will be the one hundredth part. Make AB equal to 73·8 of these parts, or nearly $9\frac{1}{4}$ inches. Join AC by a thread, this will point to the north pole of the heavens, and will be the position of the style, or the edge of the gnomon.

Now take for an equinoctial dial a circle of card or tin,

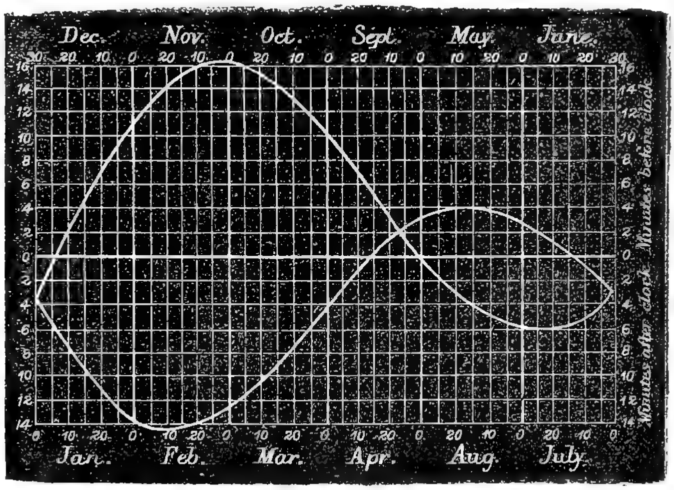

FIG. 14.

divided into 24 equal parts, and numbered as in Figs. 4 and 5. Hold it so that the thread or wire CA passes through the centre at right angles, and take care that the VI. VI. line is horizontal. Then with a candle or lantern cast a shadow of the thread on to the equinoctial dial and on the wall. When the shadow falls on the XII.

line of the equinoctial dial, it will fall on the position of the XII. line of the wall-dial, and so on for the other hours. A wall-dial cannot show the hours before VI. in the morning, or after VI. in the evening, unless it faces considerably east or west of south.

If the dial faces otherwise than due south, and is provided with a gnomon whose plane is at right angles to the dial, it will not stand upon the noon line, as in a true south dial, or a horizontal dial, but will be more or less inclined to it. The line on which the style or gnomon stands is called the substylar line. A dial of this kind may be seen on the tower of St. Clement Dane's in the Strand, near the Law Courts. The substylar line is on the XI. line in this case.

It will be observed that if the dial be arranged for latitude 90, that is, for the pole, the point R, Fig. 8, will be identical with the point F. This will be the centre of the dial, and if the hour lines be drawn it will be found that they simply radiate at equal angles of 15 degrees. The proof of this the reader will find to be an easy and not uninteresting problem.

The following method of dividing a dial was extensively used by the dial makers, since not only the hours, but the quarters and even minutes, can be set out with little difficulty. The method consists in the use of scales with specially prepared graduations. These scales are often to be found in old sets of instruments, but their use is almost forgotten.

There are two scales, the one a "scale of latitudes," the other a "scale of hours." The former is graduated as follows:—From the centre A, Fig. 12, draw the circle BCDE, regarding BD as poles, and EC as the equator; mark off F as the latitude of the place, the angle CAF being the angle of latitude. Draw FG parallel to EC, and from C draw a straight line CGH through G, cutting the circle at H. Join BE. From the centre E, at the distance EH, draw an arc of a circle, cutting EB at K. The point K represents the latitude of the place on the scale of latitudes EB. The scales are usually marked with every degree from 0° to 60°.

The scale of hours is of simpler construction. Divide the arc DE into six equal parts for the four lines, and sub-divide the hours into quarters or minutes. Join ED, and draw the line LM parallel to ED, touching the circle. From the centre A draw lines through the divisions on the circle, cutting the line LM. LM will be a scale of hours.

The scales are used thus:—Draw the meridian line AB, Fig. 13, or if a thick gnomon is to be used draw a double line. Draw the VI. line at right angles, and from the centres of the dial set off on both sides the distance EK on the scale of latitudes, along the VI. line. Then take the scale of hours, and, placing one end at the point thus found, let the other end fall on the meridian line. Straight lines drawn from the centre through the divisions on the scale of hours, will give the hour lines and other divisions on the dial.

On the circumference of a circle of $5\frac{3}{4}$ inches diameter, a division representing five minutes of time is about one sixteenth of an inch long.

An ordinary sun-dial will only show the correct time on or about the 15th of April, 15th of June, 1st of September, and on Christmas Day. On other days a correction must be made by adding or subtracting from the time as shown on the dial. This correction is called "the equation of time," and varies slightly from year to year, the second year after leap year being about the mean; this variation, however, amounts only to a few seconds, and therefore does not concern us here. The following table should be provided in some form or other with every dial. The seconds have been omitted, and the days are given on which A stands for "add," and S stands for "subtract." For example, on the 1st of January, when the sun-dial shows 10 o'clock, the real time is four minutes past ten. Again, on the 5th of December, we should have to substract nine minutes from the time as shown on a dial.

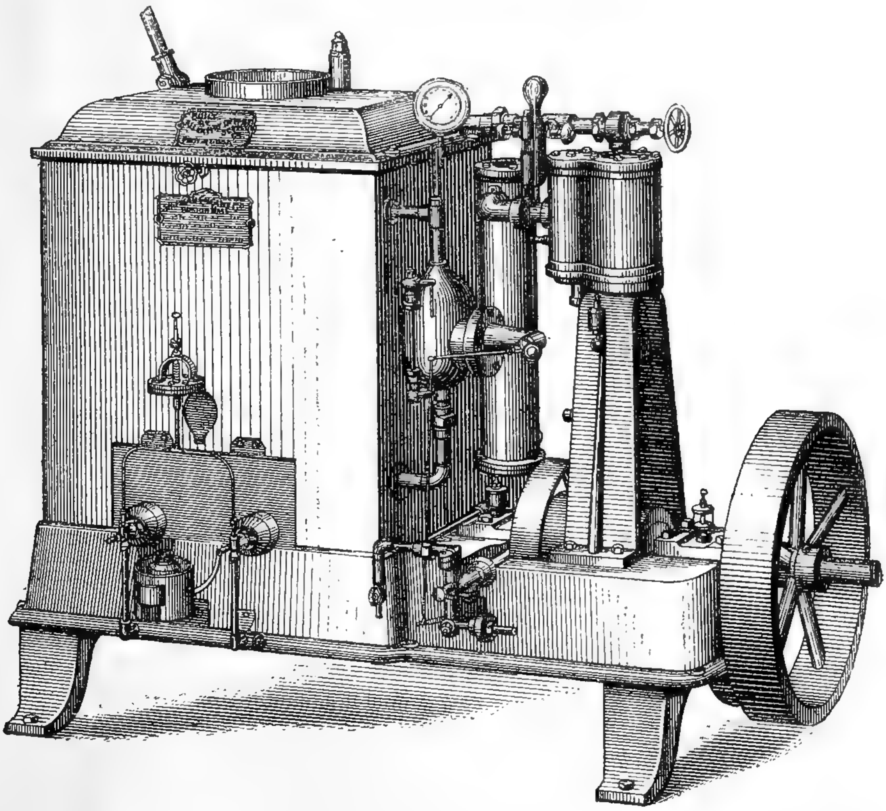
This table may be represented by the diagram Fig. 14, which explains itself. It may be arranged in other ways, and there are a number of different modifications of the ordinary sun-dials by which, if the time of year be known to within a day or two, the true time can be read off at a glance. It should be noted that if it is desired that Greenwich time be shown, a constant correction of four minutes per degree of longitude must be made. This is to be subtracted if the place be to the west of Greenwich, and added if it be to the east.

THE SHIPMAN AUTOMATIC ENGINE.

THE chief objections to the more general use of small steam yachts and launches are the difficulty in carrying fuel to run them when coal is used, and the cumbersomeness of the engines, which require a trained engineer to keep all in order. These difficulties have been largely overcome by the introduction of the Shipman automatic steam-engine, of which we give an illustration. The fuel used is petroleum, and the boilers are made of wrought-iron and steel, tested up to 350 and 400 pounds hydrostatic pressure; it is said that they are absolutely safe against either fire or explosion. Steam and oil are discharged together in a very fine spray through an atomizer into the fire-box, the supply of oil being automatically controlled by the steam pressure in the boiler operating upon a diaphragm, which may be set at any desired limit, so that when the pressure reaches this limit, the supply of oil is entirely cut off until the pressure drops again. The oil tank is placed at any convenient distance from the fire-box, so that there should be no more danger in using petroleum, in the way it is supplied by this system, than in ordinary lamps. The water supply is also automatic, the feed water pump being in operation, whenever the engine is in motion, and a ball-float connected to the cut-off valve in the pump regulating the supply. The combustion is as perfect, and ordinarily as free from smoke, as in a well-trimmed lamp. Until the steam pressure is obtained in the boiler, an air pump is worked by hand to feed the fire. This is only necessary for a few minutes, and the fire afterwards takes care of itself, just sufficient oil being automatically supplied to keep the steam pressure within the limit which has been set. This arrangement prevents waste of fuel, as the supply of oil to the fire-box is always controlled by the amount of steam taken to work the engine, the engine itself putting out its fire when no steam is taken, and relighting it again. The average quantity of oil used per horse-power per hour is said to be about two quarts. The simplicity of construction and the excellence of material used in this engine, with its automatic water and fuel feed, well adapt it for all uses where it is desired to dispense with the services of a fireman or engineer, while its compact form renders it especially available for use on small steam yacht



pleasure boats. It is also suitable for all stationary purposes, as well as for marine work.

EXTINCT BRITISH BUTTERFLIES,

And the Continuity of Existing Species by Means of Migration Considered.

(*Continued from p.* 160.)

THE other species mentioned, namely, *Pieris daplidice*, *Argynnis lathonia*, and *Lampides boetica*, though single specimens of each of these have, at different intervals, for a long succession of years been taken on our southern and south-eastern shores, they all seem incapable of breeding here in a state of nature. A single instance is on record of a female *Pieris daplidice* which was captured near Dover, depositing some ova which were kept in confinement and produced three imagines the following year. Most of the species mentioned above were once probably truly indigenous to this country, but adverse climatic influences have done their work, and they are no longer able to find here a permanent home.

Only about fifty years ago five species of copper butterflies belonging to the genus *Polyommatus* occurred in this country, while now there is only one—namely, the Small Copper (*Polyommatus phlœas*).

The Large Copper (*Polyommatus dispar*) used to occur very abundantly in the counties of Norfolk, Suffolk, Huntingdon, and Cambridge, and its extirpation in these districts has been attributed by one author to the rapacity and greediness of collectors, though far more probably the drainage of the fens this insect used to frequent is the real secret, its pabulum, the great water-dock (*Rumex hydrolapathum*), being a marsh-loving plant and only able to thrive in such situations. We may also mention that this butterfly has been recorded in times gone by from several midland localities in South Britain, and was therefore once probably found over a very wide area in this country. In addition to the Large Copper (*Polyommatus dispar*), three allied species—namely, *P. chryseis*, *P. hippothöe*, and *P. virgaureæ*—all used to occur in this country.

The former of these (*P. chryseis*) is recorded to have been taken by that eminent entomologist Dr. Leach in Epping Forest, for several successive seasons, in abundance, and was also said to have been captured in Sussex.

Polyommatus hippothöe was formerly found in Whittlesea Mere, in company with *P. dispar*, and also, it is said, in Kent, while *P. virgaureæ* used to be taken in Cambridgeshire (the Isle of Ely) and in Huntingdonshire.

Alas, all these beautiful insects are now extinct, and in future we may only hope to see their elegant forms in books! (Many specimens of *Polyommatus dispar* still exist in cabinets.)

It is to be hoped that our only living species of the genus may long be spared to grace our collections.

Of the *Lycænidæ*, or "Blues," a very interesting species which has become extinct is *Lycæna semiargus* (=*L.acis*). Only about twenty or thirty years ago this butterfly used to occur in a great number of localities in England and Wales, but, strange to say, it has entirely disappeared, and no longer finds a place in our lists.

The butterfly under consideration used to occur plentifully in one locality near Birmingham, but is not found there at all now. In this case its extirpation has been attributed by a local entomologist to the ravages of picture-makers. Here, then, man is the principal instrument in exterminating a species. He is probably answerable for many more.

The extinct "Satyrs" are represented in this country by the following; namely, the Silver Ringlet *(Hipparchia hero)*, which was formerly taken on the borders of Ashdown Forest in Sussex, and the Arran Argus *(Hipparchia ligra)*, specimens of which were captured in the Isle of Arran by Sir Patrick Walker and Mr. Alexander Macleay, but no examples of either species have been seen for many years.

A very interesting species of butterfly which formerly inhabited this country is the Goddess Fritillary, probably better known as Weaver's Fritillary *(Melitœa dia)*. The interest in this insect is derived from the great controversy which held sway for some time in the scientific magazines of the time regarding its claim to be inserted in the British lists. It was first captured by Mr. Richard Weaver, in Sutton Park, in Warwickshire, and a little later by another collector, Mr. Stanley, in Cheshire.

Mr. Weaver, who was the discoverer of this pretty butterfly, was treated in a very disgraceful manner by the entomologists of London and Paris, and great thanks are due to Mr. F. O. Morris, the well-known author, for his vindication of the character of this collector. Concerning *Melitœa dia*, we have recently been informed by the Rev. Canon Bernard Smith (late of Oscott College, near Birmingham), who knew Mr. Weaver personally, that the identity of the insects (two in number) in the cabinet of the fortunate collector was established by a friend; for then Mr. Weaver was only a beginner, having taken up the study of entomology to benefit his health. He was a bootmaker by trade. The fraud attributed to him by less fortunate collectors (who were probably jealous of his discoveries), of palming off foreign insects as British, is entirely without foundation, as Mr. Weaver did *not* collect foreign insects, for he used to say that the British were more beautiful (the insular prejudice held its sway in those days).

Mr. Montagu Browne, F.Z.S., curator of Leicester Museum, informs us that he saw the specimens of *Melitœa dia* (in addition to the specimens of *Polyommatus dispar* and *Lycæna semiargus*) in Aston Hall Museum, Birmingham, about twelve years ago, the same that were reported to have been caught in Sutton Park by Mr. Weaver. Unfortunately, the present curator of Aston Hall Museum does not know the rudiments of entomology, and cares for it, possibly, even less; but one could scarcely have believed that such rare insects should have been allowed to rot in the cellar of this scientific institution (?), yet this is too surely the case.

In addition to the species mentioned in this essay which have become extinct, there are many others of which we possess only faint records.

We should, however, like to caution our readers against accepting the supposed occurrence of many European species in this country, such, for instance, as *Colias myrmedome* and *C. chrysotheme* of English authors, which are merely varieties of *Colias edusa*, and also such as *Lycæna dorylas* which is supposed to be only a pale variety of the common blue *Lycæna icarus* (= *L. alexis*). In addition to these, there are many others which have been erroneously introduced into our lists at various times, either through want of authenticity, identity, or confusion of synonymy. Unscrupulous dealers are also answerable for a great many errors which have occurred in past times, by palming foreign specimens as British upon unsuspecting collectors. We now, however, live in a scientific age, and the facilities for cheating are not so great as formerly.

The remarkable fluctuations in the appearance of many butterflies would afford in itself a very fertile topic. During a certain season a particular species suddenly becomes abundant, though for several years previously it may have been very scarce and only occasionally met with. In 1884 the Red Admiral *(Vanessa atalanta)* occurred throughout the country in the utmost profusion, though for several years previously it had been comparatively scarce. In the following year the beautiful Peacock *(Vanessa io)* occurred in great abundance in several midland localities, though it had been very uncommon for a number of seasons. Many other similar instances have come under our notice. How these striking occurrences are brought about we are not able to ascertain at present, until more is done towards the elucidation of the economy of the species in question. How far, therefore, they are due to migration is at present involved in mystery; but apparently there is some kind of periodicity in these remarkable appearances which may eventually prove to coincide with a periodicity in the seasons of their migration.

Many species of butterflies migrate about from one part of the British Isles to another, in which case it would only be a local migration, and probably quite independent of any outside influences.

There are many other species, undoubtedly independent of migration, which sometimes appear in immense numbers locally, such, for instance, as *Thecla rubi*, *Lycæna argiolus*, *Gonepteryx rhamni*, *Argynnis selene*, and *A. euphrosyne*, which are in other seasons very scarce; then, again, others, which are usually tolerably plentiful, such as *Polyommatus phlæas*, *Euchlöe cardamines* and *Pieris napi*, are very scarce in certain seasons, though apparently there is no accounting for the phenomena. There is very wide scope, therefore, for any one who may wish to take up this interesting subject. What is greatly wanted is a number of trustworthy observers and reliable recorders in different parts of the country, with a well-organized staff to collect and arrange the data furnished.

The recent progress of science forcibly teaches us that the grandest and safest conclusions are best attainable by means of the most minutely accurate observations, persistently conducted according to some well-arranged and comprehensive plan.

In the numerous cases cited above numberless experiments are being carried out before our eyes, and if we are to profit by them we must watch them with the clearness of vision and keenness of intellect demanded by the physicist in his laboratory.

General Notes.

Earthquake in Maine.—A sharp earthquake shock was felt in the vicinity of Winthrop Maine, on the night of the 14th inst., but no damage was caused.

Geology of the Balkans.—Professor Toulo, of the Polytechnique School of Vienna, has been sent to Bulgaria to make a geological survey of the eastern slopes of the Balkans.

Earthquake at Honduras.—This catastrophe, though occasioning great damage, has not proved destructive to life. Curiously enough, it coincided in time with the eruption of Takamatsa, in Japan.

Exceptional Heat in Northern Europe.—Whilst Britain and France have lately suffered from abnormally low temperatures, the thermometer in Norway has reached heights such as have never been recorded in the present century. At Christiania the readings in the shade have several times been 30° to 32° C. = 86° and 89° Fahr. In Varanger Fiord, near the White Sea, the temperature at the end of June reached 95° Fahr.!

The Scottish Astronomer-Royal. — Mr. C. Piazzi Smyth, Astronomer-Royal for Scotland, and Professor of Practical Astronomy in Edinburgh University, has resigned these offices after holding them for forty-three years. His reason for retiring is, he states, not only advancing years, but "despair of ever being able to do anything good or compete with other observatories when the Government continue to refuse to do what their own Commission recommended."

The "Henry" Respirator.—M. Henry, of the Brussels Fire Brigade, has devised a respirator which enables men to remain with safety in places filled with smoke, ammoniacal gas, mephitic emanations, etc. It consists of a light metallic mask, covering the nose, the mouth, and the chin, whilst its sides form a double screen. In one there is wadding saturated with glycerine, and in the other a layer of sponge, which at the moment of use is sprinkled with an appropriate liquid, such as lime-water, which absorbs carbonic acid in case of burning buildings, or a solution of sugar of lead if it be necessary to enter cesspools, sewers, etc.

A New Comet.—From a circular just issued from Lord Crawford's observatory at Dunecht, we learn that another new comet has been discovered by that most indefatigable and successful American discoverer, Mr. W. R. Brooks. The present comet was found at his new station, Geneva, U.S., on August 7, when its position was R.A. 10hr. 5min., Dec. 44deg. 30min. north. The place is near the third magnitude star Lambda, in the Greater Bear. No particulars are given of brightness, but it is stated that it is moving eastwards.

Electric Conductivity of a Vacuum.—According to *Cosmos*, as certain physicists, such as Goldstein, Edlund, and others, have maintained that a vacuum is a good conductor of electricity, Prof. A. Foeppl has resolved to verify this supposition. The circuit having been formed of homogeneous gases, highly rarefied, the passage of the current ought to manifest itself in various manners whether by its action upon a magnetic needle or by the production of induction currents. The experiments, though carried out with great skill, led to a conclusion absolutely opposite to that of Goldstein, that a vacuum does not conduct electricity.

Fires Extinguished on Ship-Board.—A process devised by Messrs. Coates and Carver, of Manchester, has recently been tried with success at Liverpool. The process consists in turning the products of combustion from the boiler-furnaces into the hold where the fire is raging. A French contemporary remarks that the carbonic acid and *carbonic oxide* gases given off by the furnaces come here in play. Now that carbonic acid gas extinguishes fire is well known, but no reliance can be placed upon carbonic oxide, which is distinctly inflammable. It must not be inferred from this comment that we question the value of the invention, which in the trial made was splendidly successful.

Government Aid to Agricultural and Dairy Schools.—The Lords of the Committee of Council for Agriculture have awarded the following sums out of £5,000 granted by the Government for the present financial year in aid of the agricultural and dairy schools, viz.:—The Cheshire County Dairy School, £150; Aspatria (Agricultural) School, £250; Edinburgh University, £300; Glasgow and West of Scotland Technical College, £200; Kirkcudbright Dairy Association, £70; Ayrshire Dairy Association, £125; Wigtownshire Dairy Association, £101 10s.; and to Dumfriesshire Dairy Association, £28 10s. The applications from the British Dairy Farmers' Association, the Norfolk Chamber of Agriculture, and others were deferred for further consideration.

Falling Stars and Meteoric Dust.—*Apropos* of the now recurring showers of shooting stars, a correspondent of the *Vossische Zeitung* mentions the probability that Professor Nordenskjöld's experiments have decided in the affirmative the question whether the remains of shooting stars that have been burnt in our atmosphere are found on the surface of the earth. Nordenskjöld caused large masses of snow to be melted, and found left behind a very fine powder, which proved to be metallic iron. The first experiment had been made in Stockholm so that it was not impossible that this iron dust might be of terrestrial origin; therefore the experiment was repeated in the Finnish forests, with a similar result. Still more decisive was it when the experiment was repeated with the snow in Spitzbergen, more than 400 miles from any human dwelling; and metallic iron was found there also in the form of a fine dust, which makes it extremely probable that the cosmic significance of this iron is connected with the shower of falling stars. Of whatever kind the combustive product of these falling stars may be, it is certain that it must fall on the earth, and that it gradually increases the mass and weight of the latter in a manner which is not unimportant, considering the ages during which the earth has existed and is likely to exist.

International Geological Congress.—This Congress meets only once in three years, and it is to hold its next meeting in London from September 17th to the 22nd.

The Congress originated in 1876, at the Buffalo meeting of the American Association for the Advancement of Science, and meetings have since been held at Paris, Bologna, and Berlin. It is expected that the London meeting will much exceed in numbers any previously held, as over 200 foreign and colonial geologists from twenty-one countries have already notified their intention of being present, while the number of British geologists will be at least as large. The meeting will be held at the London University, Burlington Gardens, and among the questions to be discussed will be the geological map of Europe; the classification of the Cambrian and Silurian rocks, and of the tertiary strata, and the Organising Committee propose to devote a special sitting to a discussion of the crystalline schists. The excursions at present suggested are—(1) The Isle of Wight—cretaceous, eocene, oligocene. (2) North Wales—pre-Cambrian and the older palœozoic rocks. (3) East Yorkshire—jurassic and cretaceous. (4) Norfolk and Suffolk—pliocene (crag) and glacial beds. (5) To the jurassic rocks of central England. (6) West Yorkshire—silurian and carboniferous limestone. The short excursions during the week of the Congress will probably be to Windsor and Eton, St. Albans, Watford, Brighton, Erith, and Crayford, etc., and the Royal Gardens at Kew.

The Late J. C. Houzeau.—The funeral of this eminent *savant* took place on July 15th at three p.m. The usual discourses were pronounced on the occasion by Lieut.-General Liagre on behalf of the Belgian Academy of Sciences, by M. F. Folie in the name of the Observatory, and by M. Ch. Ruelens on behalf of the Royal Belgian Geographical Society. Jean Charles Houzeau de Lehaie was born at Mons in 1820. He studied first at the college of his native town and afterwards at the University of Brussels. His career of research in physics, astronomy, meteorology, and climatology opened in 1843. In 1846 he became an assistant at the Observatory. Here, however, his political tendencies became incompatible with the discharge of his duties, and he resigned in 1849. In 1857 he emigrated to America, spending several years in Texas, Mexico, and Jamaica, and making a number of valuable observations in natural history. The first of his labours appeared in his "*Etudes sur les facultés mentales des animaux comparées à celles de l'homme,*" a work published in 1872 at Kingston, in Jamaica. Here he distinctly declared that man differs from the lower animals not qualitatively, but quantitatively, and rejects the assumed distinction between "reason and instinct." In 1870 he returned to Belgium as Director of the Observatory. Space does not permit us to enumerate the researches of the departed, but we do not hesitate to say that if he had eschewed politics, and especially Socialism, he would have been a second Humboldt.

The Public Health.—The Registrar-General's return for the week ending August 11th shows that the deaths registered last week in twenty-eight great towns of England and Wales corresponded to an annual rate of 17·6 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Derby, Huddersfield, Portsmouth, Hull, Sunderland, and Bristol. In London 2,228 births and 1,476 deaths were registered. Allowance made for increase of population, the births were 454 and the deaths 203 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 15·9 in each of the two preceding weeks, rose last week to 18·0, and exceeded the rate recorded in any week since April last. During the first six weeks of the current quarter the death-rate averaged 16·0 per 1,000, and was 5·4 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,476 deaths included 51 from measles, 17 from scarlet fever, 25 from diphtheria, 27 from whooping-cough, six from enteric fever, one from ill-defined form of continued fever, 138 from diarrhœa and dysentery, five from cholera and choleraic diarrhœa, and not one from small-pox or typhus; thus 270 deaths were referred to these diseases, being 164 below the corrected average weekly number. In Greater London 2,929 births and 1,791 deaths were registered, corresponding to annual rates of 27·6 and 16·9 per 1,000 of the estimated population. In the outer ring 21 deaths from diarrhœa, four from measles, and four from diphtheria were registered. The fatal cases of diarrhœa included four in Mortlake and five in Walthamstow subdistricts.

The Archæological Institute.—The excursion last Tuesday week commenced with a visit to Hatton, where the fine old church in which the celebrated Dr. Parr ministered has given place to a modern edifice. The building was inspected, and Baddesley Clinton Hall, with its moat, were examined. The party next proceeded to Knowle, and made an examination of the church, a description of which was read by the Rev. Canon Howe. Solihull was the next place visited, where the party were received by the Rev. M. Hartwright, the curate, who opened the registers, which date back to the time of Henry VIII., and which contain curious entries of persons who had died unbaptized or excommunicated, and had been buried in wool. The company then paid flying visits to Meriden and Berkswell, the churches at these places being explained by Mr. W. G. Fretton, F.S.A. At the evening meeting, Sir T. Baker presided, and proposed a vote of thanks to the Mayor and Corporation of Leamington for the hearty reception and hospitality extended to the Institute on the occasion of its present visit to the Royal borough. This was unanimously adopted. Wednesday, the concluding day of the congress, was spent in a journey by train to Melton Mowbray, where the noble parish church was inspected under the guidance of the vicar, the Rev. Mr. Collins, and its restoration by Sir Gilbert Scott was admired, as was also the architecture of the western entrance, which forms a sort of "Galilee." After luncheon, the first halt was at Burton Lazars, where the church was inspected. A drive of some three miles took the party on to Burrow or Burgh Hill, where Colonel Bellairs read a paper mainly based on Nichol's "Leicestershire," in which it is asserted to be an undoubted Roman encampment, and such appeared to be the opinion of the party, though many thought it to be Roman work imposed on the British fortification. The other churches visited in the afternoon were Ashby Folville and Gaddesby, both very interesting in their several ways, and the last named being remarkable for its fine, pure, and external carved decorations, and for its wooden seats of the 15th century. At half-past five the party reached Ratcliffe College, over which they were conducted by Father Hirst. After inspecting the college chapel and library, they returned to Leicester.

PORTABLE MAGIC LANTERN.

A VERY compact form of magic lantern is illustrated in the cuts accompanying this article. It is adapted for all experimental purposes, as well as for the projection of views. The best way to give a correct

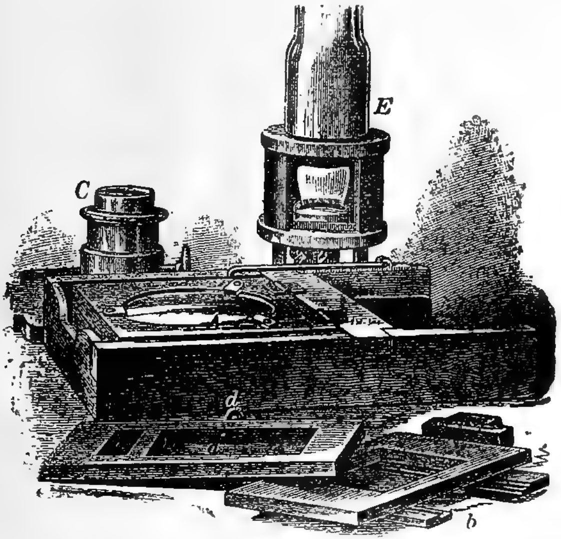


FIG. 1.

idea will be to take, as example, a $4\frac{1}{2}$ inch condenser lantern, and give the dimensions of the different parts, as shown in the cut. The size of the condensers settles the question of the measurements of the other parts.

The two condenser lenses, plano-convex, are mounted each in a separate board. A circle is turned out with a rabbet in each board, in which the condenser seats itself,

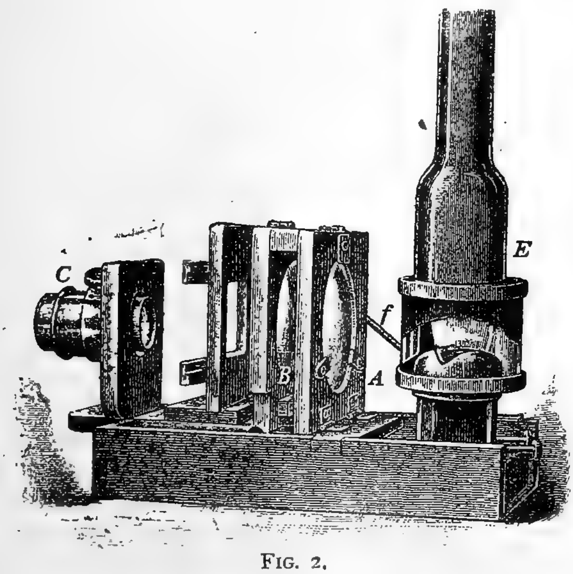

FIG. 2.

and is secured therein by three buttons. The rear condenser board, A, is $6\frac{3}{4}$ inches square. The front board, B, is of the same width, but $8\frac{1}{4}$ inches long. To the rear one a strip is screwed across the top edge, and the front one is hinged to this strip. At their bases, coming between them, two small abutting strips are secured. The thickness of the strips is such that the boards, when brought together, with the strips in contact, are strictly parallel, and the lenses are held apart from each other.

The frame or base of the lantern is a rectangle, a little over $6\frac{3}{4}$ inches across, and 13 inches long in internal measurement. It is closed at the front and open at the back of the lantern. It is $2\frac{1}{2}$ inches deep; $7\frac{1}{2}$ inches from its front, the back condenser board is hinged to a strip that runs across the top of the frame, and is screwed firmly thereto, flush with its upper surface. A long brass hook, *f*, and staple is provided, for holding the condensers in place when vertical. The boards are held together, when desired, by another shorter hook, *c*, with staple. The condensers are then in place for horizontal projection. To arrange them for vertical projection, the small hook, *c*, is unfastened, the front condenser, B, is pushed up until the two are at an angle of 90°, and a plane mirror is inserted, resting

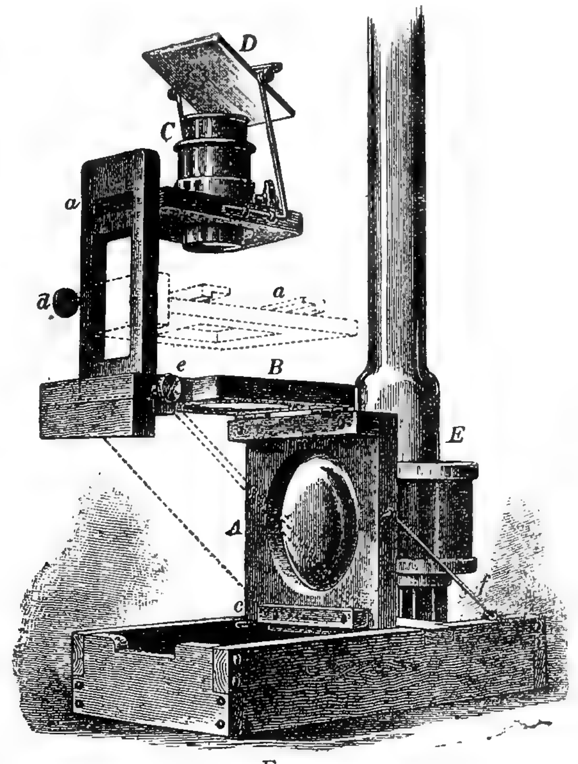

FIG. 3.

against the two bottom strips. The mirror should be mounted on a thin board or on a brass plate, so as to provide strength and protect its back.

A mortise is cut in the front condenser $6\frac{3}{4}$ inches from its top, $\frac{5}{8}$ inch wide and $3\frac{1}{8}$ inches long. A piece of board, *a*, is cut to slide smoothly back and forward through this mortise. For retaining the strip in any desired place, a hand screw, *e*, is placed on the side of the condenser board, which is notched at both its lower corners. A strip of brass is attached to the side of this strip for the screw to press against.

The strip carries the slide carrier *b* and lens *C*. The lens is attached to a board about 4 inches wide and $5\frac{1}{2}$ high, with a tenon projecting from its base. A mortise is cut near the end of the sliding strip to receive this tenon.

A second mortise or slot, $4\frac{1}{8}$ inches long and 2 inches wide, is made in the strip *a*. The slide carrier, *b*, is a board $6\frac{1}{2}$ inches high by $4\frac{1}{2}$ inches wide. To its base is attached a piece of wood 3 inches square. This is $\frac{1}{2}$

inch thick, and below it is a second piece of the same length, but just 2 inches wide. The second piece enters the slot in the sliding strip, *a*, and the slide carrier rests upon the shoulders formed by the upper block. A hand screw, *d*, is arranged to hold the slide carrier in any desired position.

A smaller movable mirror, *D*, is supplied to be supported above the objective when the lantern is to be used for vertical projection.

A piece of sheet iron is fastened across the bottom of the main frame, on which the lantern, *E*, rests. In the front of the same frame a notch is cut in which the piece, *A*, rests. To make its position in the front condenser board more secure, a second strip may be attached just below the mortise and to the back of the board.

For lantern any good form of screened lamp may be used. If necessary, a sheet-iron box may be arranged to inclose the source of light; but with such a lantern as is here shown it is quite unnecessary.

In the drawings, Fig. 1 shows the whole ready for mounting, the lamp being lighted and ready for work. The lamp should always be lighted before beginning, as it may take five minutes for it to attain its full power. Fig. 2 shows the whole put together and arranged for exhibiting views. By removing the slide carrier the entire space between condenser and objective is free for the introduction of apparatus or performance of experiments. A soap bubble can be blown and projected in this space. A glass of water can be very prettily shown, and the lantern will be found admirably adapted for the experimenter's use. Fig. 3 shows the lantern arranged for vertical projection, the outline of the mirror being given in dotted lines. As the slide carrier is not always used for work in this position, it, too, is shown in dotted lines.

If all is properly constructed, the apparatus will be susceptible of all kinds of adjustments. The sliding board, *a*, can be moved back and forth in the mortise in the front condenser board. The slide carrier can also be moved backward and forward. By these two adjustments the slide carrier can be brought to any point desired in the cone of rays converging from the condensers. By moving the lantern backward and forward, any modification in the direction of the light rays emerging from the condenser can be given.

A lime-light can be used instead of an oil lamp; but as the object was to show a portable lantern, the former has been shown in the cuts.—*Scientific American.*

NOTES FOR YOUNG COLLECTORS.

THE following notes, the result of long experience abroad, may not all be available for entomologists in Britain. But in view of the increasing facility and cheapness of travelling and the frequency of emigration, it may be hoped that more and more of our rising entomologists will no longer confine themselves to British insects, but go out to wider and less threadbare fields. In no other part of the world is so much annoyance sustained from the trespass laws and from the interference of gamekeepers. In other countries, so long as you do not encroach upon lands under actual cultivation, you need fear no interference.

Perhaps the first caution to be observed by the young collector is to avoid the interior of forests, as comparatively barren. Their margins, whether bordering on arable land, pastures, heaths, or pieces of water, are very generally found fruitful. Lanes or avenues cut through a dense forest often yield a rich harvest. So do openings of a few score yards in width, screened from the wind on all sides, especially if they include a pool or a patch of marshy ground. One of the best of all localities is a clearing where the trees have just been removed and the stumps are still standing.

A great variety of lepidoptera, and not a few beetles, especially the splendid *Buprestidæ*, come to feast on the sap oozing out of the wood.

Chalk, sand, and gravel pits, especially if they have been left undisturbed for some time, are always worth a careful examination. The margins of foot-paths leading across pastures and meadows and through corn-fields are often rich in *Elateridæ*, especially species of *Gtenicera.*

Stony and shingly districts are often rich in ground-beetles, *Carabs, Harpalidæ*, etc., which may be found by cautiously turning the stones over. This applies, however, only in localities where stones are naturally prevalent. A casual heap of stones in other localities rarely yields anything worth picking up.

Rivers in time of flood are often very prolific. If the collector provides himself with a small water-net with a long handle, and takes his stand at some point where the current is obstructed—*e.g.*, by the piers of bridges, jetties, etc.—he may sometimes scoop up beetles by the pint, *Geodophaga* of almost every description occurring in the neighbourhood, *Necrophaga, Geotrupidæ*, and many others. The best way is to bring away the whole lot, and sort them at home. Those not wanted should be set at liberty, as by far the greater number of those likely to be thus captured are harmless, if not actually beneficial. You will find that Carabs, to all appearance drowned, will, if laid in a sunny spot, gradually revive and run away.

Certain localities are to be avoided as not likely to be worth the time spent upon them. Such are districts swarming with ants, whether they be woodland, heath, or desert. Here the larvæ, the pupæ, and all adult insects haunting the ground and the lower trees (with the exception of certain species which seem to live on friendly terms with the ants) will have been devoured. Grass-lands which are mown repeatedly during the course of the summer—as it is often done in Switzerland—are of little use, since many species of plants are thus extirpated, and the insects which feed upon them are banished. The neighbourhood of a flourishing rookery is seldom rich in insects; these birds are very diligent and successful in digging up and devouring buried larvæ and pupæ, and in ransacking small carrion, dung, etc., for a variety of insects.

Where moles abound the prospects of the collector, at least as far as certain groups of insects are concerned, are not very bright. Land which has been heavily dressed with chemical manures is often shunned by insects, whilst, on the contrary, many kinds flock where farm-yard manure, night soil, crushed bones, etc., have been applied.

Plank-fences and the sides and tops of sheds and out-houses which have been recently coated either with gas-tar or wood-tar may be let alone by the collector, for they will assuredly be boycotted by insects.

Very much depends upon the kind of weather. Prolonged drought and prolonged wet are equally objectionable to our creeping and flying friends. They prefer a mixture of sunshine and showers, with as little wind as possible. In tropical climates the beginning and the end of the rainy season, and especially any intervals of fine weather which intervene, are good times for collecting.

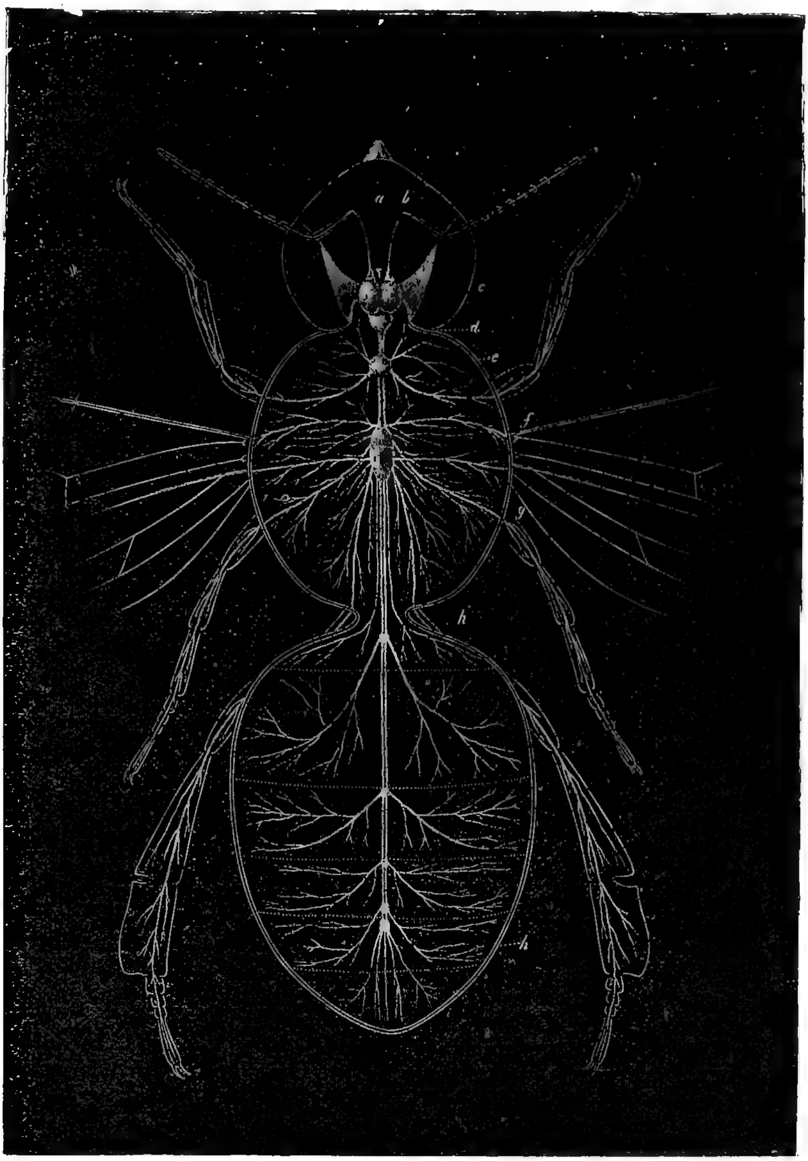
Natural History.

THE SENSES OF INSECTS.

I. Preliminary.

The manner in which, throughout animated nature, the nervous system deteriorates, so to speak, by slow but sure degrees as we pass downwards in the scale, cannot fail to have greatly struck all those who have enrolled themselves as workers in the field of comparative anatomy. This system attains, of course, its highest perfection in man, whose intellectual requirements have to be provided for as well as those mental and physical needs which he possesses in common with many of the lower animals, while that same intellect endows him with special capacities for the appreciation of pleasure and pain, which in their turn also imply an unusual completeness in the development of the nervous system. Then, as we work our way from mammals to birds, birds to reptiles, reptiles to fishes, and fishes to invertebrates, each descending step shows us a corresponding deterioration, until in some of the lower forms of life we fail to discover any traces of a nervous system at all.

Especially do we find this to be the case with the brain. In man, of course, that organ is quite unique in character, greatly excelling in comparative bulk, and still more in quality, that of any other animal. But putting man altogether upon one side, and taking the monkey type as the most physiologically perfect, we may trace the gradual degradation of the brain even in the mammals, which degradation, becoming still more marked in the birds, the reptiles, and the fish, ends in the apparently complete effacement of the organ in question in that most singular creature the *Amphioxus*, which seems to be a link between the vertebrates and the invertebrates, connecting the two great classes together.



Nervous System of Bee.

In the molluscs, however, which stand foremost in the invertebrate class, the brain reappears, but now in a different form. In place of a localized organ, situated in the head, we find it broken up, so to speak, into a number of *ganglia*, or miniature brains, placed in different parts of the body, but communicating with one another by a double chain of nerves, which may or may not be analogous to the spinal cord possessed by higher forms of life. This structure is still more strongly marked in the case of the Insects, with which we have now more particularly to deal; and in them the brain may be defined as divided into eight, nine, ten, or more portions, lying in a chain extending from the head to the extremity of the abdomen, and connected with one another in the manner above described.

Now this distribution of the nerve-centre into different regions of the frame leads to one most important result, for it restricts, and restricts very greatly, the functions of that particular ganglion which for our present purpose it will be convenient to term the brain, although it is in reality but a small portion of that organ. In all the higher animals the brain is, of course, the ultimate terminus of every nerve in the body, the seat of all sensation, intelligence, and volition, and the centre of that nervous activity which enables the vital functions to be maintained. Pain, in whatever part of the system inflicted, is felt by the brain; motor stimulus, of whatever muscle or muscles, proceeds from the brain. And it is also the recipient of those impressions which are due to the sensory organs, and which are conveyed to it by special nerves, modified in character to suit their special purpose. Thus its functions are many and complex, and it becomes, as it were, the one great director and commander-in-chief of the whole physical and mental organization.

But in the insects it is not so. From each of the ganglia in the ventral chain proceed nerves which, branching and ramifying again and again, supply motor force to those regions of the body in which they lie, or provide for such sensory properties as may be necessary for the individual species. Thus a very considerable proportion of those functions which in vertebrate animals are apportioned to the brain are in lower forms of life dissevered from the cephalic ganglion, which may be taken as representing that organ, and transferred to such nerve-centre as may be nearest to the region or the members in need of supply. Each ganglion, in fact, is a kind of subordinate or deputy brain, a seat of motor and sensory power for the service of a certain portion of the body. And so the head-brain, or principal ganglion, is set almost wholly free for the reception of impressions conveyed to it by the sense-organs, and for the transmission to the secondary nerve-centres of impulses consequent upon those impressions. At the same time, it is probably affected, although not in any great degree, by sensations experienced even in the remoter regions of the body, for otherwise it were hard to explain the function of the *double* communication-cord which links all the ganglia together.

Another result follows upon the first. The functions of the brain being, as we have seen, almost wholly restricted to the reception of sense-impressions and the transmission of impulses to which those impressions give rise, it is only natural to infer—more especially as the ganglion in question is of considerable size—that such impressions must be unusually keen, or at least those appertaining to senses whose external receptive organs are peculiarly developed. We might consider, for instance, that the sight of insects would be especially perfect, considering the wonderful array of eyes, often in two or even three forms, which are ordinarily present. And such is in fact the case, as we shall subsequently see when discussing the individual senses. Insects are beings whose very nature, whose bright and vivid life, whose matchless activity render highly developed sense-organs an absolute necessity. They are primarily creatures of the air, and that fact alone implies the possession of perceptions unusually acute. Such we find to be the case in the bat, whose highly sensitive wing-membrane endows it with a sense of touch so marvellously perfect that it can *feel* the presence of an object when several inches away. Such we find to be the case with the birds, whose eyes combine in themselves the properties of both telescope and microscope, and also possess the power of altering their focus with almost incredible rapidity and exactness. And such, too, is the case with the insects, whose sight, scent, and hearing are in many instances very highly developed, while it is at least an open question whether they do not possess other senses unknown to ourselves, but of great and indeed inestimable value in their own daily lives.

What, for example, are the functions of the antennæ? We cannot connect them with any of the five senses which we generally recognise, yet their invariable presence surely points them out as organs of extreme importance. They are occasionally employed as instruments of touch, it is true, as in the case of the ants. But this is the exception and not the rule; and, on the other hand, we find that those insects in which they are developed to the greatest extent never employ them for such purposes at all. And what can be their office? For it is not Nature's way to provide bodily members in any animal without at the same time apportioning duties for those members to fulfil.

The possession by insects of additional senses, however, is a possibility and nothing more. However far the progress of science may take us, we shall never be able positively to assert either that such senses are present or that they are not. And for this simple reason, that, not possessing them ourselves, we cannot form any idea whatever of what they may be in others. One blind from his birth could call up no idea of colour, neither could its character be explained to him. A man born without nerves of taste could never be brought to understand the nature of flavour. And in the same way we can form no notion of any sense which is not a development of one or more of those which we ourselves possess. Thus, in discussing the presence in insects of an additional sense or senses we are passing the bounds of science altogether, and entering upon the regions of pure speculation; and to bring the question into scientific limits is from its very nature—or perhaps it would be more correct to say from *our* very nature—impossible. We must, therefore, confine our investigation to those five senses of which alone we can take any cognisance; and these, as developed in insects, we will discuss in turn in subsequent papers.

Sulphur as a Remedy for Locusts.—An interesting fact in connection with the late inroad of locusts in Algeria, is that one vine has escaped alone in the midst of a vineyard where otherwise not a leaf has remained undevoured. A few days before the arrival of the swarm this vine had been well dusted over with sulphur as a cure for mildew.

THE BOTANY OF BRISTOL.—I.

FOR natural history purposes the neighbourhood of Bristol may fitly be considered co-extensive with the area of the Bristol coal-fields as defined in the geological map of Mr. Sanders. A district thus limited has already been adopted by local entomologists, geologists, and botanists, in portraying the Bristol features of their respective branches of science; and to the student it is an undeniable advantage to carry on field work of this kind within boundaries which are substantially natural, instead of drawing an entirely arbitrary line around the city taken for a centre. We speak of the Bristol district, therefore, as bounded on the west by the Severn and the Bristol Channel; on the south by the river Brue, which falls into the mouth of the Parrett, just below Burnham; and as extending north to the town of Berkeley, and east to the cities of Bath and Wells. Portions of North Somersetshire and of West Gloucestershire are included in this area, and are separated, save for a short distance, by the river Avon, which, passing through Bath and Bristol, joins the Severn at Avonmouth. Obviously we have here an extensive tract of country to work over. However, one may justly say that every part of it is not only of great interest to the naturalist, but is easily accessible from Bristol. In these days facility of locomotion is so great that a run of ten or fifteen miles out and home is within the reach of anyone who has half a day to spare. By rail, by cycle, or by "Shanks's pony" (and the field botanist being essentially a pedestrian will commonly prefer the latter) every portion of the district can be reached and explored without undue fatigue or an unendurable tax upon a slender purse. Moreover, our chief botanical wealth lies in the immediate neighbourhood of the city, where, upon St. Vincent's Rocks and on the Downs, in the Avon Gorge, Leigh Woods, or the Frome Valley, the stranger who visits Bristol in search of plants, while rambling amid delightful scenery, will become acquainted with many of the greater rarities. Before mentioning these plants in detail it will perhaps be well, for the benefit of readers unfamiliar with the country, to give a brief topographical sketch of its natural features and surface condition.

The city of Bristol lies in a somewhat triangular basin at the confluence of the rivers Avon and Frome, the latter a small tributary from the north-east, which flows through the picturesque Glen Frome, and is not to be confounded with the larger stream passing by the town of that name. Around the city arise hills which are more or less broad tablelands or plateaux. The steep acclivities on the north are beds of carboniferous limestone and millstone grit. To the south the swelling slopes of Knowle and Totterdown extend to Dundry Hill, which rises to 769 feet above mean sea level. Solid Jurassic beds are the cause of the existence of this high ground, which bounds the horizon for a considerable sweep. On the east of the city there is an irregular elevation, with an average height of about 180 feet. This extends from the river Frome on the north-east to the cliffs which bound the Avon by Conham and Brislington, and consists for the most part of coal measures, containing the sites of numerous coal-pits. It is the hard Pennant sandstone of the coal period, which is cut through by the Avon in the picturesque winding of the river by Conham. The influence of the tide is shut off near this point, and the river being locked becomes a canal joining the Kennet and Avon system, and forming, before the development of railway traffic, one of the most important links of inland navigation between Bristol and the Metropolis. Travelling eastward, the riverside scenery and botany change to the commonplace, and from the Pennant valley to Bath do not invite our special attention. In its tidal course to the Severn below Bristol the river passes by the Hotwells, under Clifton and St. Vincent's Rocks, and onward between the cliffs and quarries of the Avon Gorge. Lower down it passes through an extensive tract of alluvial flats drained by numerous intersecting ditches, chiefly brackish. These abound with algæ and other interesting matter for investigation. Small brooks, draining respectively Bedminster Meads and Ashton Marshes, with the meadows behind Long Ashton, flow into the Avon at Bedminster and Rownham. Other principal sources of drainage in the district are the Chew, the Trym, and the Axe. The former runs through rich pastures between Dundry and the Mendips, by way of Chew Magna and Stanton Drew, falling into the Avon near Chewton Keynsham. Most excellent botanizing is to be had throughout its course.

Either on the banks of the Chew or on ground rising from them a number of good plants may be gathered, including *Helleborus viridis*, *Viola odorata*, *V. alba*, *V. Reichenbachiana*, *Saponaria officinalis*, *Stellaria umbrosa*, *Rubus silvaticus*, *R. Radula*, *Rosa subglobosa*, *Epilobium roseum*, *Senecio saracenicus* in profusion, *Inula Helenium*, *Mentha sylvestris*, *M. piperita*, *Polygonum Bistorta*, *Daphne Laureola*, *Salix alba*, and the barren plant of *S. fragilis*, which is unknown elsewhere in the district; *Populus canescens*, *P. tremula*, *Orchis latifolia* (type), *Juncus compressus*, *Calamagrostis Epigejos*, *Glyceria plicata*, *Polystichum aculeatum*, and *P. angulare*.

The Trym is a smaller stream of less importance. It collects the drainage from the high lands about Henbury, and passing through Westbury and Coombe Dingle, falls into the Avon at Sea Mills, amid a submaritime marsh flora.

Besides the already mentioned Dundry, there are in the vicinity of Bristol some isolated hills of an altitude of from 250 to 300 feet. But the chief elevations are on the great Mendip range, a few miles to the south-east, and among the southern spurs of the Cotswolds, which come down into the north-eastern portion of the area as far as Wotton-under-Edge. The latter afford some enjoyable rambles from stations on the Midland Railway, being sometimes wooded, and their slopes sprinkled with abundance of belladonna, lily of the valley, *Polygonatum officinale*, and good orchids; or open and grassy, flecked with patches of *Hippocrepis*, *Trifolium medium*, *Rosa tomentosa*, and *Brachypodium pinnatum*. This grass has foliage of a bright yellowish-green colour, contrasting strongly with the brown hue of the turf around, and rendering the spots where it grows conspicuous at a long distance.

The Mendip Hills are, for the most part, huge masses of limestone, rocky and precipitous in places, but chiefly consisting of rough pasture and rugged slopes, presenting to-day the same features and appearance that they did when Roman miners delved and pitted their surface in the search for ore. The levels vary up to the top of Black Down, a wide expanse of elevated open moor and heath rising to an altitude of over 1,100 feet. The only true bog we possess occurs upon this range. In consequence, we find on Mendip several paludal species that are unknown or uncommon elsewhere about Bristol; for example, *Viola palustris*, *Peplis Portula*, *Scutellaria* *minor*, *Eriophorum vaginatum*, and *Lastrœa spinulosa*. Other noteworthy plants associated with these hills are *Helleborus viridis*, *Thlaspi occitanum*, *Alsine verna*, *Gnaphalium sylvaticum* and *Herminium Monorchis*. Cheddar deserves to be treated separately on account of the great natural phenomena there exhibited, and the exceptional richness and peculiarity of its flora. The grandeur of its magnificent cliffs and caverns will amply repay a traveller, even if he have journeyed far to witness it; and the delight of a botanist can be imagined when, for the first time, he sees above and around him fine tufts of the beautiful *Dianthus cæsius* conspicuous with colour, nestling in clefts and crannies of the heights. Underneath by the roadside are *Sedum rupestre (majus)*, *Saxifraga hypnoides*, thrown as a matted mantle over the rocks; and, earlier in the year, *Cochlearia officinalis*, with *Cerastium pumilum*. Here and there large yellow blossoms of *Meconopsis* make a brave show, and the limestone screes bear abundance of *Phegopteris Robertiana*. If his vasculum be not yet filled to repletion, the student may venture on the critical task of determining how many forms of *Thalictrum* grow at Cheddar; and should he do so, it is not lack of material which will hinder a satisfactory conclusion.

Below the zone of undulating moorland, breezy heath, and old grey rock there are many little rivulets winding and turning down the boggy slopes until lost in the sphagnum where the sundews grow; and stretches of aboriginal copsewood afford suitable spots for many sylvestral plants. *Lithospermum purpureo-cæruleum* makes its home on the sunny borders of these woods. The splendid hue of its petals, its porcelain fruit, and remarkable mode of growth give it a high place in our estimation apart from its rarity. Here too the Bee Orchis makes a profuse display when it chooses; but, as is well known, the appearance of most Orchids is uncertain and seemingly capricious.

The Mendips in Somerset and the Cotswolds in Gloucestershire alike, each overlook a great alluvial plain, stretching away westward to the Severn and the Bristol Channel. Reclaimed from the sea at some distant date, these extensive tracts are now fertile pasture, rich in aquatic and paludal species that find congenial stations in the frequent marshes, ditches, still pools, and sluggish drains. Approaching the Channel shore, numerous estuaries and tidal inlets locally termed "Pills" materially add to the number of our plants, and influence in some degree the character of the vegetation to a considerable distance from their waters. About their banks such plants as delight in a saline soil or atmosphere, but shun the exposure of the open coast, find suitable resting places. The coast itself, a long and little-varied line of sand and mud bank, with now and then a low cliff or a bank of shingle, offers all the conditions required by many maritime species.

From what has been stated it will be evident that the neighbourhood of Bristol possesses widely varying peculiarities of physical configuration and geological structure, and furnishes nearly every kind of locality that a botanist desires for his researches. One may even say that the additions of mountain and bog are mainly all that are required to render the Bristol district a typical portion of Great Britain. The distribution of plants being largely dependent upon the nature of these features, the flora is, as might be expected, proportionately extensive.

(To be continued.)

Reviews.

Transactions of the Cumberland and Westmoreland Association for the Advancement of Literature and Science. No. XII., 1886-7. Carlisle: G. and T. Coward.

The Cumberland and Westmoreland Association is a league entered into by nine societies in the two counties, though individuals not belonging to any of the above bodies may become direct members of the Association. Of the affiliated societies, one only, the Carlisle Scientific Society and Field Naturalists' Club, is devoted to science alone, the remainder, like the Association in general, being concerned with both literature and science. Each affiliated society has the right of recommending one original paper for publication in the Transactions, and such as have more than 150 members may send in two such papers.

The number of papers in the volume before us is not very great. The literary portion includes "Memoirs on the Maryport Camp," "Brampton in 1745," and "Former Social Life in Cumberland and Westmoreland." The scientific section includes "Zoological Record for Cumberland, 1886," by Rev. H. A. Macpherson, M.A., and W. Duckworth; "Our Summer Visitors," by T. Duckworth; and "Ice Work in Edenside," by J. G. Goodchild, F.G.S. Of the nine affiliated societies, three have contributed nothing to the Transactions. This is much to be regretted. In the "Zoological Record" and in "Our Summer Visitors" some interesting facts are placed on record. Thus, from the former memoir we learn that on a recent occasion a dipper (*Cinclus aquaticus*) was observed capturing a small fish in the Calders. "The dipper emerged from the stream, and on reaching shallow water released the captive, which made off at once for deep water. After allowing the fish a start, the dipper darted after it, and recaptured it, subsequently releasing and recapturing it alternately, until tired of play; the fish was then bruised by repeated pecks and swallowed head foremost. The deplorable mortality in May, 1886, among small birds, especially swallows, is duly noticed. In one case twenty swallows were found dead on the window-ledge of a small clay cottage; in another the exhausted birds invaded a smithy in search of warmth and food.

The authors have reason to believe that in the Carlisle district the white wagtail (*Motacilla alba*) occasionally interbreeds with the pied wagtail (*Motacilla lugubris*).

It is suggested by Mr. Eagle Clarke that many birds in their autumnal migrations pass from Scotland to North Wales by way of the Isle of Man, *avoiding* the coasts of Cumberland and Lancashire.

The persecution to which that harmless and useful bird the night-jar is subject is no less rampant in Cumberland than in other parts of the kingdom. An incident here given confirms Waterton's opinion that the average gamekeeper is a ruthless assassin and, as far as in him lies, extirpator of every bird not in the game-list.

The author of "Ice Work" concludes that a period of 20,000 years since the close of the Glacial Epoch is amply sufficient to account for all the denudation that can be demonstrated to have been accomplished in post-glacial times.

It is worthy to be noted that concerning the alternate glaciation of the two hemispheres geologists are not absolutely unanimous. Mr. J. G. Goodchild considers that in the north the glacial period is now waning, while in the Antarctic region the glacial period has not long ago set in. Others contend that the northern hemisphere reached its greatest warmth some five centuries ago, and is now on its way back to a glacial condition.

Management of Accumulators. By Sir David Salomons, Bart. Fourth edition, revised and enlarged. London: Whittaker and Co.

We gave unqualified praise to this book in our recent notice of the third edition, both because it contained a great deal of useful information upon a subject too little understood even by many electrical engineers, and because it filled a want, as has been amply proved by its rapid sale. We hoped in the present edition, which is said to have been revised as well as enlarged, to find that the serious faults not only in literary style, but in grammar, would have been corrected. Faults, such as those which meet the eye even on the first page, may be pardoned in the early attempt of one who is wrapped up with the importance of the information he has to convey; but are inexcusable in a fourth edition which "has undergone a thorough revision."

We hope to find improvements in future editions, and in the meantime, despite one or two technical statements of doubtful accuracy, it is on the whole an extremely useful handbook.

My Microscope and Some Objects from my Cabinet. By A Quekett Club Man. London: Roper and Drowley.

From the advertising pages at the end of this book we learn that the "Quekett Club Man" is also the author of a work entitled "My Telescope." It will doubtless surprise our readers to find one and the same man fully familiar with two instruments used in such very different sciences, and being at once a microscopist and a "telescopist."

The Quekett Club Man has only eighty small pages to devote to his subject, and is hence obliged to consult brevity. But we fear that a reader who is "under the cloud of innocence on the subject," will find some little difficulty in understanding the first section, entitled "The Instrument." He will be apt to ask, what is this or the other accessory apparatus, and how is it to be used?

The author's caution against buying a microscope without the advice of an expert, and against low-priced instruments, is very sound. The number of bad microscopes now made is something frightful, and frightful, too, is the bewilderment into which they may lead the tyro.

In the chapter on "Diatoms" the "Quekett Club Man" mentions an "irreverent friend" who when shown such an object exclaimed, "What a waste of beautiful work! for the chances must have been a million to one that no one ever saw it."

But such thought is even more unscientific than irreverent, since it involves the old delusive notion that everything exists for man's use and gratification.

The following is a somewhat curious sentence: "The great guns of the microscopical world differ on the question as the poles from the antipodes." We scarcely can agree with the author in the following passage; speaking of a geometrical spider (*Epeira*) he says, "Suddenly behind him a fly gets entangled; as by electricity, the news is conveyed to him, and with the quickness of thought he turns, darts, and seizes the intruder." Now, unless the prey ensnared is comparatively large, the spider has to apply her feet in succession to different radii of the web, that she may judge by the vibrations in what direction to rush. For despite their eight eyes, the sight of spiders is not remarkably good.

The little work before us will doubtless call increased attention to the value of the microscope as an instrument of research, and on this probable result the author is to be congratulated. But we do not hope that it may serve to augment the number of that very common class of microscopists who do not intend to devote themselves to any science, but prepare and accumulate a collection of whatever is small enough to be gazed upon through a microscope.

ROMAN BATH AND RECENT DISCOVERIES.—I.

When the British Association visited Bath in 1864 all that was known of the Roman baths and of other remains of the Roman city was to be gathered from Camden and from Leland, with such accompanying information as could be found in Horsley's "Britannia Romana" and in the works of Dr. Mugrave, Dr. Guidott, Dr. Sutherland, and Dr. Lucas.

Warner had recorded all that he could collect in his "History of Bath," and more fully in his illustrations of Roman antiquities discovered at Bath, published in 1797. The remains preserved in the Literary and Scientific Institution had been carefully catalogued by Mr. Lonsdale, with the assistance of Mr. Hunter, who resided in Bath for some years. From time to time, as the foundations of new buildings were cleared and the level of the ancient city was reached, fine tesselated pavements were laid bare, and have been preserved *in situ*. These can now be seen under the Mineral Water Hospital, the Blue-coat School, and the United or Casualty Hospital.

Mr. Lysons, in the second part of his "Reliquiæ Romanæ," has illustrated and described the remains found under the present Pump-room when that building was erected, and has given conjectural restorations from fragments of sculpture then discovered.

Carter had also delineated some of the antiquities.

The beautiful bronze head found in digging a sewer in Stall Street, in 1727, had attracted much attention, and was for some time preserved in the Guildhall, but has since been removed to the Literary and Scientific Institution. It is generally supposed to be that of a statue dedicated to Minerva, who is known from Solinus to have been the goddess presiding over the hot springs. To this writer we are indebted for an account of the city in Roman times; for his description can apply to none other in Britain, and his account has been quite confirmed by past and recent discoveries.

Discoveries made in 1755 had brought to light detached portions of the grand system of baths underneath the houses of the present city, and from observations then made conjectural restorations had been given of buildings which must have reached from the present abbey church to the Pump-room and beyond it. In the year that the British Association met there (1864) was published an account of the Roman antiquities up to that date. This work, entitled "Aquæ Solis, or Notices of Roman Bath," is now out of print.

To understand the Roman city some idea should be given of the ancient walls and the gates as well as roads that entered it. The walls seem to have conformed to the nature of the ground and the bend of the river Avon, so as to include the hot springs. The structure of the mediæval walls appears to have rested upon the Roman. This has lately been found to be the case at Chester, and was undoubtedly the case at Gloucester and at Colchester. The recent examination of the walls at Chester has thrown light upon this subject. (See last number of the Journal of the Archæological Association.)

The earliest map of Bath is probably that of Dr. Jones (1568 or 1588), which is contained among the Sloane MSS. (2596), from which we see the main streets meeting nearly at right angles, answering to the four gates. The circuit of the walls is a little above one mile, or a third less than the more important Roman-British cities. The line of the walls, often nearly destroyed, and greatly damaged in mediæval times, can still be traced. Within the walls the *forum* seems to have occupied a central space, and to have extended from the present abbey church to the Grand Pump-room Hotel. Under the last-named building Roman remains were found, and a concrete flooring, at a depth of not less than sixteen feet. The arrangement of the baths seems to have occupied the whole of the south front of the forum. Under the present Pump-room were found the remains of the sculptured pediment preserved in the vestibule of the Literary and Scientific Institution. Immediately opposite the Pump-room formerly stood Stall's church, which is recorded to have embodied in its structure the remains of a Roman temple. The position of the Roman forum can, therefore, be said to have occupied the present site of the abbey churchyard, the space from north to south being wider than at present. The position was not quite central, but extended more towards the east and south gates.

The present Pump-room, under which the sculptured pediment referred to above was found, marks the *entrance* to the Roman baths, but the frontage stood farther back, more to the north. The portico was probably composed of six columns in front, with a frontage of 35 feet, a height about the same, and a projection of not less than 20 feet. (See " Guide to the Roman Baths," p. 7).

In 1878 the reservoir which supplied these baths was discovered and laid open, also the Roman culvert, which has been reconstructed in places, and is now used as a drain for the waste water from the thermal springs. The hot springs were found to have been enclosed in an irregular octagon, 50 feet in length from east to west, and 40 feet wide. This is situated below the King's Bath, and forms the great well of the springs. A concrete floor has been laid over it, and the space above is still used for modern baths. The Roman reservoir is built of large masonry, 3 feet thick by 6 or 7 feet in length, and was found to be cased on the inside with lead.

In clearing out this reservoir leaden pipes and shafts of columns were found, also blocks of stone variously moulded. From this tank the great Roman bath, not far distant, and the circular bath (only recently discovered) were supplied with hot water.

The hall of the great bath, now completely opened to the view, encloses an area of 111 feet in length by 68 feet in width, but the circular bath and the hall in which it is situated have been arched over, as the space above was required for modern use. The Roman masonry, however, is carefully preserved, and distinctly marked off from the more recent additions.

It is much to be wished that the whole could have been kept open, and preserved under a shed constructed of glass with iron supports; but the space required for increased bathing accommodation rendered the sacrifice too costly. If this could have been done Bath would then have possessed the finest collection of Roman remains, illustrative of Roman manners, and far surpassing any that have been found in Europe west of the Alps. Much controversy has arisen about the preservation of these remains, but we may feel assured that the city authorities will never neglect that which places this city far above other Roman-British cities, as none hitherto explored can show such perfect remains, constructed on so grand a scale. The stone of which the baths are built was taken from the quarries, still in use, at Combedown. The blocks used in the construction of the large bath are many of them 10 feet long, and are put together with the greatest care, the masonry being of the highest order. Six steps lead into the water from the platform which surrounds the bath, and this has three recesses on each side, which contained seats and accommodation for bathers. Large fragments of roofing, composed of wedged-shaped, hollow tiles, lie in the great bath and upon the platforms, showing the construction of the arched roofs that covered the buildings; and also fragments of sculpture which had adorned the edifice. The character of the masonry and the small remnants that remain of the ornamental work carry with them indications that these baths were constructed in the earliest portion of the Roman occupation of the island.

The work about the baths can be shown to be of successive dates, but the structure of the earliest and best portions may be carried back to the reigns of Vespasian and Titus, and may have been begun even earlier. Frontinus, who was Governor of Britain before Agricola, was known for his great work on aqueducts, which he constructed in Rome for supplying the city with water. It is not at all improbable that he, when Governor in Britain, may have recognised the value of the hot springs of Aquæ Solis, and given directions for their utilization. The structure of these fine works may have been planned by him, and carried out by his successors. We may therefore place them as early as the time of Vespasian, and not later than that of Hadrian.

Much more remains still to be discovered, as a fine hypocaust has been found near to the recently uncovered circular bath, and also smaller baths, apparently for private use. There can be but little doubt that these baths had originally all the accompaniments common to such structures, as may be seen in Rome, at Pompeii, and in the recently discovered Roman town at Herbord, in France, eighteen miles from Poitiers, and within a short distance of the small town of Sanxay. Here may be studied the complete arrangements of a Roman watering-place, as we have the baths, the temple, and the bathing establishment, all contiguous. We cannot but congratulate the city of Bath upon the possession of the remains recently laid open, indicating, as they do, the prosperity and former opulence of the city. It may have received marks of imperial favour, and been honoured at times by the residence of illustrious Romans.

(*To be continued.*)

BRITISH MEDICAL ASSOCIATION IN GLASGOW.

ABSTRACT OF AN ADDRESS BY SIR H. B. MACLEOD, M.D., "ON THE PROGRESS OF SURGERY DURING THE LAST HALF CENTURY."

SINCE 1837 all the collateral sciences on which medicine so largely leans have been in a great measure reconstructed, and the very foundations on which our art is built have been in no small measure relaid. In 1837 the doctrines of Broussais, which had been accepted with the enthusiasm of a revelation, and had deeply imbued the surgical as well as the medical practice of the day, had spent their force. Hahnemann and Brown, Gall and Spurzheim had come and gone with their disturbing influence, and men turned wearily from the discussion of mere doctrines and the dogmas of authority to a careful study, aided by experiment, of *facts*. Many remarkable discoveries in mechanical science, especially that of the achromatic microscope (1824 and subsequent years), the spectroscope, and the applications of electricity, powerfully contributed to the rapid progress of biology, morbid anatomy, pathology, and chemistry. In 1838 Henle and Mandl made known what their countrymen had then accomplished, and the members of the German school have ever since been the most enthusiastic and competent workers on these subjects.

The most distinguishing features of the period under review (1837 to 1887) have undoubtedly been anæsthetics and antiseptics. They are both "epoch-making" discoveries. Each has done almost as much for surgery as the discovery of hæmostatics, and when combined may, I think, be said to excel even steam and electricity in their gracious benefits to mankind. Though from the earliest times men sought for the means of allaying pain during operation, and numerous imperfect methods (as that of Dr. James Moore of this city, the younger brother of Sir John Moore, by compressing the nerves) had been tried to effect it, yet the statement of Velpeau, published in 1839, may be taken as expressing the opinion held seventeen years before the great discovery: "All research for an agent to destroy pain in operations is a mere chimera, and unworthy of further consideration." Suddenly, however, the riddle was solved by one who, recalling the experiments of Humphry Davy with nitrous oxide and sulphuric ether, dimly perceived the use they might be put to in surgery. Whatever credit in this matter may belong to the unfortunate Horace Wells, it was really Mr. Morton who worked out the practical application of ether, and in the theatre of the Boston Hospital may still be seen the sponge by which it was administered on that memorable October morning in 1846. After the abortive trial of various other agents chloroform was brought into use by Sir James Simpson, within a year of the time when attention was directed to the subject. This, the most valuable of anæsthetics, was discovered by Soubeiran in 1831, and had been shown to be a powerful anæsthetic by Flourens some years afterwards.

Local anæsthesia in its present form is also a conquest of the last half century, and though many agents possess this power, and some of them, like cocaine, are specially valuable for particular purposes, the finely divided ether spray introduced by Dr. Richardson (a distinguished student of the Glasgow school) in 1866, is more efficient and easy of application than any other for practical purposes. I need hardly say that anæsthesia has changed the whole face of surgery. "The lion heart" is no longer the requisite of a surgeon. Finesse and manipulative skill now take the place of force. Innumerable operations are rendered possible which could not before be attempted, and the surgeon has benefited almost as much as his patient.

There is no more interesting study in surgical history than the development of our present practice as regards wounds, from the blind groping of the surgeons of last century, to discover the secret enemy which baffled their best efforts, to the brilliant dawn which we have been permitted to see. The proper use and best form of deep and superficial stitches and dressings are also now well established, and the reign of dirty sponges and foul instruments and hands has passed away for ever. Modern pathology has put an end to the keen controversy which for 150 years bulked largely on surgical attention regarding purulent infection. The direct absorption doctrine of Boerhaave held the field to the middle of the eighteenth century, and was followed by the hydraulic, the metastatic, the spontaneous generation, the phlebitic (in various forms), and other theories, till Virchow (1846-56) threw a new light on the subject by his researches on thrombosis and embolism, after which the investigations on sepsin, blood ferment, and micro-organisms explained what was still unintelligible.

As a result of the misfortunes of the Crimean war, and to a less extent perhaps from the alarm caused by the cholera epidemic of 1852, the construction and organisation of hospitals and other public institutions have received more attention during the last twenty-five years than during the previous seventy-five which had elapsed since Tenon wrote.

Of the advances in doctrine and practice since 1837 much might be said. Not only has general anatomy been greatly advanced, but pathological anatomy has been created, while physiology has become a new and practical science under the influence of experiment. Chemistry has also been reconstructed. Experimental and microscopic research have elucidated in a remarkable manner the whole phenomena of inflammation and the febrile condition. The blood and its vessels, the reaction of the tissues involved, the part played by the nerves, the nature of the exudations, with their destinations and changes, as well as the growth, degeneration, and metamorphosis of structures, have all been laboriously studied by the aid of the microscope and by chemical processes. It was within the years 1838-39 that the cellular pathology was born. It took the scientific world by storm. Though no doubt it can be plausibly asserted that both John Hunter and Raspail dimly foreshadowed it, certain it is that Schleiden, Schwann, and Müller laid its true foundations, while Virchow and his pupils worked it out. Constant advance continues to be made by the use of new and improved methods of rerearch, so that our knowledge of the ultimate elements of the tissues is daily increasing. An immense scientific activity followed the year 1840. Within a few years almost all the tissues and organs and the secretions of the body, both in their normal and altered conditions, were laboriously studied, and the phenomena of the respiratory, digestive, and nervous systems, as well as the great subject of embryology, which throws so much light on congenital deformities, were largely investigated, and by none with more ability than by my late colleague, Professor Allen Thomson.

Within the last half century, and especially since the discovery of anæsthetics, all surgical operations have been greatly improved, and many new ones have come into use. The operator being no longer hurried, or his feelings harassed by the sufferings of his patient, and happily possessing better control of the result, is left free to plan and conduct his operation without embarrassment. In this progress of operative surgery amputation has largely shared. The improved methods of arresting bleeding, both during and after operation, have essentially contributed to its perfection. The indiarubber (1873), and more lately the spiral wire tourniquets of Esmarch, and the "bloodless" system, though now no longer carried out as at first practised, which these appliances rendered so easy of application, have been of the most eminent service in amputations and excisions, as well as in all operations on bones and deep structures. The old method of closing arteries by torsion—used by Galen and Avicenna, but more especially studied by Amussat in 1829—was much in vogue a few years ago; but it and acupressure—described by Heister and many others—which Sir James Simpson (1859) supposed would supersede all other hæmostatic methods, have been replaced by the antiseptic ligatures now in use. The modern practice of using water at a temperature from 120 degs. to 160 degs. F. for the arrest of oozing is in my experience admirable.

Excision of joints and resection of shafts of bone, now of daily performance, were by no means common at the time of the Queen's accession.

Within the half century aneurysm has been much studied in all its aspects, and its treatment has been simplified, though the methods of dealing with it have been greatly multiplied. It has been shown to be curable by the rapid coagulation of the contained blood, and not alone by the lamination of fibrin and contraction of the sac, a fact long denied; and this has suggested some of the most recent methods of dealing with it.

Pathological research has done much within the half century as to the large and important subject of new growths. Much, however, remains to be done. Since Muller, in 1838, brought neoplasms within the pale of the cellular pathology, and Virchow added so much to our knowledge, innumerable workers, aided by many new or improved mechanical contrivances and beautiful methods of preparing sections for microscopic examination, have turned their attention to the subject. A simpler classification and arrangement have resulted, with a better understanding of the clinical progress and results of tumours.

In no department of surgery has so much that is new and notable been achieved as in injuries and affections of the head. Much has been done, both by experiment and clinical observation, in the localisation of the phenomena of motion and sensation, and though much remains to be done which can only be cleared up by long and accurate research, still results have been garnered sufficient to give a confident hope that before long a complete and reliable map of the brain will be at the service of the practitioner. The brain areas which supply the face, the tongue, the limbs, and the muscles of respiration have been clearly defined by British and foreign physiologists. Clinical observations on man have supplemented experiments on animals, and already fruitful practical results have been obtained, so that the trephine has again come into use, but on far different grounds from those theoretical ones which guided its application at the beginning of the century. The first operation for the removal of a cerebral growth planned on the modern physiology was performed so recently as 1885. The new American perforator is much more precise and speedy than the old trephine, especially when worked by the "surgical engine," which has been invented for driving saws and perforators.

The galvano-cautery was first used in England by Professor Marshall in 1850, but to Middeldorpff of Breslau we chiefly owe its sytematic use in a large variety of surgical cases, where its rapid action, manageability, and the very light which it emits can be utilised. It can never, however, replace the knife for the mere division of structures, nor the actual cautery for counter-irritation in chronic inflammation. Electricity has made great advances as a practical agent since 1872. In experimental physiology, and as a diagnostic and curative agent, Erb's recent work will do much to promote its more precise use. To Duchenne (1855) must, however, belong the credit of having first recognised its importance; and it is probable that, with the aid of improved batteries and the modern "accumulator," better work will be done in the near future. Among the many ingenious and useful instruments for clinical research and demonstration, the ophthalmoscope stands pre-eminent. Foreshadowed by Babbage in 1847, its present important position in ophthalmic surgery is due to Von Helmholtz, who took it up in 1851, and with Ruete perfected it as a clinical instrument. To it we owe a knowledge of the pathology of the deeper structures of the eye, and the suggestion of various operations which have proved of the greatest service. The introduction of cocaine, since 1884, as a local anæsthetic, has added largely to the progress of ophthalmic surgery. The otoscope, the laryngoscope, and other similar instruments naturally followed on the construction of the opthalmoscope, and have been fruitful of good in their respective departments. The sphygmograph, made practically useful by Marey in 1860, realising the idea of Hales (1748) and of Herisson's sphygmometre, has largely aided the diagnosis of many conditions of the circulatory system and by its pictorial tracings secures permanent records of their variations. The sphygmophone, which professes to render the arterial sounds audible, is still of no practical use. The endoscope, which was much improved by Désormeaux, after 1853, has never attained a practical position, from the difficulty of using it, and the limited field to which it can be applied. Recently, however, Leiter, by using the smallest Edison lamp, and improving the construction, portability, and cost, has provided an endoscope which may possibly promote its employment. The thermometer, first used in medicine by Boerhaave and his pupil, De Haen, has become one of the most important clinical guides in consequence of the researches of Traube (1850), Wunderlich, and Zimmermann.

The beautiful discovery of skin-grafting by Reverdin, in 1869, provides us with a valuable resource in many difficult cases of delayed repair and deformity. The permanence of such grafts is not, however, as yet fully assured. The transplantation of periosteum, muscle, bone, nerve, and even eye tissues, has also been achieved of late years under the magic shield of aseptic surgery. Hydrophobia promises to be deprived of its terrors. Extensive burns are no longer dangerous when kept free from pollution, as the intestinal lesions which Curling drew attention to (1842) are now known to be due to septic poisoning. Nerves are stretched, with or without previous exposure, to the relief of many complaints;

nay more, divided nerves and tendons also are successfully united by suture. Thermal, chemical, and sea baths have their appropriate domain assigned them. Cod-liver oil and many concentrated foods, easy of assimilation and rendered more so by the addition of digestives, have come into use. Patients are no longer reduced by diet, purging, and bleeding, or blindly over-stimulated with alcohol, but a a dietary founded upon their requirements is prescribed before and after operation. The therapeutic advantages of change of scene and climate are fully taken advantage of, as the means of locomotion have been improved and cheapened. Of the innumerable new drugs with which chemistry has endowed us many highly valuable ones have come into general use, while greater concentration and more elegance have been employed in their manufacture. The surgical instrument maker has, by his ingenuity and skill, simplified and improved the surgical armamentarium, and for every purpose has supplemented our manual dexterity.

I have thus, in the limited time at my disposal, and to the best of my power, noted the changes and improvements in surgical theory and practice which have emerged during the last half century. The task I set myself has proved longer and more difficult than I anticipated, as the harvest has been extraordinarily abundant. I am conscious of having omitted much from want of time and knowledge; but I trust I have succeeded in showing that in every branch of the surgical art there has been a wondrous advance, and that the profession to which we belong marches in the very van of the great army, recruited in all climes, whose aim it is to enlarge human knowledge. Such a retrospect as I have attempted makes us reverence a profession whose hope and ambition it has ever been to abate suffering without distinction of race or creed. We see how an abiding and ever-increasing purpose has run through these long ages, and that while we now rejoice at being no longer bound by the authority and crude doctrines which shackled our forefathers, we can yet honour the traditions of the past, and appreciate the efforts of that great host of devoted men who have by their unselfish labours built up the famous temple of our art.

Visitors to Museums. — The Rev. H. H. Higgins divides such visitors into three classes: students, observers, and loungers. The students, who form, perhaps, 2 per cent. of the total, are those who go with a definite purpose, seeking the solutions of questions which have occurred to them during reading or reflection. The observers, who may range from 50 to 78 per cent., have no conscious definite object, but fix their attention with more or less intelligence on the specimens displayed, and generally carry some knowledge away with them. The loungers go to spend time, especially as the museums are places which "one must have seen." They are most numerous at South Kensington.

The Production of Iron.—According to *Dingler's Polytech. Journal*, the mean annual production of iron in the years 1880-1884, inclusive, has been, in Britain 4,275 kilos; in the United States, 4,674; in Belgium, 532; in Germany, 3,181; and in France 2,164 kilos. During these years the British production has been approximately stationary, that of Germany has increased nearly 30 per cent., and that of France by about 10 per cent. In Britain the maximum production was in 1883, but in America and France in 1882.

Abstracts of Papers, Lectures, etc.

JUNIOR ENGINEERING SOCIETY.

On the 20th ult. a number of members of this Society visited the Hampton and Kew Bridge stations of the Grand Junction Water Works, through the kindness of Mr. Fraser, engineer to the works. At the Hampton station an explanation was given of the two systems in operation there, viz., one for supplying London direct with 800,000 to 1 million gallons of filtered water hourly, and the other for passing 17 million gallons of unfiltered water a day on to Kew. The engines, pumps, boilers, etc., having been seen, the party proceeded outside to the reservoirs and filter beds, one of which latter being in course of reconstruction, the different layers of filtering material and culverts were fortunately all exposed to view. The Kew Bridge station is arranged to filter the water received from Hampton, and also to filter about 600,000 gallons per hour, drawn direct from the river. The pumps raise both supplies to a head of 150 feet. The filter beds and reservoirs at Kew are on a larger scale than those at Hampton, and the manager gave an interesting explanation of the different operations involved in charging, emptying, cleaning, and maintaining them. The engines, pumps, etc., here also proved of considerable interest.

A visit to the works of the Southwark and City of London Subway took place on the 27th ult., Mr. Greathead, Engineer to the Company, having kindly granted the necessary permission. The party met at the Harleyford Street workings, Kennington Park, and after descending the shaft where the passenger lifts will be fitted, walked down one of the tunnels, which are 10 feet in diameter, to the working face. Here the resident engineer fully explained the ingenious arrangements devised for driving the tunnel; setting the segments of the cast-iron rings composing it; and for filling with grouting of blue lias lime the small annular space left between the tunnel cutting and lining. This last highly important detail of the construction is successfully effected by forcing the mixture by atmospheric pressure through the holes left for the purpose in each segment. A vote of thanks was accorded to Mr. Greathead and the resident engineer at the conclusion of the visit.

THE CAMBRIAN ARCHÆOLOGICAL ASSOCIATION.

The forty-third annual congress of the Welsh Archæological Association was opened by the Bishop of Llandaff, the president-elect, on the 13th inst., at the Town Hall, Cowbridge, who expressed the hope that the visit would furnish them with ample materials for archæological study. Among the various objects of antiquity which were to be found within easy distance of their present place of meeting there were some which would serve to call their thoughts back to the time when the Druids worshipped with their intricate and it was feared too often cruel system in temples which consisted of nothing more than a collection of colossal stones untouched by the hammer or chisel of the workman, while at other spots would be found remains more or less perfect of the grand old abbey or more modest parish church, in which the varying styles of Christian architecture followed each other in succession, each in its own peculiar gracefulness and beauty. Referring to the most ancient or British period, perhaps the most interesting monument within the verge of their present resources was the vast cromlech near Duffryn, in the parish of St. Nicholas. It was, he believed, one of the largest, if not the largest, of the Druidical remains to be found in the kingdom. Other remains of the same period, devoted to the same object but of smaller dimensions, existed in the immediate neighbourhood. But the remains of the British period still in existence were not confined to those of structures devoted to religious purposes. Encampments of greater or less extent, scattered at intervals over large portions of the land of Morgan, served to remind them that their forefathers were not so wholly engrossed in peaceful pursuits as to neglect to guard themselves against the attacks of their enemies. Passing from the British period to the Roman occupation, which commenced about the middle of the first century of the Christian era by the victory of the Roman general over Caractacus, he remarked that doubtless at the moment the conquest of the British and the captivity of their brave leader were regarded as a terrible national disaster; but by God's providence that event was productive of the holiest blessing which our land had ever inherited in the first planting of Christianity within its borders, and the seed out of which first sprang the ancient British Church, which from that day to this, notwithstanding many trials, had been continued in unbroken continuity during the past eighteen centuries. But apart from the interest which attached to the introduction of Christianity into Britain, regarded in its religious aspect, in some at least of its results it had a peculiar interest for the archæologist, since there were few objects which he investigated with greater pleasure and satisfaction than the remains of those ancient Christian temples which were raised by our pious forefathers to God's honour and glory. His lordship proceeded to notice some of these remains which were more immediately connected with the advent of the Romans, and then passed on to remark that the period that followed the departure of the Romans had few objects of interest for the archæologist. The northern invaders' rule was unlike that of the Romans and provoked a more obstinate and prolonged resistance. The results of this were still to be seen in the remains of the many Norman and English castles which abounded in that and the neighbouring counties of South Wales, and which furnished for the archæologist some of the most interesting objects of research. Many of the parish churches, he added, would be found interesting on account of their peculiar construction and the various styles of architecture; and he particularly referred to the Church of St. Iltyd, or Lantwit-Major. He also alluded to some recent discoveries at Cardiff Castle, and expressed his best wishes for the success of the present Congress.

Mr. E. Laws then read a paper on "The Black Friars of Cardiff."

On Tuesday morning the members started by road for St. Hilary, Old Beaupre, St. Athans, Fonmon, Penmark, Llancarvan, and Llantrithyd. It was a beautiful summer day and the scenic attractions of the country were much enjoyed. One of the first objects of the excursion was Beauper Castle, as it was originally written, which supplies an example of the classic style of architecture engrafted on the Gothic, and where the remains of an ancient Welsh fortress may be traced. The Castle of Fonmon is a large Norman structure, one of the class referred to by the Bishop of Llandaff in his inaugural address, but long since modernised and adapted for present occupation.

In the evening the following papers were read:—On "English and Welsh Law in the Marches;" on "The Norwich Taxation and Diocese of Llandaff," by Archdeacon Thomas; and on "The Manor of Llanblithian," by Mr. J. A. Corbett.

The members on Wednesday visited the ancient village of St. Bride's Major, and afterwards inspected Ewenny Abbey, the residence of the Turberville family, a Benedictine priory, founded early in the twelfth century by William de Londres and his son Maurice. The priory contains some of the finest Norman work in Wales. A meeting was held at Cowbridge Town Hall in the evening, under the presidency of the Bishop of Llandaff, when Mr. Stephen Williams read an interesting paper on "The Recent Excavations at Strata Florida Abbey."

On Thursday an old fortified town was first visited under the guidance of Mr. Thomas Rees, the Mayor, and Mr. Iltyd B. Nicholl, F.S.A. The ruins of St. Quintin's Castle were afterwards inspected, and a visit was paid to Llanmihangel-place and Llantwit-Major, where the ancient monastery was, according to tradition, founded by Garmain (St. Germanus), Bishop of Auxerre, during one of his visits to Britain to counteract the spread of Pelagianism. The village of Marcross and the historic St. Donat's Castle were next visited. In the seventeenth century Archbishop Usher took refuge in the castle, and remained there some months after the collapse of the royal cause at Naseby. The site known as Caer Wrgan, on which the Cardiff Naturalist Society have made some excavations, was examined, and the inscribed crosses of Llantwit-Major were described on the spot by Mr. J. G. Allen, F.S.A. In the evening a paper was read by Mr. Edward Lawson on "St. Fagan's Fight."

WILTSHIRE ARCHÆOLOGICAL SOCIETY.

The annual meeting of the Wiltshire Archæological and Natural History Society opened on Aug. 7th at the Town Hall, Calne. The Rev. Archdeacon Buchanan presided.

The Rev. A. C. Smith (one of the general hon. secretaries) read the annual report, of which the following is an abstract:—The committee recorded steady progress, the number of names on the books being 363, an increase of thirteen during the year. They deplored the death of nine members, including their valued curator, Mr. Henry Cannington. The balance-sheet showed, on Dec. 31st, a balance of £195 13s. 5d., but a large portion of it would soon be absorbed in defraying the cost of publications which the society had in hand. The society had made a divergence in the direction of publishing a large octavo volume of 512 pages on the flowering plants of Wiltshire, for which it had secured the services of the Rev. T. A. Preston. That volume the society hoped to present to members in the course of a few days. The museum and library had received additions by donations of various sorts and from various quarters. In the work of the society afield they had very important matter to communicate, for, in the extreme south of the county, excavations on a large scale had been made this spring by General Pitt-Rivers, and sections of considerable dimensions had been cut, under the immediate direction of that experienced archæologist, in one of the old boundary ditches, known as "Bokerley Dyke."

It had been generally believed by the great majority of Wiltshire archæologists that Bokerley Dyke, together with its fellows, "Grims Dyke," in the south of Salisbury, "Old Dyke," which runs over Salisbury Plain to the north of Heytesbury, and their own "Wansdyke," in the immediate neighbourhood, were—whatever might have been their object and whoever their authors—at any rate of pre-historic date; that, whether they were the work of the early Britons, the Celts, or the Belgæ, they were at all events pre-Roman. But now, in removing a considerable portion of the bank at Bokerley Dyke, and exposing the original surface on which the excavated soil had been placed, General Pitt-Rivers had come upon large quantities of Roman pottery and several hundred Roman coins of a late date. This was evidence which, however unpalatable to some of them, could not be gainsaid, and they might take it as proved that Bokerley Dyke, which Canon James, when writing on the subject, considered to be the oldest of the Wiltshire dykes, and whose date he attributed to some two or three centuries before the Christian era, must henceforth be allowed to be of late Roman, if not of earlier times. They must say all honour to General Pitt-Rivers, who had set at rest for ever the question of date with regard to Bokerley Dyke. In conclusion, the report pointed out that a vast amount of material still remained for the careful examination of the members of the society in all parts of the county. The committee trusted that as the older members dropped off, younger and more active workers would come forward to take their places, because they were well assured that continual and prolonged efforts must be made before they could claim to have in any degree mastered the ancient and natural history of Wiltshire.

In the evening the anniversary dinner of the society took place at the Town Hall, after which a conversazione was held, when papers were read by the Rev. Canon Jackson on "Calne"; and by the Rev. W. C. Piender-leath on "Cherhill Gleanings."

INTERCEPTING TELEGRAMS.—The Austrian War Office is stated to be paying great attention to a matter which is of the greatest importance in the use of the telegraph in the field. It has been ascertained that the telephone is so acute of hearing that before it every secrecy of telegraphing disappears. If, formerly, it was desired to ascertain the secrets of the telegraph wire the latter had to be cut and an apparatus inserted. Now, with the help of the telephone, all telegrams may be read easily, even from a considerable distance. It is only necessary to carry a telegraph wire of moderate length parallel to the original line, and insert in it a telephone, from which the Morse signs may be read off by ear. This would, of course, be very awkward in the case of war telegrams. The question has naturally arisen how this difficulty is to be met. The problem is solved in a surprisingly simple manner by Herr Heinrich Discher, who proposes cross telegraphing for the purpose. He says that if telegrams are sent from opposite directions on the same wire at the same time, the listener at the telephone only hears a medley of confused sounds. In practice the matter may be dealt with in the following manner:—One station sends actual telegrams, the other a despatch previously agreed upon. As long as the operator at the former station sees this despatch coming in, he may make sure that no eavesdropperis able to read the telegram he is sending.—*Times.*

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

FORMATION OF ICE.

I should like to offer for the consideration and criticism of your readers the following idea as to the possible formation of ice. I do not know if it has occurred to any one before, and I may perhaps be saying nothing new. We know that water at ordinary temperatures, say 45° F., will contract if the temperature be lowered to about 39° F. This is to be explained by the molecules of water being separated by interspaces, as shown to exist by the experiment of dissolving a certain amount of powdered sugar in it, without the bulk of water being increased. As soon, however, as 39° is reached, or thereabouts, water begins to expand until it is converted into ice at 32° F.

Now, whenever water freezes, it does not solidify into a mass of accurately fitting crystals, like rhombs of calc-spar, which have no interspaces, but always in "macles" or compound forms, so well seen in a flake of snow; and these necessitate an abundance of interspaces. Although a block of ice *appears* to be perfectly homogeneous, like a block of transparent Iceland spar or rock crystal, yet, as Prof. Tyndall showed many years ago, by transmitting a beam of electric light through it, it immediately revealed its anatomical structure; it is really composed of myriads of "ice-flowers."

Hence my idea or theory is that at 39° F. the molecules of water *begin to arrange themselves into lines always intersecting each other at an angle of* 30°, and as soon as 32° F. is reached, they become revealed to our senses as solid ice.

This arrangement of the molecules into macles necessitates "re-entering" angles and angular interspaces. Consequently, bulk for bulk, a block of ice must be greater than that of the body of water which composed it.

This at the same time accounts for the decrease of the specific gravity, in as much as air must constitute a certain portion of the block of ice.

As pure, transparent glacier ice is nothing but compressed and consolidated *snow* aided by re-gelation, so, I take it, a block of lake ice is of exactly the same construction, though it be *water* directly frozen.

Bismuth is well known to be another substance which imitates ice in expanding when crystallised, and since the crystals of bismuth are also compound, and incapable of "fitting exactly" in the mass, a like interpretation will apply to it.

I should be glad to hear what any physicist or other reader may have to say to the above. GEORGE HENSLOW.

PETALS OF THE WHITE JASMINE.

Taking up a spray of this shrub, covered with blossom, I noticed that some of the flowers had four petals each, some five, and others six. I could see no indication that those with four petals had lost one or more. I therefore take the liberty of asking you or your readers if such variations are common, and, if so, what is supposed to be the cause.

SCRUTINY.

TENNYSON AS AN OBSERVER.

In your number for July 20th (p. 50) you give some instances of an accuracy of observation on the part of Laureate rarely to be met with among poets. However, cases of an opposite kind are not altogether wanting. Thus we read:

"Heavily hangs the broad sunflower
Over its grave in the earth so chilly;
Heavily hangs the hollyhock,
Heavily hangs the tiger lily."

The hanging or drooping of the sunflower, as its seeds are ripening, is a well-known fact. But the hollyhock presents nothing similar.

From the first appearance of the bud to the maturity of the seed, the flower of the hollyhock never hangs or droops, but remains pointing slightly upwards.

Browning, in the verses quoted, is astray in saying: "The bee with *his* comb." Accuracy requires "*her*," since the male bees are not let live through the winter.

AMPHION.

PECULIAR WATER.

In an old book I lately met with an account of a river in Corsica named Restonice, the waters of which are said to blanch every object placed in them. The elder Darwin (Erasmus) states that iron laid in this river for a few days looks as if plated with fine silver. At the same time the water is said to be "perfectly wholesome and clear as crystal." I should be glad if you, or any of your correspondents could tell me if these statements are founded on fact, and if so, what is their explanation? SEPTIMUS.

DYE COLOURS FROM PLANTS AND SHRUBS.

Under this title you give a paragraph (p. 28) on dyes obtained from "very common plants." But it is well to remember that these colours cannot compete either in permanence or in price with those now recognised in our dye-works. The colours obtained from elder-berries, blue-berries, etc., are sadly lacking both in fastness and lustre, and they have, therefore, been almost universally thrown aside.

PATTERN-DYER.

COBRAS.

The enclosed cutting from the *Homeward Mail* may be of interest in reference to your article on Cobras, in the SCIENTIFIC NEWS of the 10th of August. There is certainly a strong impression amongst the natives of Southern India that cobras entertain feelings of revenge against those who injure them, and I well remember on one occasion being told of an incident similar to that related in the paper, when a cobra, which had been attacked but had escaped, returned during the night and bit the man who had assailed it, with fatal results. G. G.

Grindelwald, Switzerland.

"A COBRA'S REVENGE.

"The death of Mr. Andrew Fischer, an employé of the Madras Railway Company, at the Pennar Bridge Works, on the north-west line of the railway, under most distressing circumstances, is reported. He was employed as a driver of bridge engines at the Pennar Works. While he was seated in the verandah of his bungalow he observed two large cobras on the barren plain immediately in front of the house. Arming himself with a stout stick, he proceeded to the spot and encountered the snakes. He succeeded in killing one of them, while the other, which had been slightly wounded, managed to escape. Mr. Fischer hunted about for the runaway, but could not find it. He then returned to his bungalow and rested for some time, as he was off duty. Later in the day he prepared to go to his work, and with that object got out his clothes to dress. He sat on his coat, and was about to put on his shirt when he felt something sting him on the back. He turned round, and to his horror found a snake on the cot behind him, which he is said to have recognised as the cobra he had wounded that morning. He immediately sought medical relief, and all kinds of remedies were applied, but to no effect, and he died in the evening, leaving a widow and an infant child, for whom much sympathy is felt.

"'Kellayan' writes to a Bombay paper, 'It is commonly believed among the Hindoos that no animal is more revengeful than the cobra, and that if an attempt is made to kill it, and it escapes, it never gives itself rest until it has wreaked its vengeance upon its assailant. This conviction is very widely shared by intelligent people. A particular friend of mine, now holding a very important position in Vizianagram, an M.A. and a B.L., used solemnly to tell me that this craving for vengeance on the part of cobras and alligators is not a mere figment of the fancy. Taking for granted that the facts about Mr. Fischer's death are as they are stated to be, will any of your scientific readers explain whether there is any truth in the popular belief that cobras trace at all hazards the whereabouts of their assailants, and do nothing until they have revenged the injury done or intended to be done to them? I am also informed that failing in the object of their attempt, they cease to live.'"

SPARROW HAWK (*ACCIPITER NISUS*) AND KESTREL (*FALCO TINNUNCULUS*).

I am now going to call the attention of those interested in oology to a curious circumstance to which my attention was called by my young friend, Mr. H. Jonas, *i.e.*, that the sparrow hawk and the kestrel lay their eggs in pairs. I do not intend to say that they are exactly alike, but sufficiently so to see that in a full clutch of six eggs there are three pairs; if five eggs only, then two pairs and one odd egg. Since my attention was called to this fact, I have pretty well ascertained that with the sparrow hawk the first pair laid are generally blotched or marked over the large end, the second pair marked at the smaller end, the other spotted or marked more or less all over. With the kestrel the colouring is not blotched, but it varies in intensity. I have some good clutches showing this peculiarity, and I should be glad if any collectors of eggs reading these notes will be good enough to give me any information they can upon this point.

If the recuperative power in birds was not exceedingly great, many of our birds would soon become extinct, as their enemies may be reckoned from the hand of man down to the creeping things of the earth. I will here mention some of the enemies: first of all, the boys, who take the eggs and young for the amusement of breaking the eggs and killing the young birds; then the birds of prey, followed by such birds as the raven, crow, jackdaw, rook, magpie, jay, and perhaps some others; then the foxes, cats, polecats, stoats, weasels, rats, mice, moles, hedgehogs, snakes, and snails. I do not accuse the latter of killing and eating birds, but they get into their nests and crush the eggs. The ordinary agricultural operations, such as cutting hay, ploughing, etc., destroy a vast number of eggs and young, partridges, larks, and corn buntings being the greatest sufferers. But of all their enemies the long-eared owls and the cats are their worst. The domestic cat (?)—save the mark!—when in the fields at night, is, in proportion to its size, as savage and relentless as the largest Bengal tiger. If these domestic pets are not shut up at night during the breeding season, they stray into the fields and make sad havoc with the partridges, and, like the tiger, where they make "a kill" one night they are almost certain to return the following night; they climb trees and take the young from the nests even at a very considerable height from the ground; in fact, a nest is not safe unless it is so placed to be quite inaccessible to the aforesaid domestic beast.

I cannot close these notes without adding a word or two in self-justification for having such a large number of the eggs of the common sparrow in my possession; but had I not preserved them, they would only have been trodden under foot, leaving me nothing to corroborate some of my statements. JOSEPH P. NUNN.

Royston, August 7th, 1888.

FERTILISATION OF FLOWERS.

I shall be glad if your readers can inform me how the flowers of the evening primrose and sweet-scented tobacco are fertilised. I have them growing in my garden, and frequently visit them after dark, when they are fully expanded, but have not noticed insects visiting them. L. H. A.

Chiswick.

UNUSUAL RAINFALL.—The rainfall registered at Grays, Essex, for the twenty-four hours ending 8 a.m., August 2nd, was 5·3 inches, which is a fact probably without a parallel in the meteorological records of this country. This quantity represents 119,859 gallons, or 535½ tons of water per acre.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

MECHANICAL TOY.—A mechanical toy has been patented by Mr. G. Cole. The invention relates to mechanical toys, in which a horizontal wheel, mounted in a suitable frame, is made to rotate by the revolving of an ordinary spinning top, by the former being so placed over the cup in which the top is spun that the spike of the latter is automatically brought in contact with the disc, causing it to revolve.

PROMOTING CIRCULATION.—Means for promoting circulation of blood in a living body has been patented by Mr. E. Black, and consists in enclosing the affected part of the body in a case which is so arranged that the air in it can be partially exhausted. This exhaustion causes the blood to flow to the part under operation; after this has taken place the exhaustion is stopped, and the air is allowed to again enter the case, thus allowing the blood to flow back again in the ordinary course.

SECONDARY BATTERIES.—A secondary battery has been patented by Mr. H. Mower. The support for the active material is in the form of a grid, the bent over ends of which are joined by a portion of the same strip. The spaces between the supporting strip are filled in with the active material, which is mixed with hair to give it coherence. One or more spaces are left open which allow of the plate contracting and expanding more equally without the active material becoming disintegrated and falling therefrom. At the corners are projections to keep the plates in position and shape when in the cells.

INDICATOR.—An indicator for vehicles has been patented by Mr. J. R. Lawrence. This invention is to provide means for indicating to the driver of a vehicle when the vehicle immediately in front is about to stop. This indicator is hinged to one side of the rear of the vehicle in such a way that when out of use it lies flat against the side of the vehicle, and is thus held by a spring. When the vehicle is stopping the brake is applied, which turns the signal out at right angles to the side by a rod pivotted to its inner end, and connected to receiving an endway movement from the brake by means of a bell-crank lever.

MINER'S LAMP.—Mr. J. Ashworth has patented a miner's safety lamp to enable greater control to be had over the wick flame when fire-damp explodes within the lamp. Around the reservoir is placed a perpendicular flanged ring, in which are air holes. The air is thus directed against the flame, and produces better combustion and illuminating power. The top of the oil chamber is covered with a non-conducting substance. The sieve ring carrying the gauze, through which air is admitted to the combustion chamber, is formed with a rectangular groove with holes bored through it, thus increasing the area for the admission of air.

GYMNASTICS.—A gymnastic apparatus has been patented by Mr. R. Parke. This apparatus is for expanding the chest and straightening the shoulders, and consists of a footboard placed on the ground and marked to show the positions in which the feet are to be placed. Two poles are provided having weighted knobs on top, the bottoms being formed to pass into holes in the board, one on each side of the user. The user places the poles in position, standing in the marked position and grasping the poles at any convenient height. By working the arms in an outstretched position towards the back, still holding the holes, the weighted ends throw back the shoulders, and thus expand the chest.

VENT PEG.—An automatic vent peg has been patented by Mr. C. Wayte. This peg is constructed of a hollow metal cone, the diameter and taper being the same as ordinarily, but the cone is shorter and slit downwards from the top in three of four places, so that when the upper part of the cone, which projects beyond the cask after the cone has been driven in, is laid over upon and level with the cask, the slit portions of the cone can be used for extracting the peg by means of pliers; over the smaller end of the cone is placed a piece of elastic tube, having five or six incisions, and made air-tight at its end. A piece of wire long enough to enter the small end of cone is introduced into the elastic tube, thus forming a valve which allows air to enter the cask when required, and prevent the escape of liquid when the cask is rolled. The pressure within the cask causes the incisions to close up round the wire inside the tube.

PREVENTING COLLISIONS.—A method of preventing collisions at sea has been patented by Mr. L. Somzée. The invention consists in transmitting electric currents from one vessel to another by means of the water for actuating signals and also in means actuated by the current which stops the way of the vessel. For operating the signals at a distance powerful sources of electricity are placed on the vessels, communicating with two electrodes placed in the water, so that should another vessel provided with these devices approach, the resistance between the electrodes of the different vessels will be less than that between the electrodes of the same vessel; at this moment a current will pass from one vessel to the other, and the signals will be sounded. The currents passing from vessel to vessel act upon electro-magnets, causing them to set in action mechanical devices for stopping the ship or changing its course.

ELECTRICAL SIGNALS.—An apparatus for transmitting and receiving electrical signals has been patented by Mr. T. A. Garrett. The required current is produced in the transmitting instrument by electro magnetic induction. Pieces of iron have an oscillatory motion imparted to them by means of a spring made to vibrate by being moved out of the ordinary position and then set free. The pieces of iron thus cause stationary iron cores to be magnetised and demagnetised successively in the same direction, and round these cores are wound coils of wire in electrical connection with the line, so that the movements of the pieces of iron cause currents in the line alternately in opposite directions. In the receiving instrument pieces of iron attached to springs are vibrated by currents which pass through the lines, and also through stationary coils of wire. The pieces of iron are inductively magnetised by fixed permanent magnets, and are moved alternately in opposite directions by th currents in the lines and fixed magnets.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

I am glad to see that the subject of glaciation was taken up in Scientific News of August 10th for two reasons—first, because the work done by glaciers in determining the distribution of the materials and the configuration of the present surface of the globe is so great; and, secondly, because the phenomena are on the surface within reach of all, thus affording opportunities of direct study to anybody and everybody, with a minimum of technical preparation. Other departments of geology demand a knowledge of mineralogy and palæontology, besides sections and appliances. Once acquainted with the characteristic vestiges of glaciation, they may be broadly observed from the windows of an express railway train or the deck of a coasting steam-packet, and a collection of their most interesting details may be made by carrying no other appliances than a few sheets of paper and a piece of shoemakers' heel-ball.

In England, north of Finchley, in all parts of Scotland and Ireland, and throughout middle and northern Europe and America, vestiges of ancient glaciers abound.

I had the good fortune to be started early in the practical study of the subject by attending the natural history course of Professor Jamieson in the University of Edinburgh in 1841.

He was then a very old man, the last of the Wernerian school, and very conservative; nevertheless he took up this subject with exceptional enthusiasm, although it was then an innovation. In the following summer I spent a day with Agassiz in his "Hotel des Neufchatelois," a wooden shed built on a great boulder that was floating on the Aar glacier. Here he spent his summer holidays in company with a jovial band of students, and collected the greater part of the material of his classic treatise, "Etudes sur les Glaciers," which was published at Neufchatel in 1840, and supplied Jamieson with the material of his lectures in 1841.

In order to obtain sound ideas concerning glaciation, we must first understand clearly what a glacier really is. It is not sufficient to know that it is "a sea of ice;" we must understand the difference between a true glacier and a mere accumulation of compressed snow, and the conditions upon which the formation of true glaciers depend.

We know what becomes of the redundant rain which falls on the tops and sides of hill and mountains that do not reach the snow line. It runs down their slopes in rills and torrents, forming a river in the valley below, which gathers as it flows more and more of such contributions, and finally pours them all into the sea. Broadly speaking, every valley is, at its lowest part, the bed of a river, or of a lake which is simply an outspread river.

But when we rise above the snow-line we come upon a region of solid precipitation, where the water that falls from the clouds is solid crystallised water, is snow; the height of the snow-line being that at which the annual thawing work just balances the total snow-fall of the year. Above this the total snow-fall of each year exceeds each year's thawing. Therefore, above this, there must be continual accumulation.

What becomes of such accumulation?

A full reply to this question tells the whole story of the origin, distribution, and movement of glaciers, as well as of icebergs and avalanches. I will only attempt a reply in condensed summary.

It is evident that if we had a mountain shaped as a symmetrical cone, with its apex far above the snow-line, the accumulation of snow would be piled up until the slope of its sides exceeded that of the angle of repose for such material, and then it would slide down in the form of avalanches.

The same would occur on a long symmetrical unbroken ridge of mountain. But such unbroken symmetry, even if it existed at first, would be destroyed by these avalanches. They would furrow the slopes in the course of their downsliding.

As a matter of existing fact all ordinary mountains are thus furrowed, and usually very deeply. It is evident that such furrows must determine the course of overflow of the accumulating snow. It is also a matter of existing fact that all such furrows or steep lateral valleys running downwards from great super-snow-line regions or *nevé* (as they are named in Switzerland) are either the beds of glaciers, or dangerous regions visited occasionally by avalanches and avoided accordingly.

Why should one such valley be an avalanche track, and another be occupied by a glacier?

This is a question that is rarely asked or answered, although instances abound of such discrepant valleys lying side by side, and both communicating with the same *nevé*. Thoughtful observation of such discrepancies presents a solution of the problem.

The avalanche valleys widen downwards, those which are filled with glacier ice are narrower below. In a few rare cases a dam or barrier of rock does the work of general narrowing.

The effect of such narrowing of a trough or valley outlet of the snow is easily understood. An avalanche falling down a widening furrow or valley is outspread as it descends, and thereby exposes a large surface to the summer sun; that falling into a narrowing furrow lodges and accumulates in a thick heap below, which may or may not, according to its quantity, be able to resist the summer thawing. If not, it disappears in the autumn, to be replaced next year by a similar evanescent accumulation.

If, however, the quantity is greater than the summer sun can thaw, more or less remains; to this is added the next year's accumulation, and so on until the valley is filled, and its contents become continuous with the *nevé* above. Then a true glacier is completed, which thereafter flows downwards in a continuous stream of apparently solid, but actually semi-fluid or viscous, ice, displaying in its course a series of most interesting phenomena due to the exposure of a large mass of ice that has descended far below the snow line, and is consequently in a state of continuous thaw during the summer days, and is continuously replenished by silent and invisible downflow from above.

My attention was first directed to the birth-history of glaciers in the course of a walk up the Romsdal, by observing that in nearly all the breaks and hollows of the Troltinderne there were patches of snow, some of them so low as almost to touch the oat-fields. I was puzzled by their position, only a few hundred feet above the sea in the latter part of summer, and with a nearly south aspect, but presently I observed that some of the multitude of distant cascades were temporary; further observation showed that they were not waterfalls as I first supposed, but snowfalls, that suddenly ceased, and were followed by a low thunderous rumble that settled the question of their composition. Below all these were patches or pockets of snow that only required a sufficient supply from above to become full-grown glaciers, and from which actual glaciers will ultimately become evolved, if the present conditions remain long enough, for these small avalanches have visibly rasped and smoothed and deepened the gully down which they fall, and are thereby continually deepening and narrowing it, while at the same time enlarging the upper outlet by their aid to ordinary frost and thaw weathering.

Another lesson may here be learned, viz., that a series of avalanches may do the work of smoothing, and grooving, and striation, and moraine heaping, usually ascribed without discrimination—even by our best geologists—to glaciers.

I described these in "Through Norway with a Knapsack," chapter x. In Tönsberg's "Illustrated Handbook," published sixteen years later, is a picture of the Troltinderne, showing some of the low snow patches and a large outspreading avalanche talus.

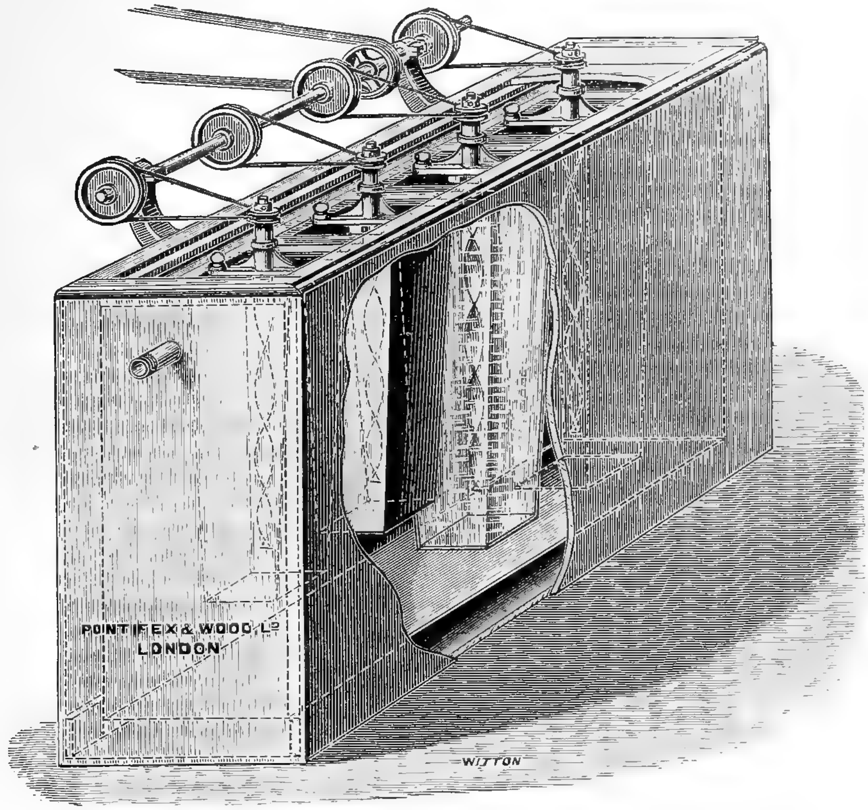
ICE-MAKING MACHINE.

REFRIGERATING machines are now very largely used for preserving meat and other articles of food, for cooling or regulating the temperature of air or water, for the production of ice, and for many other industrial purposes. In the steamships which convey meat from Australia, New Zealand, and other countries, the refrigerators are nearly always kept at a low temperature by means of air pumps, the cold being produced by the expansion of the air previously compressed. Ammonia and ether are also used, as they vapourise under the ordinary atmospheric pressure at a low temperature, and in the process of vapourising a large amount of heat is rendered latent, and thus cold is produced. Ether is, however, more troublesome to deal with, and its use is attended with greater expense, so that ammonia is more generally adopted. There are machines in which ammonia gas is compressed mechanically into the liquid state, and this liquid ammonia is afterwards vapourised so as to produce a low temperature. Another system, much used by brewers and others, is to obtain the required anhydrous liquid ammonia from the ammoniacal liquor of commerce, by the application of heat and subsequent condensation.

It is on this principle that the well-known refrigerating machine made by Messrs. Pontifex and Wood is worked. In a strong horizontal cylinder or generator a charge of the ammoniacal liquor of commerce is placed. In this cylinder there is a coil of piping through which steam is passed, and the ammonia is driven off by the heat of the steam. The ammonia then passes through a separator, in which any vapour of water which rises with it is condensed and returned to the generator. From the separator the ammonia gas is conveyed to a condenser, consisting of a cylinder containing a coil of piping through which there is a circulation of cold water. In this condenser the ammonia is condensed into the liquid form, and this liquid ammonia is then passed into another cylinder, called a cooler. When it enters the cooler the liquid ammonia has a temperature of 70° to 80° F., and it is then allowed to expand into the gaseous form. In doing so its sensible heat is rendered latent, and its temperature is usually reduced to about 10° or 20° F., say 22 to 12 degrees below freezing. In the cooler there is a coil of piping, through which water or brine is circulated, and the expanding ammonia gas cools this water or brine down to any required temperature. When the ammonia has expanded, it has done all the work of cooling which it is capable of, and it is then collected and again passed into the first cylinder or generator, to be used over again. The process is a very interesting one, the same water and the same ammonia being used repeatedly, and the changes of condition being regulated by the application of heat and cold as described.

The water or brine which is cooled by the expansion of the ammonia can be used for a variety of purposes. In breweries, for instance, the cold water required is passed direct through the coil in the cooler. For ice-making a strong solution of common salt is used instead of water as the circulating medium, as it freezes at a lower temperature, and after this brine has been reduced to a very low temperature by passing through the cooler, it is made to circulate through the ice tanks, and then to return to the cooler to be re-cooled for further use. The ice-boxes are of various forms, but the principle on which their working depends is the same in all of them.

Our illustration shows one made by Messrs. Pontifex and Wood for making pyramids of ice for table



PYRAMID ICE BOX.

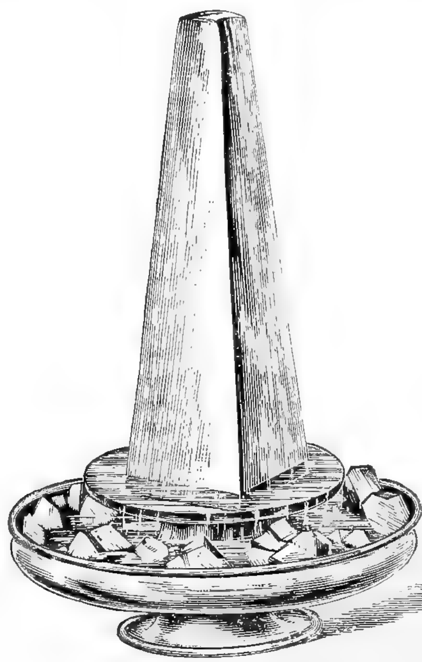
decoration, for cooling rooms, etc. The brine tank is made of wrought iron covered with wood, sawdust being placed between the iron and wood. In this tank there are four ice-moulds made of galvanised wrought iron, pyramidal in form, and in each mould there is a spiral agitator or endless screw, which is used to keep in motion the water in process of freezing. The cold brine enters the tank through a pipe at one end, and leaves the tank at the other end. In this way there is a constant circulation of the brine round the ice-moulds, and as the brine is at a temperature below the freezing point of water, the water in the moulds is soon frozen. The result is a pyramid of clear ice, as illustrated.

ON THE GEOLOGY OF BATH AND THE NEIGHBOURHOOD.

THE rocks which form the crust of the earth are either stratified or unstratified. The former of these have been deposited by the agency of water, and lie one above the other, somewhat resembling the leaves of a book. The strata do not occur indiscriminately, but are arranged in definite order, and are so classed that each formation is characterised by the fossils which occur in it, representing, of course, the life of the period during which the strata was deposited.

The unstratified rocks underlie the stratified, or have been projected into them by forces which are at present imperfectly understood.

The first great system into which the rocks forming the crust of the earth are arranged is that of the Palæozoic. The term is taken from the Greek, *palaios*, ancient, and *zoe*, life, and is applied to the lowest system as holding the most ancient or earliest-known forms of life. Next



ICE PYRAMID, MADE BY THE PYRAMID ICE BOX.
(For table decoration, and for cooling drawing, ball, and assembly rooms.)

comes the Secondary, or Mesozoic system, from *mesos*, middle, and *zoe*, life; and finally the Tertiary, or Cainozoic, from *kainos*, recent, and *zoe*, life. In considering the geology of Bath it will not be necessary to refer to strata later than the Mesozoic.

At the base of the Palæozoic series we get rocks to which the name Laurentian was given by Sir William Logan in 1854, by which term he intended to distinguish a thickness of something like 30,000 feet of strata, typically developed in the Laurentine Hills of Canada. Rocks which are probably the representatives in time of the Laurentians of Canada occur in this country, and are generally spoken of as the Archæan, a term proposed by Professor J. D. Dana, in 1874, to include the Laurentian group and rocks contemporaneous with them. The nearest locality to Bath at which rocks of certain Archæan age are exposed is in the Malvern Hills.

Next in the order of succession come the Cambrian series, in which life is abundant; but as there are no good exposures within easy range of Bath, it is not necessary to do more than mention them.

Much the same may be said of the next great formation, that of the Silurian, a term given by Sir R. Murchison to the rocks which range between the Cambrian and Old Red Sandstone. He considered them to be typically developed on the eastern borders of Wales, in a region once occupied by the Silures, and hence the name Silurian. They are to be seen in the neighbourhood of Tortworth, in Gloucestershire; but the exposures are not good, and would hardly repay a visit unless to a specialist who had some particular object in seeing them. May Hill, on the borders of Herefordshire and Gloucestershire, is a well-known locality for what Murchison, in 1834, termed the "May Hill Series," which include—

(3.) Tarannon shales.
(2.) Upper Llandovery rocks.
(1.) Lower Llandovery rocks.

The Silurian period was brought to a close by conditions which allowed of the deposition of a series of sandstones and shales known as the Dawnton Sandstone, but which are really passage-beds from the Silurian to the Old Red Sandstone. At Ledbury, between Gloucester and Malvern, these interesting beds have been cut through by the railway to Malvern, and the section thus exposed is one of the finest known. Mr. Piper, F.G.S., a local resident, has made a special study of this strata, and has obtained a good collection of the fossils which occur; among them are Cephalaspidean fish belonging to the genus *Auchenaspis Egertoni* and *A. Salteri*. Though Ledbury is located at the extreme north-western limits of Gloucestershire, it is easily accessible from Bath. Quick trains on the Midland Railway run to Gloucester, where it is necessary to change on to the new line to Malvern. On arriving at Ledbury the passage-beds are seen close to the station. For geologists who have not had an opportunity of previously examining the strata a journey is well worth undertaking from Bath.

In the Mendip area of Somersetshire, and in Gloucestershire and Herefordshire, the Devonian period, which follows the Silurian, is represented by the Old Red Sandstone and Conglomerate, but in Devonshire and West Somerset the strata of this age is all termed Devonian. One locality, where the Old Red can be studied, is below the gorge of the Avon at Clifton, a suburb of Bristol. There a continuous succession of Old Red and the rocks of the succeeding carboniferous period may be studied without a break. It is most probable that an excursion will be made to this picturesque and interesting spot during the meeting of the British Association at Bath, and therefore it will be well to refer to it in some detail.

Commencing, then, with the Old Red Sandstone, we find it represented by two types of rock—namely, (1) red and mottled sandstones, and (2) by a conglomerate. The former of these are more or less continuous from Portishead to "Cook's Folly," below Durdham Downs. The life of the period was remarkable for the fish which lived in the waters; and so characteristic are they of Devonian days that the period has appropriately been popularly termed the "Age of Fishes." They mostly belonged to the *Ganoid* and *Placoid* groups, more especially to the former. The *Ganoids* were fish having angular scales regularly arranged, composed of horny or bony plates, and covered with a strong, shining enamel. This group of fishes is now nearly extinct, the best known remaining representatives being the *Lepidosteus* (bony pike) of America, the *Polypterus* of the rivers of Africa and the Nile, and the sturgeons. At Portishead a fish-bed exists which has yielded *Holoptychius* and *Coccosteus*. At the foot of "Cook's Folly" the uppermost beds of the Old Red period are represented. They are those of the conglomerate, which is made up of opaque quartz pebbles, called by Sir H. de la Beche "veinstone quartz," and grains of sand, the whole being cemented together by a siliceous ferruginous matrix. Following the Conglomerates in the order of succession, we find the pebbles become less numerous, and finally almost disappear. The strata then becomes of a loose, sandy nature with some shales, which indicate that the conditions under which the Conglomerate was formed were gradually coming to an end, and that another period of the history of our planet was about to begin. That period was the Carboniferous, during which great thicknesses of limestone were first formed. Then an alteration took place, and vast quantities of sediment were spread over the sea floor, in much the same way that sandy *débris* is brought down into the open sea by the river Plate in South America. Apparently the limestone was deposited in the open sea, and was brought to an end by the rising of the sea floor, which allowed of the formation of the Millstone Grit from the *débris* derived from the denudation of the land. But during that time the sea-floor continued to rise, and after over 900 feet of sediment (Millstone Grit) had been accumulated, the land surfaces appeared on which vegetation grew, the carbonised remains of which we call coal.

But we must study the Carboniferous rocks more in detail. In Gloucestershire and Somersetshire they may be divided as follows :—

	Greatest Thicknesses.
Coal Measures	6,700 feet.*
Millstone Grit	900 „
Upper Limestone	100 „
Middle Limestone	1,600 „
Lower Limestone Shales..	990 „

Above the sandy beds which mark the close of the Old Red Conglomerate, we find a mixture of dark limestones and shales, hence the name Lower Limestone Shales. To understand the history of these limestones they require to be reduced to thin sections, and be

* This represents the thickness of the Coal-measures in Bristol. In the Somersetshire Coalfield the thickness is a little over 7,500 feet.

examined under a microscope. Examined as a hand specimen, many, perhaps the greater part, show no structure and we are tempted to throw specimens away as "only a piece of limestone." But make a thin section, which is not a difficult matter, and the rock will tell a different tale. Some beds are made up of little else than the valves of *Ostracoda*, a tribe of small Crustacea, which are allied to what are commonly known as water-fleas. The bodies of these little creatures were protected by bivalve shells, containing car-

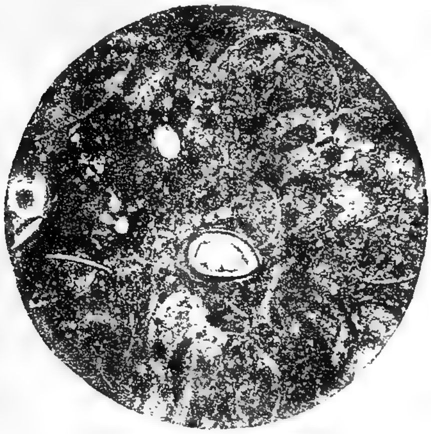


FIG. 1.

bonate of lime, and on the death of the organism the shells collected on the sea floor in such vast numbers that whole beds of limestone are made up of them. A micro-photograph from a piece of this limestone, from the Lower Limestones of Clifton, is represented in Fig. 1, and it is seen to be full of the valves of *Ostracoda*, appearing, of course, in section.

Associated with the *Ostracoda*, in the Lower Limestones,

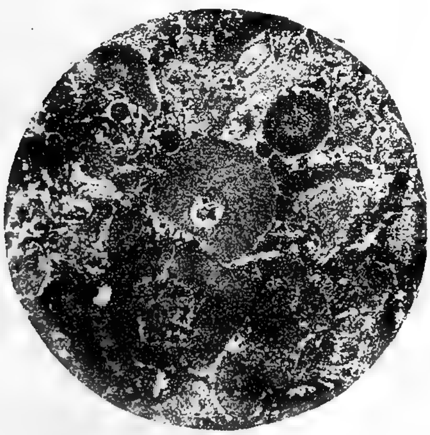

FIG. 3.

Section of the Middle Limestone at Clifton. × 40 diam. Shows it to be made up of Forminifera and the very minute Calcisphæra, represented by the circular bodies.

are the remains of Encrinites, better known as Sea Lilies, of which illustrations can be seen in most textbooks of geology.

They consisted of a stalk or stem, constructed of circular joints, which, fitting one into another with most beautiful adjustment, give the requisite flexibility and strength to enable the Encrinite to bend about in all directions. This stem supported a cup-like body or calyx, as it is termed, which was constructed of calcareous plates. From the margins of the calyx five to seven jointed arms radiated, and from these other jointed projections, called by Miller tentaculated fingers. With these the creature seized its prey, which it conveyed to the mouth, located in the centre of the calyx. Encrinites must have been most abun-

dant during carboniferous days, and the joints and plates composing their structure collected on the sea floor in such vast numbers that extensive masses of limestone are made up of them. A notable instance of this is the "Black Rock," the upper division of the Lower Limestones at Clifton, which is about 490 feet thick (fig. 2.)

To see the Encrinital remains in the Black Rock does not necessarily require a microscope, and no diffi-

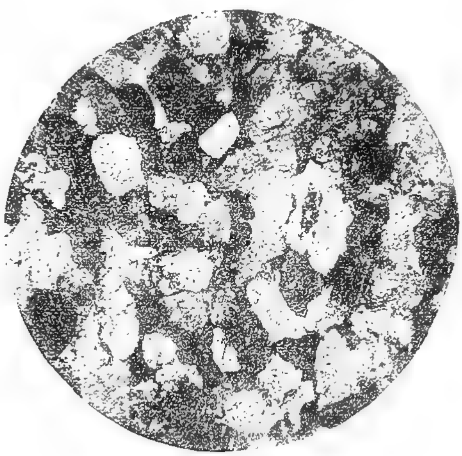

FIG. 4.

Section of Pennant Sandstone. ×20 diam. Shows it to be made up chiefly of grains of sand.

culty will be experienced in finding confirmation in hand specimens, especially if polished. This limestone is also remarkable for the fish remains which it has yielded, some of which were figured by the celebrated naturalist, Agassiz. Proceeding further up the Gorge, we pass over other limestones, one of which shows oolitic structure, and is exposed on the Gloucestershire side of the Avon, at the entrance to the Gully. We then pass to the Middle Limestone, which extends as a bold line of cliffs up to the hot wells. In this limestone corals, shells, and polyzoa will be found in some beds, but for the most part the rock appears structureless to the naked eye, but a thin section will show it to be full of the remains of microscopic organisms. These largely consist of Foraminifera and a minute organism, averaging about ·005 of an inch in diameter, named by Professor Williamson, of Manchester, *Calcisphœra.* The Foraminifera consists of minute, sometimes many-chambered shells,* filled with a jelly-like, structureless sarcode, in which the most powerful microscopes have failed to detect structure. They occur at the present time in vast multitudes in the calcareous ooze now forming in parts of the Atlantic, and in other seas of lesser depth. As to the exact nature of the *Calcisphœrœ* that at present is a little uncertain. The appearance is that of a minute hollow sphere of carbonate of lime from which spine-like filaments project. In fig. 3 these organisms appear like rings, which arises from the hollow spheres being cut in section.

The Carboniferous Limestone is extensively represented in the Mendip Hills, which extend as a lofty ridge across the northern part of that country. The scenery in the hills is very beautiful, traversed as they are by valley and gorge. The most striking of the latter is the well-known Gorge of Cheddar, situated about twenty-seven miles south-west of Bath, and easily reached by train. There the limestone cliffs rise 420 ft. above the road, crowned by rugged peaks and other grand illustrations of natural rock sculpture.

The hills are traversed by underground water courses and caves. The stalactite caves of Cheddar have long been famous, and within the last two years others have been discovered by a Mr. Gough. One of these, the "Fissure Cave," is especially instructive, as demonstrating how caves are developed out of fissures.

The Mendip Hills are also traversed by veins of lead ore, and in past times have been extensively worked. Mr. M'Murtrie, of Radstock, tells us that old records in the hands of the Waldergrave family state that at the time of Edward IV. the lead-mines of the Mendip Hills employed 10,000 miners.

Passing now to the Coal-measures, we find that within a few miles of Bath there are two coal-fields, namely, the Bristol and Somersetshire. They are regarded as having been once connected with the South Wales Coal-field, and that the separation took place at the close of the Palæozoic Period, when the strata was folded into anticlinal and cynclinal curves. The anticlinals were raised above the sea-level, and were removed by long-continued denudation, while the cynclinals assumed a basin shape, and were subsequently raised above the sea.

The Coal-measures of the Bristol Coal-field consist of three series, thus—

3. Upper Coal-measures	.. about	3,000 feet
2. Pennant Sandstone	.. "	1,700 "
3. Lower Coal-measures	.. "	2,000 "
	"	6,700 "

The lower series are worked at Ashton, Bedminster, Easton, Kingswood, and Yate. There are twenty-three seams of coal, which are separated one from another by sandstones, shales, and clays. The middle or Pennant Sandstone series are the least important, and are remarkable for the great development of blue and grey sandstone, known as the "Pennant," which is extensively worked for building and other purposes. Quarries are opened in this rock at Crew's Hole, Fishponds, Downend, and near Warmley, between Bath and Bristol. Plant remains are fairly numerous in this sandstone, and have the advantage of being more durable than those obtained from over seams of coal. They are chiefly Lepidodendra, Sigillaria, and Calamites.

* Scientific News, vol. i., 388, 413, 451.

There are fifteen seams of coal in the Pennant series, and numerous carbonaceous shales which cannot be called coal, as we understand the term. They yield a red and purple ash, and some contain what for coal is a high percentage of sulphur. They are worked chiefly for house purposes, and only to a limited extent. At Mangotsfield station, between Bath and Bristol, on the Midland Railway, there is a very fine exposure of the Pennant Sandstone with two seams of coal. An examination of this section is especially instructive as demonstrating the conditions under which the seams were formed. Each seam rests on a bed of clay, called the under-clay, and over the top of the coal is a slate, and then come beds of sandstone. Many years ago Sir William Logan pointed out that in the under-clays of South Wales there was to be found a fossil plant named *Stigmaria.* This fossil was subsequently discovered to be the root of the fossil tree Sigillaria, and still later of other varieties and allied genera included under the term Lepidodendroid plants. From this fact the inference was drawn that the under-clays were the soils upon which the coal-forming plants grew, and that the vegetation was chiefly some form of Lepidodendra or Sigillaria. The exposure of the Pennant Sandstone at Mangotsfield shows that the soil was subject to constant submergence, and on these occasions the vegetation became covered up by sandy *débris,* which in time became beds of sandstone. Fig. 4 is a micro-photograph of a piece of Pennant Sandstone, showing it to be made up chiefly of grains of sand which have been cemented together by a siliceous matrix deposited between the grains by percolating water.

The Somersetshire coal-field may be divided in much the same way as that of Bristol, but there are some seams in the Upper Coal-measures which do not occur in the Bristol area. Mr. J. M'Murtrie,* a well-known authority on the coal-field, gives the following divisions:—

Upper Divisions.	Radstock Series. Farrington Series.
Pennant Rock.	
Lower Division.	New Rock Series. Vobster Series.

From the above it will be seen that the upper series consist of two sub-series, the Radstock, and Farrington, making a total thickness of about 2,000 feet. Then follows the Pennant Sandstone, with a thickness of from 2,500 to 3,000 feet, and lastly the lower division including the New Rock and Vobster Series; the total thickness of the two representing something like 2,800 feet of strata.

(*To be continued.*)

* Paper read before the Somersetshire Archæological and Natural History Society, at Frome, 11th August, 1875.

General Notes.

Composition of Tussur Silk.—According to Messrs. Bastow and Appleyard, the fibroine of tussur silk differs decidedly in its composition from that of ordinary silk. It contains less carbon, considerably less nitrogen, and more oxygen than the fibroine of mulberry silk. It is less readily acted upon by acids, alkalies, and by chloride of zinc.

The Ruby Mines of Burma.—At depths varying from ten to thirty feet there occurs, in the flatter lands of the valleys, a stratum of corundum varying from a few inches to a few feet in thickness, and abounding in small rubies, most of which, however, are irregular in shape. So rare is a ruby of the first water that one of three carats is worth ten times as much as a diamond of the same size.

Liverpool Astronomical Society.—The Journal of the Liverpool Astronomical Society appears this month under the new editorship of Mr. Isaac H. Isaacs, who promises a "Popular History of Astronomy" from his pen, intended specially for those beginning astronomical work. This publication is a very creditable one, and contains, in addition to the more formal "Proceedings," a variety of information of a useful type.

Paraguay Tea (Mate).—Attempts are being made to introduce maté into European consumption. It is said (*Humboldt*) to contain 1·5 to 1·7 per cent. of caffeine. Its physiological action is essentially like that of tea, though it is less exciting, and does not occasion sleeplessness. It is also free from tannin, and can, therefore, be safely consumed along with gelatinous and albuminous matters. The total yearly consumption exceeds 60 million lbs., 28 million lbs. of which are produced in Brazil and the rest in Paraguay.

Action of very Cold Baths.—According to M. Ch. F. Quinquand (*Comptes Rendus de la Sociéte de la Biologie*), very cold baths occasion a notable increase of the absorption of oxygen, of the carbonic acid expired, of the total volume of air respired, and of the oxidation of the tissues. Very hot baths act in a similar manner, but to a less extent. Both very hot and very cold baths may prove rapidly fatal. A dog cooled down to a rectal temperature of 73° to 75° Fahr. can be saved by plunging it into a bath at 122°, when it recovers in a few minutes.

Archæological Association. — The British Archæological Association, of which the Marquis of Bute is this year the president, began its sittings in Glasgow on Monday. Sir James King, Lord Provost, welcomed the members to the city, and Sheriff Berry and Mr. John Honeyman, Chairman of the Reception Committee and President of the Glasgow Archæological Society, gave them greeting. The members afterwards visited the ancient Celtic camp at Langside, near Glasgow, and were present when a memorial, recently erected on the site of the battle of Langside, was handed over to the patrons of Hutchison's Hospital. They afterwards visited the cathedral.

The Grotto of Reilhac.—According to a correspondent of *Cosmos*, an interesting grotto has been found at Reilhac, in the canton of Livernon and department of Lot. The owner of the grotto, on digging, found several layers of earth, each of rather more than half a yard of thickness, and separated from each other by a kind of concrete. In these layers there have been found a number of flint implements (hatchets and knives), arrows of bone, and some truncheons of bone (for each of which the sum of 100 francs has been offered him), many antlers of deer, among which is one of extraordinary magnitude, which may have belonged to a reindeer. He found also a bone of unusual magnitude, which he parted with for 50 francs, some curious fragments of pre-historic pottery, jaw-bones and teeth of an incredible size. He is selling these bones to rag-men at 1 sou per kilo!

Contribution to our Knowledge of the Connection between Molecular Structure and Physiological Action.—W. Filehne (quoted in *Humboldt*) finds that it is possible from atropine, which has feeble locally anæsthetic properties, to split off tropaic acid and tropine. In like manner, from homatropine, which has a decidedly more paralysing action upon the ends of the nerves of sensation, there may be split off amygdalic acid and tropine, and from cocaine, benzoic-ecgonine. Amygdalic acid stands chemically in the middle between benzoic acid and tropaic acid. The conjugation of ecgonine with benzoic acid seems to be the essential point in the decisive anæsthetic property of cocaine, since ecgonine itself is inactive in this respect. We have thus a series of increasing activity passing from tropaic acid through amygdalic acid to benzoic acid. The author, therefore, conjectures that the substitution of benzoic acid for tropaic acid or amygdalic acid would produce anæsthetics more powerful than atropine and homatropine. The benzol tropine thus obtained verified his conjecture. A series of other alkaloids were combined with benzoic acid, and all these benzoyl-derivatives proved to have an action like cocaine.

Lightning Accidents.—In the *British Medical Journal* there is an account by Drs. Cook and Boulting of the injuries received by two sawyers on the Spaniards Farm at Hampstead. The man most injured, the elder of the two, was leaning against an oak tree. There was no rain nor any sign of a thunderstorm. The other was sitting on a block of wood 3 ft. away, and two saws, 6½ ft. long, were leaning against the fence about 2 ft. from the trunk of the tree. The first man saw nothing and felt nothing; he was struck senseless instantaneously. The second heard a deafening thunder clap and felt stunned for some minutes, but had no sensation of pain. Then he discovered that his clothes were smoking and burning, although not ablaze. He then saw his companion lying senseless on the ground, quite still, as if dead, and his clothes partially torn from him. Having put out the fire in his clothes, he crawled (he could not walk) to the road near and shouted for assistance, which soon arrived, and both men were conveyed to the infirmary, where, upon being roused, the elder man regained consciousness to a slight extent. Burns were found on the right side from the shoulder to the feet. The legs of the other man also had marks as of burns; both were in a state of collapse. After eleven days in the one case and fourteen in the other the men recovered.

The doctors remark that it should not be forgotten that dangerous return discharges from the earth to the atmosphere may take place at a considerable distance from an atmospheric storm.

THE LATE MR. W. H. BAILY.—The death is announced of Mr. William H. Baily, acting palæontologist of the Geological Survey of Ireland. Born at Bristol in 1819, deceased secured an appointment in the Bristol Museum at the age of 19. This he held until 1844, when he was attached by the late Sir Henry de la Beche to the Geological Survey of England, first as a draughtsman, and afterwards as assistant naturalist under Edward Forbes and subsequently under Professor Huxley. In 1857 Mr. Baily was transferred to the Irish branch of the Geological Survey as palæontologist, and this post he held until his death. He was also demonstrator in palæontology to the Royal College of Science, Dublin. Mr. Baily was a frequent contributor to the Proceedings of the Royal Irish Academy, of the Linnean and Geological Societies of London, and the Royal Geological Society of Dublin, as well as of various kindred societies in Europe and the United States. He was also an assiduous attendant at the meetings of the British Association. Mr. Baily's most important work was his "Characteristic British Fossils," which was produced at great expense, and was incomplete at the time of his death. He was also the author of a work published last year, entitled "Rambles on the Irish Coast; especially relating to its Geology, Natural History, and Antiquities."

OBSERVATIONS ON THE PERCEPTION OF COLOURS.—H. W. Vogel communicates some interesting results to the *Naturwissenschaftliche Rundschau* and *Humboldt*. It is already known that a table of colours if illuminated with the monochromatic yellow sodium light makes no coloured impression. The several colours appear merely as gradations of black and white. The yellow squares appear white, partly a purer white than the white paper upon which they are fixed. It is further known that the several colours at once appear as soon as a bright candle is placed alongside the sodium flame. But this experiment has hitherto not succeeded with any other light. Vogel has at last succeeded in producing other monochromatic lights by using green lamp-cylinders of chrome-glass and dark-red cylinders of copper glass. If such cylinders are used with powerful petroleum lamps, and if all white light be excluded, a result is obtained analogous to that with the sodium-light. With the red light all red colours appear pure white, and all others grey or black. With the green light there is a corresponding phenomenon. With blue cobalt-glass the experiment succeeded only if a solution of copper oxide in ammonia was interposed in the course of the light, as cobalt-glass transmits a part of the red ray along with the blue ray.

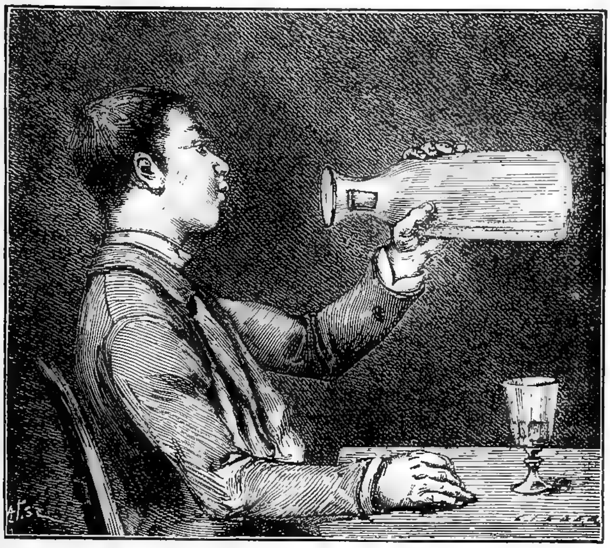
THE PUBLIC HEALTH.—The Registrar-General's return for the week ending August 18th shows that the deaths registered during that period in the 28 great towns of England and Wales corresponded to an annual rate of 16·4 per thousand of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Nottingham, Bolton, Birkenhead, Birmingham, Bristol, and Sunderland. In London 2,604 births and 1,330 deaths were registered. Allowance made for increase of population, the births were 187 and the deaths 310 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 15·9, 15·9, and 18·0 in the three preceding weeks, declined again last week to 16·2. During the first seven weeks of the current quarter the death-rate averaged 16·0 per 1,000, and was 5·2 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,330 deaths included 33 from measles, 17 from scarlet-fever, 13 from diphtheria, 20 from whooping cough, two from typhus, two from enteric fever, one from an ill-defined form of continued fever, 162 from diarrhœa and dysentery, four from cholera and choleraic diarrhœa, and not one from smallpox; thus 254 deaths were referred to these diseases, being 138 below the corrected average weekly number. In Greater London 3,372 births and 1,649 deaths were registered, corresponding to annual rates of 31·8 and 15·6 per 1,000 of the population. In the Outer Ring 31 deaths from diarrhœa, eight from whooping cough, seven from measles, and five from diphtheria were registered. The fatal cases of diarrhœa included nine in West Ham district and nine in Tottenham sub-district; four deaths from measles occurred in Tottenham, and two of diphtheria in Croydon sub-districts.

THE LATE MR. P. H. GOSSE.—The death is announced of the distinguished zoologist, Mr. Philip Henry Gosse, F.R.S., at his residence, St. Marychurch, Torquay, on the 23rd inst. He was born in Worcester in 1810, and in his childhood he displayed a strong taste for natural history. In 1827 he went out in a mercantile capacity to Newfoundland, where he occupied his leisure in collecting insects. In 1833 Mr. Gosse visited Lower Canada, where for three years he specially devoted himself to the study of zoology and entomology. He afterwards travelled through the United States, and resided for about a year in Alabama. In 1839, after his return to England, Mr. Gosse published a general synopsis of his investigations, under the title of "The Canadian Naturalist." A visit to Jamaica in 1844 resulted in "The Birds of Jamaica," followed by an "Atlas of Illustrations," and "Naturalist's Sojourn in Jamaica." During the next few years he published an "Introduction to Zoology," and prepared many works for the Society for Promoting Christian Knowledge. He took a prominent part in the formation of public and private collections of marine animals, and was elected a Fellow of the Royal Society in 1856. Among Mr. Gosse's works are "The Aquarium," 1854; "A Manual of Marine Zoology," 1855; "Tenby, a Seaside Holiday," 1856; "Life in its Lower, Intermediate, and Higher Forms," 1857; "Actinologia Britannica; a History of the British Sea Anemones and Corals," 1860; "The Romance of Natural History," 1860-62; "A Year at the Shore" and "Land and Sea," 1865. He likewise pursued a series of microscopical investigations into the character of the family papilionidæ, and the first fruit of those studies appeared in the Transactions of the Linnean Society. Up to the year 1863 the Royal Society's catalogue of scientific papers contained no fewer than 51 articles attributed to Mr. Gosse's pen; and these were subsequently added to. In 1874 he published at Philadelphia his "Wonders of the Great Deep: or, the Physical, Animal, Geological, and Vegetable Curiosities of the Ocean."

EXPERIMENTAL PHYSICS.

HERE is a carafe with a wide neck, which we hold horizontally, having placed a cork loosely inside its neck. "Will you," we said to a young student of physics, "attempt to blow upon the cork? We defy you to drive it into the carafe." Our friend took the carafe in one hand, as shown in the figure (from *La Nature*), and with the calmness of a man sure of success, puffed out his cheeks, filled his mouth with air, and blew strongly upon the cork, believing that he could drive it to the bottom of the bottle. The instant he blew, the cork, as if projected by a spring inside, issued violently from the mouth of the bottle and struck the experimentalist on the lips.

The explanation of the phenomenon is easy: on blowing into the confined space within the bottle, the internal air is compressed, and then, expanding again, throws out



Bottle Experiment.

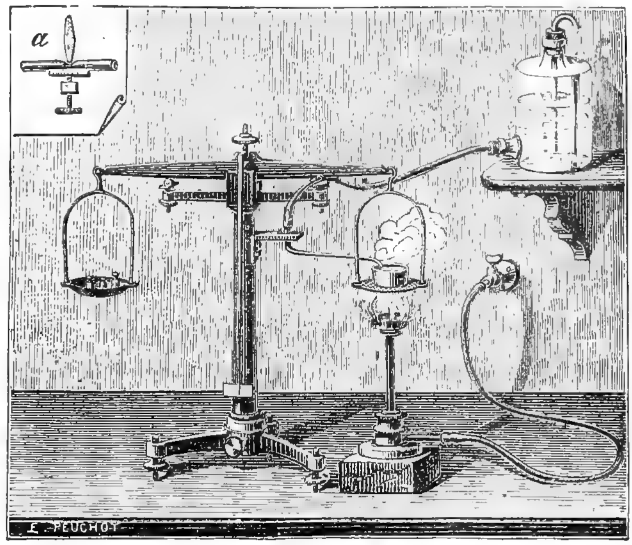
the cork, the projection of which will be more energetic the more strongly the experimentalist has blown.

Some precautions are necessary for success: the carafe must be perfectly dry, especially in the neck, as moisture might cause the cork to adhere, and it must also be very smooth.

AUTOMATIC CONSTANT-LEVEL BALANCE.

THE analysis of potable or of mineral waters generally requires the evaporation of 2, 5, 10, or perhaps even 20 litres of water, and when it is required to ascertain the residue per litre, or to determine the silica, we must operate in a platinum dish, the use of porcelain or glass not being possible. This operation must also be conducted with care, because brisk ebullition might occasion a slight loss, especially in case of a magnesian water. All spirting must also be avoided. The appliances devised for this purpose not working satisfactorily, M. Charles Truchot proposes, in *La Nature*, the apparatus of which we copy the figure and description. It consists essentially of an ordinary balance supported on a pillar and corresponding in size with the capsule to be used. One of the pans is substituted by a piece of wire gauze upon which is set the capsule. In the other pan are put weights so as exactly to counterpoise the capsule. By means of a slight modification in the fork, which checks the oscillations of the beam, a narrow caoutchouc tube may be compressed between the beam and this fork.

The tube communicates, on one hand, with a Mariotte's bottle containing the water to be evaporated and the bent end of which ends above the capsule. Things being thus arranged the water will flow into the capsule as soon as its weight is insufficient to overbalance the counterpoise. This counterpoise is so arranged that when the capsule is three-fourths full it slightly preponderates. The beam then lowers, pinches the caoutchouc tube, and the flow of water stops. If there is a gas burner placed below the capsule, as in the figure, the evaporation soon begins, the capsule becomes lighter,



Automatic Balance.

the beam rises, ceasing to press upon the flexible tube, and the water flows again.

Experience shows that the apparatus is self-acting, so that the water falls drop by drop at the rate of 30—60 drops per minute according to the rapidity of the evaporation, so that the level is kept constant. The level depends simply on the tare and the number of drops must depend on the intensity of the evaporation, consequently on the temperature applied.

If it be feared that the supply may cease when the bottle is empty and the deposit may be calcined the other end of the fork may be made to pinch the tube which supplies gas to the burner. If the capsule is not supplied the gas flame lowers and is extinguished before the deposit becomes dry.

ODOURS, AND THEIR FUNCTIONS.

THAT almost all plants and animals throw off volatile matters which affect our sense of smell is a fact perfectly admitted. That the more susceptible olfactory organs of certain lower forms of life will be more vividly impressed than our own will also not be disputed. But when we come to ask why this or that organic species gives out some peculiar scent, we are still very much at a loss. Much good work has, indeed, been done of late years in explaining the use of the odours of certain flowers in attracting insects whose visits are essential to their fecundation. The results of such investigations will, of course, be familiar to most of our readers. But there are in this connection a multitude of unsolved questions, and to these we wish to direct the attention of young naturalists as a fruitful field for study and observation.

In the first place, there are flowers not a few of which give off scents ranging from the slightly disagreeable to the positively loathsome. There are the sickly smell of the common elder blossom or the sunflower, the peculiar bitter—we use this term for want of one more definite—of most of the Compositæ, such as the dahlia, the common marigold, the African marigold, and in a more intense degree Coreopsis Drummondi; the indescribably fetid exhalation of certain Aroids, and of a giant Bulbophyllum referred to in our recent article on orchids. What function do these smells subserve? Are they, like perfumes, to attract some insect which may convey the pollen of one flower to the pistil of another, and thus promote fecundation? If so, what insect? Certainly no bee or butterfly. The likings of these insects as regards odours are admittedly not like our own. We see both butterflies and bees preferring the sugary but sickly aroma of the privet, the African sedum, the sweet marjoram, and the prickly comfrey to the delicious fragrance of the syringa, the orange-blossom, or the lavender. But for all this none of them, as far as we have observed, like positive stenches.

In some cases flowers seem to find their advantage in smelling like carrion. Blow-flies are seduced, as may be found mentioned in the text-books, into depositing their eggs in such flowers. The young grubs perish as a matter of course, and the flower, in some manner which requires further investigation, preys upon their remains. But many evil-smelling flowers do not in the least remind us of putrid animal matter, and in fact have not been seen to be visited by blow-flies.

Have the offensive smells been developed in order to repel some enemy? If so, they often fail. Every gardener knows, for instance, that the destructive earwig is found as abundantly in the disagreeably-smelling dahlia, sunflower, or marigold as in the fragrant carnation or white lily.

Then we have to consider the smells, good or bad, proceeding not from the flowers of any plant, but from the fruits, the leaves, the stem, or the roots. Here the fecundation of the seed and the prevention of self-fertilization do not come into any direct play. Not a few plants have altogether very agreeable odours. Of these, the sweet briar is the most familiar instance. What advantage, if any, does it gain in comparison with other members of the great rose family by the fragrance which pervades its leaves and its shoots? So far "the oracles are dumb." On the opposite side we have plants which give out a more or less disagreeable smell, especially when crushed, such as the so-called dead nettle. But the function of this and similar unpleasant scents, *e.g.*, that of the leaves of the common scarlet geranium, is still a matter of doubt. The odours of a number of plants, such as thyme, mint, and lavender, have been explained as protective, not against insects but against cold. The scents of such plants, indeed of the Labiates generally, are due to essential oils, which being very volatile, constantly envelope the plants in an atmosphere which hinders them from losing heat by radiation in a chilly night as readily as it would otherwise be the case. This explanation is the more probable, as the Labiates for the most part are intolerant of frost.

Another explanation of the smells of parts of plants other than the flowers, is that they are intended to attract, or respectively to repel, animals which might eat such parts. We may easily conceive that it might suit the—of course unconscious—purposes of a plant that its fruits should be eaten by some kinds of animals and not by others. If consequently it develops a scent which attracts the former and repels the latter, it may find a benefit. Now, a scent good or bad will have this effect, and as all animals do not approve of the same kinds of scents, the effect will possibly be selective. If the question be raised why it should make any difference to the plant by what animal its fruits are consumed, the answer is not far to seek. One species may swallow the seeds unbruised, and may afterwards excrete them uninjured. In this manner their dispersion will be promoted, and each will be accompanied by matter which will promote its germination and growth. Another fruit-eating species, *e.g.*, rodent mammals, may gnaw the seed to fragments, especially if large, or may swallow it whole or in pieces and digest it, as do many birds. It is plain that to be eaten in this manner is a hindrance to the perpetuation of any vegetable species.

It must be remembered that the smell of a fruit or other part of a plant does not by any means invariably give a clue to its taste. Thus the smell may be more or less repellent, but if this warning be neglected the taste may prove pleasant. The most striking instance of this is the durrian, of the Malay Islands.

Every stranger, on his first contact with this fruit, loathes its smell, and we believe every one who makes the experiment finds its taste delightful.

A less striking, though unquestionable case, is that of the onion family, universally denounced for their smell, but almost as universally eaten. Farmers are often annoyed at the avidity with which their cows will browse the wild onion, if accessible, thus injuring the flavour of the milk and butter. The smell of the onion is thus no protection.

On the other hand, a pleasant odour may accompany a very unpleasant taste. In decoctions of certain very bitter roots, such as gentian and calumba, a fruity odour may usually be perceived. What can be the purpose of the smell?

Very many kinds of trees and shrubs when first coming into leaf, and before the flowers appear, have a decidedly pleasant odour. Prominent in this respect are the Canada poplar, the pines when putting out fresh growths, the birch and the oak. Here, again, we do not know what purpose is thus served.

It is not easy to imagine how a plant of any kind can be benefited by having its leaves or sprouts eaten away, whether by cattle, rabbits, locusts, cockchafers, or slugs. Yet odours which effectually repel such attacks are very rare.

To conclude with an irrelevant and, we fear, unanswerable question, we must ask whether the snails and slugs were originally consumers of dead and decaying vegetable matter, and have since extended their ravages to healthy leaves, fruits, and flowers, or whether they were originally devourers of fresh plants, and have subsequently taken to eating vegetable refuse?

Natural History.

THE SING-SING ANTELOPE.

TRUE Africa—the Ethiopian region of Sclater and Wallace—is remarkable for its number of antelopes, which seem here to replace the deer of Asia, Europe, and America, never found to the south of the Great Desert. From deer, which they much resemble in form, in diet, and in general habits, the antelopes are most easily distinguished by their horns. The horns, or antlers, of deer are shed and renewed annually, and consist of solid bony matter throughout. The horns of the antelopes, like those of oxen, are permanent structures, each consisting of a so-called "core," a bony process of the skull which supports a sheath of horny matter. This matter is in its chemical composition very distinct from bone, and differs little from that of hair, nails, skin, etc.

The animals of Africa proper—that is, the part lying to the south of the Sahara—vary exceedingly little throughout a vast range of country. Hence there has arisen confusion. A traveller observing some unrecorded animal, say in the south of Abyssinia, gave it a distinct name, though in reality it might be merely a local variation of some species which has already been described from some distant side of the continent.

THE SING-SING ANTELOPE (*Kobus sing-sing*).

Such is the case with the "sing-sing" antelope (*Kobus sing-sing*), a figure of which we here borrow from *La Nature*.

The Jardin des Plantes has quite a herd of these fine animals, the issue of a male and two females brought in 1880 from the Senegal by M. Brière de l'Iske, who had been governor of that colony.

These "kobs," as they are called in Senegambia, are of a robust but elegant form. Their pointed horns diverge like the arms of an ancient lyre, and are then again slightly curved inwards at the extremities. They are marked with rings for two-thirds of their length.

The neck of the animal is clad with a sort of mane. The rest of the body is covered with hair, shorter than the mane, but longer than that found in many kinds of antelopes, and constantly saturated with a fatty matter. This peculiarity was observed by Laurillard, who proposed to give this species the name *Antilope unctuosa*.

The general colour is a light-reddish maroon, passing into a yellowish white on the posterior region and the inner side of the limbs, and into a greyish white on the throat and the cheeks. The lower parts of the limbs are of a dark brown. The tail, relatively thin, ends in a tuft of black hair. The ears, edged with black on the outside, are garnished within with long white hairs, and there are white lines or patches near the hoofs, above the eyes, on the upper lip, and the chin.

The kobs of Senegambia are found commonly in the Cayor and Upper Senegal, and, according to Gray, on the banks of the Gambia, a region decidedly tropical. Yet these animals, if transported into Europe, do not appear to suffer from the severity of our winters. At the Jardin des Plantes they spend much of their life in the open air, and have no shelter except a shed not heated. Yet they preserve their health and multiply as well as in their native country. No fewer than ten of these antelopes have been born in the gardens. It is thought that this species might exist at large in France. In England its naturalization, if practicable, would not be desirable, as every game bird or beast introduced serves merely as a focus for the contending powers of gamekeepers and poachers, each body suspecting the botanist, the entomologist, the geologist, or the artist of being an ally of its enemy.

It seems probable that the antelope discovered in Abyssinia by Ruppell, and named by him *Antilope defassa*, is identical with the kobs or sing-sing of Senegambia. Mr. J. Murie (Proceedings of the Zoological Society of London) states that some skins of the antelopes in question, brought from the region of the Upper Nile, twenty years ago, by Baron von Harnier, and preserved in the Grand Ducal Museum of Darmstadt, possess neither the unctuous feel nor the long tufty hair of *Kobus sing-sing*. The skin is also of a colour less reddish and more brown than that of the Senegambian species. The horns, however, are exactly like those of the sing-sing, and the same characters are found in the head of an antelope brought from Uganda by Captain Speke, and belonging, doubtless, to the species which he calls *Antilope N'samma*. The *Antilope Mehedehet*, killed by Sir S. Baker on the banks of the Asna, approaches closely to the sing-sing.

In South Africa there exists another species of *Kobus*, of a more powerful build, called the "crescent kobus" (*Kobus ellipsiprymnus*), on account of a white band which descends from the sacrum and terminates in a point on each thigh. The skin is of a yellowish grey, passing to a reddish brown on the forehead and to a white on the throat, the muzzle, and above the eyes. These animals feed along the banks of rivers in small herds, consisting of several females, two or three young males, and a single adult male, who watches over the safety of the band. If alarmed they rush into a marsh, and thus escape their most terrible enemy, the lion. The natives of South Africa do not hunt this species, on account of the intense rankness of its flesh.

A Luminous Coleopterous Larva from Brazil.—Herr von Jhering (*Cosmos*, from *Berlin, Entom, Zeitschrift*) states that this larva is distinguished from other luminous insects by its double light, which is fiery red at the head and the posterior extremity, but green at the stigmata. The larva was found accidentally by night on turning over a stone, and was about 2 inches in length. The green light issuing from the stigmata seemed to be continuous and independent of the will of the larva, but the red light at the two extremities was sometimes brighter and sometimes fainter. Unfortunately, the creature escaped before its systematic position could be ascertained. According to Von Jhering it appeared similar to the larva of an *Elater* (wire-worm). Dubois thinks that the red light at the extremities may obtain its colour by transmission through red chitine.

The Food of the Sparrow.—The following facts, observed by S. A. Forbes, of Illinois, and recorded in the *American Naturalist* for 1881 (p. 393), may, perhaps, convey a useful lesson to the advocates of the sparrow. The food found on opening twenty-five sparrows shot in and near Aurora, Illinois, in September, "consisted almost entirely of grain." At a time when 30 per cent. of the food of the (American) robin, 20 per cent of that of the catbird, and 90 per cent. of that of the blue bird consisted of insects, no insects were found in the stomachs of these birds, except traces of grasshoppers, making, perhaps, 6 per cent. of the food.

A Cloud of Bees.—On the 22nd inst. a great number of bees made a descent on the confectionery stalls of Bishop Auckland market, and literally took possession of them. Business was stopped, and the owners of the stalls took to flight. It is presumed that the cold and inclement season had deprived the insects of their ordinary source of sustenance, and that they were driven by famine from the country into the town.

Helix Harpa in Switzerland.—According to *Humboldt*, the Belgian naturalist, Alfred Orasen, has found this species upon the Riffel Alp, near Zermatt, at a height of 6,200 feet. Hitherto it has been seen only in Arctic regions and in the north of the United States. It lives under detached pine bark. This is a fact of much interest, as *Helix harpa* has been found inclosed in amber, and has, therefore, not altered its habits since the amber-age.

Abnormal Habits of Animals.—A correspondent of the *Field*, who signs himself "The Doctor," describes certain nocturnal cave-dwelling birds in Trinidad, which, instead of preying on moths, devour the fruit of palm-trees. In another cave in the same island live a colony of bats which have left off insect hunting and live by catching fish! So little can we judge of the habits of an animal from its structure!

Protection for the Sand Grouse.—Baron Von Lucius, the Prussian Minister of Forests, Domains, and Agriculture, recommends that the sand grouse, until further notice, shall be entirely unmolested in all royal forests and domains.

Remedy for the Coffee Disease.—According to the *Medical Press*, Dr. Burck, of the Government Botanical Garden, near Batavia (probably Buitenzorg?) proposes a very dilute solution of chloride of iron as a remedy for the coffee disease, (*Hemileia vastatrix*.)

THE BOTANY OF BRISTOL.—II.

(*Continued from p.* 182.)

THE "Flora of the Bristol Coal-fields," published by the Bristol Naturalists' Society, with its supplements, contains records of about 1,010 flowering plants and vascular cryptogams, excluding varieties, aliens, and casuals. To that work can be referred all those inquirers who desire to become more closely acquainted with our plants in their respective habitats. Three species found in the district do not grow elsewhere in Britain. They are *Dianthus cæsius*, *Arabis stricta*, and *Allium sphærocephalum*; the two last being peculiar to St. Vincent's Rocks and Durdham Down. The pink is also a limestone plant, but grows only at Cheddar, where it is still abundant. *Arabis stricta*, the Bristol rock-cress, is to be found in fair quantity about the rocks overlooking the Avon, and, more sparingly, on the opposite bank of the river, so that it can be claimed by Somerset as well as by Gloucester; but its whole area is extremely small, and it behoves all true botanists to use extreme care in dealing with it. The Downs, rocks, and quarries on the banks of the Avon below Bristol yield most of the limestone species, including many of our best plants. Besides those already mentioned there are met with on St. Vincent's Rocks *Hutchinsia petræa*, *Arabis hirsuta*, *Cheiranthus Cheiri*, *Hippocrepis comosa*, *Pyrus Aria*, *Sedum Telephium*, *Rubia peregrina*, *Blackstonia perfoliata*, *Rumex pulcher*, *Allium vineale* (*compactum et bulbiferum*), *Geranium sanguineum*, *G. rotundifolium*, and *G. columbinum*. On some of the ledges can be seen *Sedum rupestre* (*minus*), flowering but rarely, and it occurs also on the other side of the river. The ivy clothing some of the precipices is much infested with *Orobanche Hederæ*, while the handsome *Veronica hybrida* is plentiful but mostly out of reach. The Alexanders, Parsley, and Fennel may perhaps remain from ancient cultivation, and be descended from pot-herbs used by the hermit who, tradition says, at one time inhabited the Giant's Cave. Early in the spring the flowers of *Potentilla verna* are seen in profusion, and for a week or two one can readily distinguish the spikes of *Carex humilis*. After flowering, the sedge blends its foliage with the turf, and entirely justifies its specific name. If the season be damp and cool, *Cerastium pumilum* is fine and abundant, but a hot dry spring, like that of 1887, gives a tiny annual small scope for development. *C. semidecandrum* grows about the edges of the paths and under the seats, while a dwarf form of *C. tetrandrum* is frequent in the turf near the Observatory, together with *Trifolium subterraneum* and *T. scabrum*. These likewise grow together on Brandon Hill. *Scilla autumnalis* was lost sight of for many years after the construction of Clifton Suspension Bridge, but happily has now been rediscovered within a short distance. The rocky side of the river below St. Vincent's Rocks belongs to Clifton and Durdham Downs. Here may be discovered *Aquilegia vulgaris*, *Spiræa Filipendula*, and *Trinia vulgaris*. The best grasses are *Gastridium lendigerum*, *Avena pubescens*, *A. pratensis*, *Sieglingia decumbens*, *Koeleria cristata*, *Festuca myurus*, *F. sciuroides*, *Bromus erectus*, *and B. madritensis*. All these grow within a very small area. The Fly and Bee Ophrys have become scarce, but *Spiranthes autumnalis* is scattered freely on the Downs. In furzy spots we find *Ulex Gallii*, *Carex pulicaris*, *C. pilulifera*, and *C. panicea*, which flourishes alike on limestone or in marsh. *Carex digitata* is well concealed under bushes, and wants a good deal of looking for. In Leigh Woods it is larger and more abundant. Further westward beyond the limestone there occur on the river bank many other interesting species, from which we may select for mention *Allium oleraceum*, *Trifolium maritimum*, *Lathyrus Nissolia*, *Bupleurum tenuissimum*, *Aster Tripolium*, and *Alopecurus bulbosus*; while in the marsh districts towards Avonmouth are plenty of *Ranunculus Baudotii*, *Ruppia*, *Zannichellia*, and *Potamogeton pectinatus*. The botanist will be equally charmed among the copses and coombes of Henbury and Westbury, or on the wooded banks of Leigh. Leigh Wood is the great hunting ground for mosses, yielding as many as 200 species. Several very rare musci also, including *Grimmia orbicularis* and *Tortula Hornschuchiana*, are to be found on the Gloucestershire side. Mr. Cedric Bucknall has catalogued a very large number of Bristol fungi, some new to Britain, and a few new to science. The latter include *Agaricus Bucknalli*, and will be found described and figured in the transactions of the Bristol Naturalists' Society.

To the deficiency of arable land may be attributed the absence of some agrarian weeds common in other localities. And here comes in the consolatory thought that the cultivation of the soil is not likely to be so much extended in the future as to alter the features of the flora to such a great degree as has occurred in the more highly cultivated and exclusively arable portion of the kingdom. Very much of the land around Bristol is not suitable for the plough. Speaking generally, the owners profit most by allowing it to remain in its original state, either as woodland or for grazing. But although during the last half-century cultivation has not threatened to reduce the number of our plants, yet the advance of bricks and mortar in the rapid expansion of this great city wears another aspect. However, we believe that up to the present time hardly a single species correctly reported as native in our area has become extinct, though with a few existence is precarious. As an instance may be mentioned *Thalictrum minus* on Durdham Down. Known by Sole in the last century to occur in small quantity, this rare plant is now represented at Bristol by two specimens only, and these are very much at the mercy of scrambling boys whose heedless feet will one day be the cause of their decease. Another plant in danger of destruction is *Cyperus longus*, at Walton-in-Gordano. This rare and beautiful sedge has grown from time immemorial in a small plot of very wet marshy ground, believed to have been anciently a fish-pond, and situated behind some cottages in the upper part of the village. Sole, in MS. dated 1782, says of it, "Abundantly in a pond at Walton-in-Gordano, near Possit, Somerset, a village belonging to Sir Abraham Elton" (Possit-Portishead). The plant continued to be plentiful until 1882, when the occupier of the land ploughed it and planted potatoes. At the end of August, 1883, we found many stems coming up by the sides of two ditches which intersect the field, and also among the crop; but in consequence of the disturbance their development was much retarded, and flowering delayed nearly two months. Since that time, owing to the drainage and cultivation, the sedge has become reduced in quantity, and the stems produced in successive seasons have failed to come to maturity, whence it is to be feared that *Cyperus longus* will soon head our list of lost rarities.

Those botanists (but they are surprisingly few) who delight to study the critical groups of aquatic Ranunculi, brambles, and roses will find ample material close at hand. The genus *Batrachium* is so well represented in our marshy ditches and brackish pools that the majority of British forms can be recognised.

It is to the keen observation of a lady that we owe the latest discovery of a choice species—namely, that of *Blysmus compressus*—on the coast near Burnham; and, in deference to the sex, we devote the last paragraph of this imperfect sketch to a notice of the ladies' favourite order. Ferns, however, are scarce about Bristol, and are receding farther from the city since their cultivation became a fashion. If the ruthless uprooting and transference to death in a garden continue, we may bye and bye have only a few fronds of bracken left. *Cetarach* is a feature of local botany, and one of the prettiest ornaments of our limestone walls. *Cystopteris* and *Osmuuda* formerly grew in Leigh Woods; but for the first, one must now go in the direction of the Mendips, where it is frequent; and for the second, to the peat moor, on the southern limit of the district. On the peat grow also *Lastræa Thelypteris* and *L. spinulosa.* There is evidence, too, that *Phegopteris Dryopteris* once grew in Leigh Woods; the place has been pointed out, but the fern is no longer there. *P. polypodioides* is known in one spot near Wells; and the occurrence of *P. Robertiana* at Cheddar has already been alluded to. *Asplenium lanceolatum*, on sandstone rocks in Glen Frome, has, we fear, shared the fate allotted by collectors to all good things. Ten years ago it was spoken of as being only obtainable with the aid of a quarryman and a rope; and this information has since been confirmed.

But in spite of possible losses, we trust yet to add largely to our knowledge of the rich botanical resources of one of the most delightful, interesting, and exhaustless districts in the country.

NEW PROCESS OF SUGAR-REFINING.

It is singular that almost at the same time that the conference for the abrogation of the sugar bounties begins its work we should receive intelligence of a new process which seems destined to entirely revolutionise the sugar-refining industry. This method, which, after repeated testing, is said to have proved capable of accomplishing all that has been claimed for it, depends for its action upon the use of electricity. Its discoverer, Professor H. C. Friend, of New York, who died in May last, unfortunately before the realisation of its commercial success, must have been mentally characterised by an extraordinary combination of inventiveness and secrecy. He had made a careful study of electricity, and especially of its applicability to sugar-refining, for several years before his work and hopes were finally rewarded by the production of a hard sugar of almost perfect purity. It is said that he was the discoverer of quite a considerable number of useful and valuable inventions, which, on account of his extreme aversion to publicity and possible piracy, have never been disclosed or utilised for purposes of manufacture. This secretiveness was, of course, equally, if not to a greater degree, manifested in respect of his sugar-refining process, but fortunately, there was no need to conceal the product, which was fully submitted to those engaged in the sugar trade. The unanimous verdict of all who examined and tasted it was that no such sugar had ever previously been produced, and that if it were offered for sale at the same price as the other kinds nothing could compete with it. This led to the formation of a Company about four years ago, with a capital privately subscribed for of a million dollars, of which three-fifths were to be retained by the inventor as payment for his discovery and the right to work it at home and abroad. Not only were all the shares taken up, but they have since been at a premium as high as 400 per cent. Many are held in this country, especially at Liverpool and Birmingham. The large proportion of shares held by the Professor practically gave him control of the Company, and enabled him to manage matters in the secret manner which suited his disposition and which has tended to bring about the delay in practical working which has ensued. Hence, although large manufacturing premises were acquired in Brooklyn in 1886, and adapted to the requirements of the electric process, and though much of the necessary machinery had been planned and ordered two years previously to that, the internal fittings are not yet complete. The Professor had such a dread of his secret leaking out that the various parts of the machines were made, according to his instructions, at towns widely separated from one another and from New York, and the natural difficulty of fitting together the parts thus constructed was, of course, greatly increased by the fact that it had to be done entirely by the very few persons who alone were allowed to see or touch them. These persons seem to have been the Professor, his wife, and a Mr. Howard, whose knowledge of mechanical work was necessary for designing and constructing the apparatus, and in whom the Professor felt he could place complete reliance. The promoters of the Company proposed at the outset to keep the invention entirely secret, and, of course, not to patent it, as the publication of the specifications would have revealed the whole process. This intention no doubt arose in the main from the Professor's influence, as he did not even impart his secret to any member of the Company. By means of small machines constructed by Mr. Howard several demonstrations of the capabilities of his process were carried out, in which raw sugar was supplied to the Professor by invited members of the Company, and he afterwards turned it out from his machine as refined sugar of the particular size of grain that had been previously determined on and named by his visitors. Before the operation the visitors were allowed to inspect the room and to feel the machine through a cloth which was placed over it. After satisfying themselves that there was nothing in the room but the machine, the raw sugar they had brought, and the empty vessels to receive the refined product, they withdrew and waited outside the door, where they could hear the sound of the machinery in motion. After about an hour and three-quarters, they were readmitted, and in place of the raw sugar found the empty vessels filled with snow-white sugar crystals of the size they had specified.

Professor Friend's refusal to impart his secret to anyone but his wife might easily have prevented it from ever being utilised, if a stipulation had not been made, on behalf of the Company, that it should be expressed in writing and deposited with trustees, who should open it in the case of the death of both the inventor and his wife. Since his death, however, the embargo of secrecy has been so far removed that the Company have opened negotiations for disposing of the working rights in Great Britain, some of the British colonies, and in France.

In as far as the process has been permitted to be divulged, it appears to possess several remarkable features, more remarkable than would be expected from the mere use of electricity, except by those whose ignorance leads them to credit that agent with any possible or impossible kind of mysterious power. In the first place, no syrup is produced, and consequently boiling does not enter into the process; animal charcoal is also dispensed with, and through the whole of the operations the sugar is used in the dry state only. The refining process lasts about four hours; that is, the refined sugar is formed within four hours of the time when the machinery is set in motion, and is then produced continuously as long as the raw sugar is supplied. The lowest qualities of crude sugar are refined with as much ease, and as inexpensively, as those of the best quality. The quantities dealt with, which have included beetroot, Java "stoops," etc., have been from ten pounds up to over three tons at a trial, and the machinery now nearly completed is estimated to have a daily output of 500 tons. The product is described as a hard, white, crystalline, sugar, containing 99·90 per cent. of pure cane sugar—that is to say, practically of perfect purity. This result contains within one per cent. of the whole saccharine matter of the raw sugar, whether it be in the condition of cane or invert sugar and whatever its quality. Any description of refined sugar can be produced, and any size of grain. The crystalline form and structure as seen under the microscope differ entirely, it is said, from those of ordinary sugar. There are, it seems, two main divisions of the machinery—one by which a molecular transformation in the sugar is produced, and the other in which the transformed sugar is formed into crystals of the required size. This second, or granulating part seems to be that in which a difficulty has occurred in manufacturing on a large scale. This difficulty, however, is stated to have been overcome. The first division of the machinery is that which contains the Professor's chief secret, and of which he was most jealous of all. He had it established in a special strong room at the top of the building, and over the door was affixed an announcement which declared that any one venturing inside this secret apartment would meet with instant death—a threat which we are told, he had taken precautions to carry into effect.

The cost of production is, of course, one of the chief considerations to be weighed in the establishment of a manufacturing enterprise. In this respect the Electric Sugar Refining Company seems very fortunate. The cost of the refining process is not to rise above 3s. 9d. per ton, or at least the Professor's shares are to receive no dividend if that price be exceeded. By this means a profit of £4 per ton is said to be possible. The introduction into New York of the new manufacture is said to be looked forward to in the hope that it will break the great monopoly called the Sugar Trust, which controls all dealing in this article. If the anticipations of the Company be realised at least two great benefits will be conferred on sugar consumers—the diminished cost of sugar will provide a further source of cheap food, and the clear crystalline structure of the new production will greatly increase the difficulty of adulteration.

THE MAGNETIC PROPERTIES OF GASES.—According to the recent experiments of Professor Toepler, oxygen is the most magnetic of all gases; next follow atmospheric air, nitric oxide, hydrogen, and carbon monoxide.

Reviews.

Bees and Bee-Keeping; Scientific and Practical. A Complete Treatise on the Anatomy, Physiology, Floral Relations, and Profitable Management of the Hive Bee. By Frank R. Cheshire, F.L.S., F.R.M.S., Lecturer on Apiculture at South Kensington. With numerous Illustrations of the Internal and External Structure of the Bee, and its Application to Plant Fertilisation; Bee Appliances and Methods of Operation, Diseases, etc. Vol. I., *Scientific.* London: L. Upcott Gill.

To many persons, even of the "educated and respectable" classes, an elaborate work in two goodly volumes on the hive-bee will seem a surprise. But if they will take the trouble to follow the author they will, we believe, find here matter of great and varied interest. Mr. Cheshire is a man evidently familiar—practically familiar—with his subject. But at the same time he is miles apart from the rule-of-thumb bee-master of the old school. He tells his readers that "practice without intelligent insight only stereotypes; but practice, hand-in-hand with accurate knowledge and observation, works out perfection"—a principle that holds good in every sphere of industrial art. He, therefore, takes his stand upon a sound general acquaintance with insect structure and insect life, more especially that of the Hymenoptera, and most especially with the *Apidæ*, the group to which the domestic honey-bee belongs.

The account given of wild and hive bees, of the economy and general structure of the latter, and of their nervous and digestive systems, etc., is not merely accurate but has the advantage of being conveyed in intelligible language, not over-loaded with newly-coined technical terms, and is illustrated with clearly drawn figures.

A very interesting chapter is that devoted to the organs of special sense, the antennæ and the eyes. The author considers it highly probable that bees—he might have extended this proposition to insects generally—"possess modifications of sensibility which we can no more truly realise than can the blind imagine the difference between red and green." This opinion few observant entomologists will seek to gainsay. The sense of touch he refers to the tactile hairs distributed in different parts—an adaptation which we find to some extent even in vertebrate animals, *e.g.*, the whiskers of the cat. Taste he seeks for in the mouth and tongue, and also, possibly, in the nerve endings of the epipharynx. Hearing and smelling he places both in the antennæ, which he describes and figures very carefully. That these wonderful appendages are at the same time the organs of touch, as we find it to be the case in some mammalia, need not surprise us. He points out that Sir John Lubbock does not deny to bees the possession of hearing, but merely takes a negative position, his own experiments having proved indecisive. These experiments, however, the author regards as inconclusive in face of certain facts which may be observed in dealing with bees. Hence he does not deny all possible value to the "key and swarming-pan" of old times.

Facts which he mentions prove not merely the possession of smell by insects, but its localisation in the antennæ. He refers to the collection of moths by the practice of "sembling," which he has personally witnessed on Bagshot Heath. Among bees he mentions that the drones have a far more highly developed sen sory surface in the antennæ than have the workers and queens. This superior development of the olfactory organs in the male sex is what we find in many moths, in gnats, and in many beetles, and has its obvious physiological meaning. We do not find that the author refers at all to the utterly untenable hypothesis of Wolf and Graber, who actually say that "no one has proved that the antennæ of insects display any sensitiveness to odoriferous matters."

The simple eyes which bees have on the top of the head, in addition to the facetted eyes, Mr. Cheshire considers adapted for sight at short distances. The reason why some insect species possess this two-fold visual apparatus whilst others have only the large compound eyes has not been fully ascertained.

Experiments—especially those conducted by Sir John Lubbock—have shown that bees distinguish colours, and have their preferences for certain tones.

From considerations of space we are compelled to pass on to a very interesting chapter, which treats on bees as fertilisers, florists, and fruit-producers. Beginning at the end of this chapter, we find notice of a fact, little known, but equally noteworthy for its scientific interest and its practical importance. An apple, for its production in perfection, "demands no fewer than five independent fertilisations. If none are effected, the calyx, which really forms the flesh of the fruit, instead of swelling, dries and soon drops. An apple often develops, however, though imperfectly, if four only of the stigmas have been pollen-dusted, but it rarely hangs long enough to ripen, the first severe storm sending it to the pigs as a windfall. I had 200 apples, that had dropped during a gale gathered promiscuously for a lecture illustration, and the cause of falling, in every case but eight, was traceable to imperfect fertilisation."

Another very interesting fact here recorded is that some blossoms, *e.g.*, the great wild bindweed (*Convolvulus sepium*) remains open at night if the moon is shining, and thus is able to attract moths, which carry on the task of fertilisation when bees, wild and domestic, are asleep. But the whole of this chapter we can recommend for most careful study as giving excellent instances of the mutual action of insects and flowers. It is to be regretted that some persons still believe that the visits of the hive-bee, or indeed the so-called humble bee (should be *hummel* bee), to gardens and orchards are for the purpose of devouring the fruit, especially raspberries. The author is justified in saying, by way of peroration:—"The bee, with all her wonderfulness, is only one wheel within many; she takes to truly give, for seeds, flowers, and fruits follow in her train. Her honey is but a fraction of the results of her labours." Rightly does he remind us that a great part of the mischief of a bleak, ungenial season like the present is not so much the direct action of chilly winds and unseasonable frosts as of the circumstance that the bees are hindered in their work of fertilisation.

ROMAN BATH, AND RECENT DISCOVERIES.—II.

(Continued from p. 184.)

THE records of Roman life in Britain are but few, and chiefly confined to military movements and successive acts of subjugation, but we know that after the subjugation of the south and west of Britain, under the Emperor Claudius, this part of the island was not harassed by war, and seems to have developed its resources under an orderly government, as we find throughout Somerset and Gloucestershire, as well as in Wilts and Dorset, remains of fine Roman villas, situated on the lines of main roads which traversed the country in different directions. Beautifully executed mosaic pavements have been found in these villas, as at Woodchester, Lydney, Cirencester, Bath, Wellow, and places too numerous to mention. Within a radius of five or six miles around Bath fourteen or fifteen sites have been opened. Along the line of the Mendip hills abundant traces of Roman mining have been left, and many pigs of lead, bearing the Roman stamp, have been found, from the date of the Emperor Claudius to that of the Antonines. Hoards of Roman coins have also been discovered, one very lately at East Harptree, between Wells and Bristol, on the line of Roman road along the Mendip Hills, connecting the Roman port on the Severn, at the extremity of Breandown, near to Uphill, with Old Sarum, and from thence leading to the seaports on the south coast of Britain. In the district of Mendip was obtained the lead which is found so copiously used in the coating of the Roman baths at Bath and in the formation of the pipes for conveying the hot water to the baths. A pig of Roman lead bearing the stamp of the Emperor Hadrian was found in Bathwick, on the site of Sydney Buildings, and is now in the Museum of the Literary and Scientific Institution. The lead-workings in the Mendip Hills lie chiefly on the surface, and the lead ore has been entirely extracted by the Romans, as no fresh veins have been found; and lead, in more recent times, has been procured by re-smelting the Roman scoria which covers many acres, and from re-washing the old refuse from former washings, called "slimes." Coins of a very early date are found among the refuse, as well as Roman finger-rings with engraved stones.

The Roman coins found in Bath and the neighbourhood begin with the name of the Emperor Claudius, and continue to the latest period of Roman occupation. Much variety of pottery has been found, and glass, as well as bronze implements, most of which are preserved in the Museum of the Literary and Scientific Institution, though many curious articles and articles of value are known to have passed out of the city and found their way into private collections. The inscribed stones found within and around the city are not the least interesting remains to be recorded.

They consist of altars to the tutelary goddess Sul, or Sul-Minerva, and confirm the statement of the historian Solinus. She is also coupled with the "Numina Augustorum," or divinity of the reigning emperors, on one altar, and there is also a tombstone to her priest, named Calpurnius Receptus, and an altar to her attendant nymphs, called *Sulevæ*. There are seven stones which record her name. Many funereal monuments have been preserved, though many have been lost, of which a record remains.

They are some to soldiers of the 20th Legion, located at Chester. One to a soldier of the 2nd Legion, entitled Adjutrix, Pia, Felix; one to an aged *decurio* or magistrate, of Gloucester, Glevum being ranked as a *colonia*.

A stone found at Combe Down, a mile south-west of Bath, records the restoration of the officers' quarters, which had fallen into decay, another the repurgation of a *locus religiosus*, dedicated afresh to the divinity of the emperors. Among the many fragmentary remains found in clearing out the Roman reservoir into which the hot springs were received, were two small bronze tablets containing inscriptions difficult to decipher, and only one of which has been read, but variously interpreted. It seems to be either an imprecation (*defixio*) or anathema, having a list of names attached to it. Many coins and two metal vessels and other articles were also found, which are now lodged in cases in the Pump-room, but are very indifferently arranged. It would be impossible in this short notice to particularize all the objects of interest which have been discovered, but which when arranged may help to furnish a very instructive museum of Roman remains, if united with those already preserved in the Museum of the Literary and Scientific Institution.

No notice of Roman Bath can be complete without specifying the roads which led to it and the bridge by which the river Avon was crossed. The present bridge has succeeded a bridge constructed in Roman times, some indications of which still remain. The principal Roman road, called the "Foss," coming from the seacoast of Devonshire, and traceable nearly from Seaton, passed through Ilchester, a well-known Roman station (Ischalis), continued on until it crossed the Mendip Hills near Shepton Mallet, and afterwards approached Bath by what is still called "Holloway," below which it crossed the river Avon and entered Bath by the south gate.

This road is laid down on the ordnance map, and remains perfect in many places, having recently been examined and its structure recorded. It passed through the city by the north gate, now destroyed, but the mediæval gate seems to have incorporated the Roman gate in its structure, if you can trust the drawings that remain. From this point it passed through the suburb of Walcot, and its course has been traced by the remains of Roman interments and memorials which have been found along its course, until it came to Bath-Easton, where it ascended the hill and made direct for Cirencester, the ancient Corinium. The course thither is distinctly traceable past the *shire-stones* which mark the contact of the three counties Somerset, Wilts, and Gloucestershire. It afterwards continued its course to Lincoln (Lindum), and from thence to the sea.

Another line of Roman road came from South Wales. Leaving the Roman stations of Caerleon and Caerwent, well known as the location of the "Legio Secunda Augusta," it crossed the Severn above its junction with the Avon, and came on to Bitton, where are distinct remains of a Roman station, and from thence entered Bath, passing through Weston and entering by the west gate of the city. It united its course with that of the Foss until it came to Bath-Easton, where it branched off and passed up the hill to Bathford, and continued its course straight to Marlborough (Cunetis), and so on to Silchester, the ancient Calleva.

These were the *main roads* in Roman times, but others, of inferior construction, have been traced.

A principal road came from Gloucester (*Glevum*), which united with the road commonly called the *Via Julia* not far from Bristol, and so passed on to Bath. The Roman town of Bath was thus connected with all the principal stations in the west of England; and though there are no lapidary records by means of which we can ascertain by what troops the city was garrisoned, or any stamped tiles such as are found at Caerleon, bearing the impress of a particular legion, yet there is no doubt that Aquæ Solis was fortified and held by Roman troops.

The tombstones that are found record the names of legionary soldiers, both infantry and cavalry, also of centurions, but these may have come for the benefit of the thermal springs, and have died in Bath.

Remains of Roman camps exist on Lansdown and on the Bathwick side of the river, which seem to have been occupied as summer stations.

Very interesting remains have been found at Camerton, on the Foss Road to the south-west of Bath, which appears to have been a Roman posting-station, and remains of many houses have been found there, as well as the foundations of a semi-circular building. Many coins have also been found here, which were collected and recorded by the Rev. J. Skinner, a former rector.

Those members of the British Association who visit Bath at the approaching meeting and are interested in the Roman remains will find ample opportunity of gratifying their taste, and will also find every facility, as a handbook has been prepared specially for the visitors, giving complete details of the city and its surroundings.

MEETING OF GERMAN NATURAL PHILOSOPHERS AND PHYSICIANS AT COLOGNE.

At the last meeting of the Society of Natural Philosophers and Physicians in Wiesbaden, in 1887, a resolution was passed appointing Cologne as the centre for the sixty-first meeting of the Society, and, thanks to the untiring activity of the several committees and the co-operation of the Town Council, preparations for the reception of the guests are well advanced.

The Wallraf-Richartz Museum, the Museum of Industrial Arts, the Historical Museums, and the Rathhaus (Council Chambers), in Cologne, will be opened free to members on production of their cards, at any time during the week of the meeting.

There will be three general meetings, on the 18th, 20th, and 22nd September, in the large Gürzenich Hall; the meetings of the thirty sections from the 18th to the 20th September will be held in the halls of the Grammar School (Kreuzgasse 2-4), and of the Girls' High School (St. Apernstrasse 53-59).

Tickets for members and non-members (as well as ladies), and for the banquet (5 marks each) will be for sale at the Enquiry Office, from the 1st to the 12th September. Members are recommended to bespeak their apartments early.

The committee hopes for a large attendance of natural philosophers, physicians and friends of science, and will endeavour to accord them a fitting reception.

All communications referring to the sections must be addressed to the chairman of such sections; those concerning the exhibition must be addressed to the secretary of the exhibition committee, Herrn Dr. Eltzbacher, in Cologne, Sachsenhausen 9.

Foreign members can obtain their tickets in advance by applying to Herrn Banquier Moritz Seligmann, Kasinostrasse 12 and 14; 12 marks must be sent for members, 6 for a lady's ticket.

Herr Th. Deichmann has very kindly arranged that all the offices are to be in close proximity to the central station; the reception, boarding, and enquiry committee are all located at No. 6, Bahnhofstrasse. These offices will be open on the 16th September and following days, from 8 a.m. to 8 p.m. The necessary cards, badges, for the members and their ladies, the programmes of the meetings, the daily papers, etc., together with the tickets of the banquets, theatre, and Rhine excursion, will all be obtainable at the enquiry offices.

The boarding committee will supply all necessary information about apartments.

Abstracts of Papers, Lectures, etc.

IRON AND STEEL INSTITUTE.

The autumnal meeting of this Institute was opened at Edinburgh on the 21st inst. by the Lord Provost, who said that on the part of the Municipality he had the greatest pleasure in giving them a very hearty welcome to the ancient city of Edinburgh. His predecessor in office was once asked what was the principal industry of Edinburgh. He (the late Sir George Harrison) answered that it was education. If that was true at the time in question it was still more true now; and Edinburgh was a great resort from all parts of the world for educational purposes. What he would like particularly to bring before them was this, that in all their large schools in the city technical education formed a very important part of the instruction. He did not know that there was a large school in Edinburgh, either private or public, in which there was not a very large technical department, and during the last two or three years the old institution of Heriot's Hospital—a building which, he was sure, those of them who were strangers to Edinburgh would be glad to see, as being not only notable architecturally, but educationally—had been re-modelled, and in unison with the Watt College combination, had added very much to the technical instruction carried on in the city. First of all and foremost, however, they had now a Professorship of Engineering in the University, and, fortunately, also, they had a Professor of Engineering who devoted all his energies to the advancement of engineering. Quite recently, he was glad to say, Professor Armstrong had been fortunate enough to obtain a very large legacy from a citizen of Edinburgh, who lately died; and he had no doubt that, in a short time, and through that legacy, the material used in the department for the purposes of instruction would be augmented in a very important manner.

After Mr. Daniel Adamson, the President, had replied on behalf of the members of the Council and of the members present, the members adjourned to the Examination Hall, where the business of the Institute was conducted.

The President, on taking his seat, said that in the first place the Council had unanimously chosen Sir James Kitson, of Leeds, to be the president of the Institute for the two succeeding years. He thought it was a fitting thing that a gentleman connected with the old Yorkshire iron industry should be appointed to that position. The members would be interested in learning that the autumnal meeting of 1889 was to be held in Paris.

After the minutes of the last meeting had been read and approved, the President read a paper—"On a horizontal compound lever testing machine of 15,000 powers, with further recording lever of 15,000 powers." The machine was composed of one strong box framing, and being self-contained, only required a very light foundation, the object being more especially to prevent vibration, which might destroy the high sensitiveness of the machine when testing with great delicacy. The quadruple levers are enclosed in a box having glass sides, so that the operation might be seen, and in order to note the force by the floating weights on the fourth or registering lever. After giving a technical description of this valuable machine, Mr. Adamson concluded by saying that he did not claim to be the author of the multiple lever testing machine. In the earliest investigations, a single lever was used, the load being measured by suspending 56lb. weights, and when the full load was put on the specimen instant rupture followed, the load not being capable of being reduced as the breaking elongation took place. This latter principle was made known by him in a paper which he read before this Institute at Paris in 1878. The American "Emery" machine now being exhibited in London was also a multiple lever apparatus, but it had two hydraulic chambers with reducing areas, as 1 is to 20—the lever system being as 1 is to 20,000—making the total ratio of the hydraulic chambers and the lever system together as 1 is to 400,000; and it was reported that the motion of one-millionth of an inch on the specimen produced a motion of the indicator rod o four-tenths of an inch. This high indicating power would be found of great value in noting the amount of force necessary to produce permanent set. The earlier tests made by Mr. Kirkaldy, in Glasgow, were with a single lever machine, but he no doubt saw the necessity of greater accuracy and higher refinement. Mr. Adamson believed that Mr. Kirkaldy was the first to adopt the multiple lever system, and his tests were taken as the standards of accuracy by the whole of the professional community.

Sir Lowthian Bell (who presided during the discussion on Mr. Adamson's paper) said his recollections of the iron industry of West Yorkshire extended back for many years. In those early times no manufacturer thought of employing a testing machine on his own premises. Now, however, it was necessary for a manufacturer of any pretentions to have such a machine. The qualifications of testing machines involved not only great accuracy of performance, but, owing to the amount of work to be done by them, they must be of such a construction as to enable those entrusted with them to do the greatest amount of work in the shortest possible time. He believed that no one had contributed to popularise the use of testing machines more than Mr. Adamson.

Mr. R. A. Hadfield (Sheffield) then read a paper on manganese steel. He said that it would hardly have been thought probable that the ordinary properties and nature of the metal iron could be so completely changed as it is now known to be by its alloy with a second metal, manganese. This new steel had drawbacks that at present interfered with its usefulness and commercial introduction. The chief one met with was its hardness. The majority of articles used in machine construction of any kind must be tooled, fitted, or adjusted to shape, and this was almost out of the question with this material—in fact, in its machining it might be described as equal to the hardness of chilled iron. No doubt, by experiments and perseverance, this and other difficulties would be overcome, and possibly this very drawback might eventually prove a blessing in disguise, inasmuch as should some better method of machining or finishing be perfected it should be equally beneficial to all branches of engineering. He briefly described the early history of manganese, ferro-manganese, and the manufacture of ordinary steel, observing how much the world at large has been indebted to the early experimentalists with that now all-important metal manganese. Mr. Hadfield described in detail the experiments on manganese steel, remarking that this material is not so liable to honeycombs as ordinary steel, and the addition of silicon is unnecessary. It is very fluid, and can be run into thin sections, but cools more rapidly than ordinary steel, and its contraction is decidedly greater. It is manufactured by any of the ordinary steel-making processes, the basis, *i.e.*, the material before the ferro-manganese is added, being preferably decarbonised iron (practically pure iron, Fe) or mild steel. The ferro-manganese is added in a molten state, or very highly heated. The steel is then ready for casting into ingots or other forms. It is most important that the carbon should be kept as low as possible, especially in the 14 per cent. material, where it should not exceed about 1 per cent., or the product will be inferior. For this reason, the ferro-manganese used should contain high percentages of manganese, such as 80 to 84 per cent., now easily procurable at as low a price as £9 per ton. About 0·50 per cent. of the manganese is oxidised—that is to say, to obtain a steel with about 13 per cent. about 13½ per cent. of manganese must be added. It will be readily understood that the ordinary crucible steel-making process is not suitable for the making of this manganese steel, on account of the manganese cutting or slagging the pots. He then proceeded to give a more exact description of the qualities of the material. Referring to its peculiar hardness, he said it was somewhat difficult to describe this quality, because all the specimens are exceedingly hard—in fact, it is scarcely possible to machine any of them on a practical scale. Yet such hardness varies considerably in degree, being most intense in the cast material containing 5 to 6 per cent. of manganese which no tool will face or touch. A slight decrease then occurs, and the 10 per cent. material gives comparatively the softest condition. Upon a further addition of manganese an increase again takes place, and at 22 per cent. it is very hard, though still not so much so as in the 5 per cent. material. It was difficult to explain the cause of this hardness, because manganese, when added to copper, does not produce this remarkable change, and why, therefore, should manganese added to iron, which in its pure state is but little harder than copper, produce such a hard alloy? Apparently iron must have some property of changing its form in a way not yet understood. As bearing upon this point, a well-known metallurgist, Mr. John Parry, of Ebbw Vale, said in an article on "Spectroscopic Analysis of Iron and Steel," that in his opinion the search for and determination of substances technically termed impurities in iron and steel is nearly over; we have little left for research except the iron itself. It was possible therefore that in this direction a clue might be furnished to many as yet unresolved problems, and possibly in the manganese steel there is some change in form of the iron itself. Manganese steel, notwithstanding its high proportion of metallic iron—the most magnetic metal known—possesses the peculiar property of being almost entirely non-magnetic. Rinmann, as far back as 1773, noticed that manganese alloys gave non-magnetic material. This was also noticed by Mr. David Mushet about 1830. This Dr. Hopkinson suggested that the mangenese in the steel was not merely mixed mechanically with the iron, but that it entered into the molecule in such a way as to destroy its magnetic properties, which are the same in either its cast or forged, hard or toughened state. Another peculiar physical characteristic of manganese steel noticed by Professor Barrett was as follows:—Some years ago he discovered that when iron or steel heated to whiteness was allowed to cool in a dark room, the moment the temperature of the steel reached obscurity a sudden revival of temperature occurred, an outward rush of heat taking place, and the steel glowing again red hot. This afterglow or recalescence, which occurred in all ordinary steel, did not take place with this material, as was the case in other non-magnetic metals, such as platinum, silver, copper, etc. In some recent experiments it had been noticed that drillings of 20, 30, and 36 per cent. manganese steel, which were practically unattracted by the magnet, after being heated to redness and allowed to cool, exhibited a considerable increase in magnetic susceptibility. This occurred even when the drillings were heated and cooled in hydrogen. The fact stated could scarcely be due to oxidisation of the manganese owing to heat, because the weight before and after the experiments was the same. In conclusion, he said it was not possible within the scope of a paper to deal with the many interesting points raised by the peculiar qualities of manganese steel. His hope in bringing this matter before the Iron and Steel Institute was as stated by Mr. Howson, when addressing the Cleveland Institute of Engineers last year: "Individual effort, although exerted in the most useful direction, is often of but small account when taken alone. It is only when submitted to the scrutiny of many minds, and freely discussed, that it proves of real value." He hoped it might be so in the present instance.

In the course of the discussion, M. Gautier described experiments made in France in the application to practical uses of manganese steel. The first application, he said, was in the direction of making horse-shoes. The alloy contained 12 per cent. of manganese. But a difficulty was found in the fact that if nails of the same material as the shoe were used for fastening on the shoes, no file could be found of sufficient hardness to operate upon them. Nails, however, of ordinary steel were used without any practical disadvantage, when the heads were embedded below the surface of the harder metal. Experiments on a large scale were being made with some regiments of French cavalry. Some success had attended the casting of wheels of manganese steel for small mining cars. The difficulty they found was to withdraw the castings rapidly enough out of the moulds, because, as stated in the paper, the manganese steel was much improved by softening in water. It was a curious fact that that which was a hardening process for other metals was a softening process for manganese alloyed with iron. The difficulty was to put it into the water quickly enough and at the proper temperature; the cast wheels when extracted from the moulds shrinking, if the extraction was not done rapidly. To overcome this was, however, a question of practice. Then experiments were being made in the manufacture of armour plates. The difficulty here was the management of heavy weights of the steel. They found also that the manganese steel which they made contained too large a percentage of carbon, and some cracking occurred when the plates were dipped into water. They would, he believed, soon be able to manufacture a better quality of steel, which would resist the impact of the shells. The shell was broken, but the plate also was broken and cracked, and two or three shots brought it down. He should be glad at the next meeting of the Institute to give more information on this practical question.

In the afternoon a visit was made to Leith Harbour and Docks, down the north sides of the Albert and Edinburgh Docks, round the east end, and up the south, to North Leith Station, where the train for Edinburgh was joined.

On the 22nd, the first paper read was on "The Forth

Bridge," by Mr. F. E. Cooper, M.I.C.E., resident engineer. After a reference to the Forth Bridge as a most important link in railway communication, he said—The total length of the viaduct will be 8,296 ft., or nearly 1⅝ mile. There are two spans of 1,710 ft., two of 680 ft., and fifteen of 168 ft. girders, four of 57 ft., and three masonry arches of 25 ft. The clear headway for navigation will be not less than 150 ft. for 500 ft. in the centre of the 1,710 ft. spans. The extreme height of the structure is 361 ft. above, and the extreme depth of foundations 91 ft below the level of high water. There will be about 53,000 tons of steel in the superstructure of the viaduct, and about 140,000 cubic yards of masonry and concrete in the foundations and piers. The main piers, three in number, consist each of a group of four masonry columns, faced with granite, 49 ft. in diameter at the top and 36 ft. high, which rest either on the solid rock or on concrete carried down in most cases by means of caissons of a maximum diameter of 70 ft. to the rock or boulder clay, which is of almost equal solidity. The stresses to be provided for are those arising from the weight of the structure itself, the rolling load, and wind, as well as from change of temperature. The rolling load has been taken as one ton per foot run on each line of rails over the whole structure, or a train on each line, consisting of 60 short coal trucks of 15 tons each, headed by two locomotives and tenders, weighing in the aggregate 142 tons. The wind pressure provided for is a pressure of 56 lbs. per square foot, striking the whole or any part of the exposed surface of the bridge at any angle with the horizon, the total amount on the main spans being estimated at nearly 8,000 tons. The material used throughout is open-hearth, or Siemens-Martin steel. That used for parts subject to tension is specified to withstand a tensile stress of 30 to 33 tons to the square inch, with an elongation in 8 in. of not less than 20 per cent.; that subject to compression only a tensile stress of 34 to 37 tons per square inch, with an elongation in 8 in. of not less than 17 per cent. Strips of each class 1½ in. wide are to bend cold round a bar, the diameter of which is double the thickness of the strip. The tensile strength of the rivet steel is 26 to 30 tons per square inch. The superstructure of the main spans is made up of three forms of double cantilevers resting on the three piers before mentioned. Those on the shore sides are 1,505 ft, and that on Inch Garvie (an island fortuitously dividing the deep water space into two channels of nearly equal width) is 1,620 ft. in length. The effective depth over the piers is 330 ft. and at the ends 35 ft. The centre portions of the two 1,710 ft. spans on each side of Inch Garvie are formed by two lattice girders 350 ft. in length and 50 ft. deep in the centre, and 37 ft. deep at the ends.

Mr. T. G. Clark, of New York, said the work was of such a novel nature, so different from anything which had ever been done before, that one felt extreme modesty in giving an opinion at all. The point, he thought, which would strike the visitor for the first time would be that the bridge was not only a very strong bridge, but that it looked very strong. It carried to the eye that appearance of stability which every bridge ought to have. When they looked at the bridge, they would see that it was a great object lesson in the mode of calculating the strains upon frame structures. Everything was done in a plain and common-sense manner, and the great difference between the Forth bridge and all other bridges of British construction was the fact of the great concentration of material along the lines of strain, the object being to expose as little surface as possible to the enormous force of the wind. It would not be possible to appreciate the architectural features of the bridge until the scaffolding was removed, but when that was done he believed it would be said that the structure was one of the finest pieces of architecture in the world.

Mr. Wrightson (Stockton-on-Tees) said he thought one of the features which ought to be recognised in this great engineering work was the immense leap forward which it represented in building practice. There was another bridge crossing the East River in New York, which approximated to the span of the Forth Bridge, but that bridge, wonderful though it might be, was merely an extension of the suspension principle so well known in bridge work, whereas this was, as he had said, a leap forward of a very remarkable character. He did not think there was any bridge of cantilever structure which approached even half the span of the Forth Bridge. It was always a very interesting thing to watch any sudden leap forward in engineering practice, but, as a rule, they found that the most successful works were carried out by a gradual movement forward, and not by these sudden leaps.

A paper giving a description of a new pyrometer by Professor J. Wiborgh, School of Mines, Stockholm, was read by the secretary. It was stated that compared with measures of temperature of the same sort that had previously been used, this new air pyrometer had several important advantages, as it was of a simpler construction and could be handled by a common workman.

A paper by Professor Crum Brown (of Edinburgh) on the chemical processes involved in the rusting of iron was read by Dr. Gibson. The writer of the paper said his attention was first called to the subject by observing what happened when a drop of rain fell on a clean, bright surface of iron. At first for a short time the drop remained clear, and the bright surface of the iron was seen through it; but soon a greenish precipitate formed in the drop, and this rapidly became reddish-brown. The brown precipitate did not adhere to the iron, but was suspended in the water, and became a loosely adhering coating only when the water had evaporated. In speaking of rusting he meant the formation of rust on the surface of metallic iron exposed to ordinary atmospheric conditions. It had been conclusively shown that the necessary conditions for the production of rust are—1st, metallic iron; 2nd, liquid water; 3rd, oxygen; and 4th, carbonic acid; both the latter being dissolved in the the liquid water. Iron remained quite free from rust in an atmosphere containing oxygen, carbonic acid, and water vapour, so long as the water vapour did not condense as liquid water on the surface of the iron. He then considered the action on iron of the three substances —liquid water, oxygen, and carbonic acid. The continuation of the process of rusting was not dependent on new carbonic acid absorbed from the air, but the original carbonic acid, if not removed, could carry on the process indefinitely as long as liquid water was present and oxygen was supplied from the air. Once the process was started, it went on more rapidly, because the porous rust not only did not protect the iron, but favoured by its hygroscopic character the condensation of water vapour from the air as liquid water. A piece of iron, therefore, which had begun to rust would continue rusting in an atmosphere not saturated with water vapour, an atmosphere in which a piece of clean iron would not rust, because liquid water would condense from such an atmosphere on the hygroscopic rust, but not on the bright iron.

The Secretary read a paper by Mr. W. J. Millar, C.E. (Glasgow), on the subject of the Glasgow coalfields, in the course of which he stated that the order of superposition and the average thickness of the coal seams in the neighbourhood of Glasgow to the eastwards are as follow:—Upper coal from 2 ft. to 5 ft. thick; ell coal from 5 ft. to 7 ft. thick; pyotshaw coal from 2 ft. 8 in. to 4 ft. 6 in. thick; main coal from 3 ft. 6 in. to 4 ft. 8 in. thick; humph coal about 30 in.; splint and virgin coal from 5 ft. to 7 ft.

In the afternoon a large number of members of the Institute left the city for the purpose of visiting the Forth Bridge.

On August 23rd about 500 members visited the Glasgow Exhibition, where they were hospitably entertained by the President of the Exhibition and the Reception Committee.

Halifax Scientific Association.—A party, on August 11th, under the guidance of Mr. James Spencer, visited the railway cutting at Netherton Bridge. It is crossed in an easterly and westerly direction by a great "fault," or dislocation of the strata, whereby the strata below the bridge is depressed about 48 yards below the corresponding beds above the bridge. This dislocation of the strata can be traced in a westerly direction by Illingworth Church, across Wheatley Valley and New Delight, into Luddenden Dean; and in an easterly direction by Shibden Head Pit to Brackenbeds. Another fault was pointed out running along the hillside from Netherton to Catherine Slack, and across Shibden Dale to Barehead, where it meets another great fault, which runs in a north-westerly direction from Coley Church, by Shibden Head Pit to Bradshaw, intersecting the Illingworth fault at Shibden Head Pit. Upon reaching Shibden Head Pit, Mr. Spencer pointed out specimens of nodules which are found in the hard-bed coal, and which sometimes contain specimens of fossil plants in a beautiful state of preservation. Some of these specimens were examined by the party, and explained by the guide, as were also specimens of "baum pots" containing marine shells.

Thirsk and District Naturalists' Society.—On August 20th the monthly meeting of this Society was held, Mr. R. Tennant presiding. Mr. Wm. Foggitt, botanical secretary, exhibited numerous specimens in his department which had been gathered in the locality. Mr. Robert Lee, vertebrate secretary, showed some very fine stuffed birds; he also gave some particulars respecting the sand-grouse, a native of Central Asia, several of which visited this country about twenty-five years ago, but had not been seen since until the present year, and recently they had been noticed in various parts.

Middlesex Natural History Society.—The members of this Society assembled on August 18th, at Edgware, under the directorship of Mr. Sydney T. Klein, and proceeded through the town of Edgware to the old church at Whitchurch, where the Rector most freely explained the various objects of interest, viz., the beautifully painted ceiling, the tomb of the Duke of Chandos and Buckingham and family, the organ upon which Handel played when he held the appointment of chapel-master, and in the churchyard the tomb of the harmonious blacksmith. Canons Park, formerly the seat of the Duke of Chandos, was also visited, Brockley Hill being reached by the old Roman road of Watling Street, where the site of the Roman town of Sulloniacæ was inspected. The members were then taken through private grounds to examine the obelisk of Cassivelaunus, a Roman encampment, two ancient barrows, one in course of being opened, and a facsimile of Rousseau's tomb.

Leeds Naturalists' Club and Scientific Association.—At the meeting held on Aug. 20th, Mr. John Stubbins, F.G.S., F.R.M.S., presiding, Mr. Oswald Dawson showed the following shells taken in the immediate vicinity of Leeds:—*Planorbis corneus, Limnæa stagnalis, L. vortex, Helix rotundata, Pupa umbelicata, Clausilia rugosa, Cochlicopa* (*zua*) *lubrica.* Mr. W. Kirkby exhibited the following plants from Grange and district:—*Epipactus palustris, Climatis vitalba, Polypodium calcarium, Myrica Gale,* in fruit; *Rhamnus frangula,* in fruit; *Andromeda polifolia, Rhyncospora alba, Geranium pusillum, Clavaria cineria.* Mr. J. W. Addyman also showed the following plants: *Sonchus arvensis, Angelica sylvestris, Hypericum hirsutum, Eupatorium cannabium, Gymnadenia Conopsca, Galium palustre, Epilobium hirsutum, E. montanum, E. parviflorum, Lactuca muralis, Sparganium ramosum, Alisma plantago, Stachys sylvatica, Chrysanthemum odorum, Betonica officinalis, Potamogeton perfoliata.*

Falmouth Naturalist Society.—This Society held its fifth field meeting on Friday, 24th inst., at Perran Wharf Valley. The party left Market Strand, Falmouth, and after a pleasant drive reached Sticken Bridge, where they were met by Mr. T. J. Porter (of Perran Wharf), who kindly pointed out the various objects of interest *en route* to Ponsanooth. Several elvan courses exist within a radius of a few miles of this neighbourhood. The first runs through St. Gluvias' parish, Penryn, and appears again at Mylor. This elvan is coarse-grained, and contains a large quantity of mica. At St. Gluvias it is about 4 ft. wide, dips 40 degs. S., and is very soft and porphyritic. The next elvan is in the granite at Penvose, from whence it runs on to Enys, where it is crossed by another from Treleaver. It is a hard fine-grained quartzo-felspathic rock, with patches of mica, and a few crystals of felspar. Another elvan may be seen on the shore at Carclew. It holds the same course as the one at Carnon Gate. Two elvans have also been quarried beyond Perran Wharf, at Carnon Gate; crystals of felspar, changed to kaolin, and mica, are distributed through them. Towards the back and sides of these elvans, isolated blocks of a harder quartzo-felspathic rock, with a greenish base, and crystals of felspar abundantly occur. The slate between this place and Restronguet Bar is very much contorted, forming anticlinal ridges and beds of a soft yellow sandstone from 6 ft. to 20 ft. wide. About two miles north of Penryn, an elvan has been quarried, and cut through by the railway, near the bridge, on the Truro road. It is a branch of the elvan found in the granite at Trelince. At the cutting it is in slate between granite and greenstone, which it cut through. It is very hard, and has a basis of fine-grained quartz, and felspar in places, containing small plates of mica.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

BALLOONING.

In the *Freeman's Journal* of the 22nd inst. there is a leader on balloons. It is a very interesting article, and ends up by saying that "before long these airy speculations will have assumed a very practical form indeed," meaning we shall soon be able to navigate the air successfully. There are a large number of readers of your valuable and clearly-written paper, I am sure, who would be glad to see a few good articles in the SCIENTIFIC NEWS on the subject.

Some say to even think of "aerial navigation" is absurd; and others condemn balloons altogether, and advocate "flying machines." One of your correspondents gave a very plain hint a short time ago that he possessed exceptional knowledge of the subject.

Should England be the first to become "master of the air" as well as being "mistress of the seas," her lease of life would be indefinitely extended, and the sketching visit to the ruins of London of Macaulay's New Zealander would be at once deferred to the *very* dim and distant future.

Hoping for information from you or your correspondents on the subject. W. P. W.

PRESCRIPTION FOR MOSQUITOES.

I notice in your journal of 17th August prescription for mosquitoes. You say, "We should also be happy to learn whether 'F. B.'s' mixture is better than tincture of '*Ledum palustre.*'" Will you please inform me what this is, and give me some particulars of it, as, having travelled nearly all over the world, I never heard of its being used as an antidote for mosquito bites or a protection from the same. By far the best thing I know of is a preparation from the Margossa tree of Ceylon, which, except from the scent, is unobjectionable, whereas being coated, as "F. B." recommends, with Stockholm tar would be more objectionable than being bitten, I should say. A. BROWN.

55, Woolwich Common, August 21st, 1888.

[The Marsh Rosemary, *Ledum palustre*, otherwise known as Labrador tea, is a shrub growing to the height of 3 ft. or 4 ft. It grows in swampy districts in the north-west of Ireland and Scotland, in the countries around the Baltic, in Siberia, and the Dominion, especially Labrador. The alcoholic extract of its leaves has a very peculiar but not absolutely disagreeable smell. If it be diluted with water and applied to the skin, no sand-fly, mosquito, etc., will, to the best of our knowledge, settle on the person thus protected. We have heard of this remedy and of its efficacy so long that we do not remember who first discovered and applied it. Mr. Brown is right concerning the disagreeableness of "F. B.'s" lotion; but we must remember after all that the bite of a mosquito may mean the injection into the system of the poison of yellow fever or of malaria.—ED. SCIENTIFIC NEWS.]

PETALS OF THE WHITE JASMINE—FERTILISATION OF FLOWERS.

In reply to "Scrutiny" I would observe that the genus *Jasminum* has long been noticed as varying in the number of petals. If I remember rightly, Dr. Lindley gave a series of diagrams in his "Botany for Ladies," but such variations are extremely common in many flowers, as, *e.g.*, *fuchsia*, elder, loosestrife, members of the *Alsineæ*, etc., in which the sepals, petals, and stamens may all vary together. In my work on "The Origin of Floral Structures" I have suggested that it may simply result from nutrition, which brings about such "symmetrical increase or decrease;" so that if a 5-merous state be normal, an excess will produce a flower with say 6-merous whorls; while a deficiency results in a 4-merous one.

With regard to "L. H. A.'s" observations on the flowers of tobacco and evening primrose not being fertilised, the tubular structure of the calyx in the latter, and of the corolla in the former, points to insects with long proboscides as visitors; but as neither plant is indigenous to Great Britain, it is possible that they have not met with a suitable insect; just as *Sphinx convolvuli*, being a comparatively rare insect here, *Convolvulus sepium* seldom sets any seed in our hedges.

I should like to take this opportunity of correcting a misprint in my article on the "Formation of Ice." (SCIENTIFIC NEWS, vol. ii., p. 189). Instead of "*angle of* 30 degs." it should have been 60 degs. or 120 degs.

GEORGE HENSLOW.

ANSWERS TO CORRESPONDENTS.

LEOPOLD VINNING. — The original statement is correct. Pressure per square foot is not the same as overturning force, into which leverage enters. The remarks about leaping apply equally to lifting by the hands.

ANNOUNCEMENTS.

WHITWORTH SCHOLARSHIPS.—The Department of Science and Art of the Committee of Council on Education notifies that the following candidates have been successful in the competition for the Whitworth scholarships of the value of £125 a year (tenable for three years).—James Whitaker, student, Nelson, Lancashire; James Mair, engineer, Glasgow; C. Humphrey Gilbert, engineer student, Nottingham; and John Calder, mechanical engineer, Glasgow.

Exhibitions (tenable for one year) of the value of £100 have been obtained by Harry Bamford, engineering student, Oldham; John Harbottle, draughtsman, Newcastle-on-Tyne; John Taylor, engineer, Glasgow; John Dalglish, mechanical draughtsman, Paisley; Archibald S. Younger, engineer student, North Shields; Joseph Butterworth, engineer, Rochdale; George A. Burls, mechanical draughtsman, Greenwich; Charles H. Kilby, engineer apprentice, Crewe; Charles R. Pinder, engineer student, Bristol; Robert Dumas, engineer, Glasgow; Charles L. E. Heath, fitter apprentice, Devonport; Charles Forbes, engine fitter apprentice, Glasgow; Benjamin Young, electrical engineer apprentice, Belfast; Edward Y. Terry, engine fitter, Devonport; William J. Collins, draughtsman, Woolwich; John H. B. Jenkins, assistant analytical chemist, New Swindon; John I. Fraser, apprentice engineer, Glasgow; Henry E. Cheshire, fitter, Crewe; Oscar Brown, pattern maker, Plumstead; Henry Elliott, mechanical engineer, Glasgow. Exhibitions of the value of £50 have been won by James H. Binfield, engineer student, Preston; George U. Wheeler, engineer apprentice, London; William Day, fitter, Wolverton; Samuel Lea, turner, Crewe; Evan Parry, engineer student, Bangor; Thomas O. Mein, engineer, Stratford, E.; Benjamin Conner, apprentice engineer, Glasgow; Thomas J. Bourne, marine engineer, Tunbridge Wells; George Ravenscroft, fitter, Crewe; Thomas F. Parkinson, engineer student, Bury, Lancashire.

The following is a list of successful candidates for the National Scholarships: John B. Coppock, student, Nottingham; James G. Lawn, mining surveyor, Barrow-in-Furness; Herbert Grime, teacher, Manchester; Alfred Stansfield, student, Bradford; John Eustace, engine fitter, Camborne; Edwin Wilson, student, Bradford; Lionel M. Jones, student, Llanelly; Joseph Jefferson, student, Bradford; Henry T. Bolton, student, Newcastle-on-Tyne; Ben. Howe, student, Manchester; John Yates, draughtsman, Manchester; Harry Cavendish, student, Manchester; Thomas S. Fraser, laboratory assistant, Glasgow. Royal Exhibitions have been obtained by Benjamin Young, electrical engineer apprentice, Belfast; James Harrison, shoemaker (riveter), Northampton; John D. Crabtree, student, Bradford; Joseph Burton, student, Manchester; John Taylor, engineer, Glasgow; Joseph Husband, student, Sheffield. Thomas Beatham, student, Newcastle-on-Tyne; Charles H. Kilby, engineer apprentice, Crewe; George H. Gough, student, Bristol; Henry E. Cheshire, fitter, Crewe; Ernest W. Rees, engineer apprentice, Carnarvon; Stanley H. Ford, student, Bristol; have secured Free Scholarships.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

SURGICAL SPLINTS.—Improved surgical splints have been patented by Mr. J. Mayer. These splints are made of papier-mâché, as thin as is compatible with strength, and are perforated to afford means of escape for offensive matter, and also for ventilation. These splints combine lightness, strength, and impermeability to moisture.

CLEANSING POWDER.—A cleansing powder has been patented by Mr. J. W. Paton. It is composed of carbonated soda, ash, and precipitated carbonate of lime. The powders are thoroughly mixed together in suitable quantities, and passed through a fine sieve. They are then packed ready for sale, and may be used as a polishing powder or paste, and for cleansing floors, marble, metal, and such like.

FOLDING BATH.—A folding bath for use at the side of a floating structure has been patented by Messrs. G. Sparrow and W. S. Kelly. The bath is constructed with its bottom consisting of a framework supporting a grating, and connected by rods to a platform constituting the top of the bath, from which the bathers enter the water. At the sides and ends the structure is enclosed by netting. The bath is attached to the floating structure by hinges, and is connected to a winch, by which means it may be folded up and made to assume a vertical position.

PHOTOGRAPHY.—An apparatus for washing photographic prints has been patented by Mr. E. H. Lyne. The apparatus consists of a pipe which conducts a spray of water on to the prints in a tank until the tank is filled. A self-acting regulator is provided for the water, and comprises a ball and plug; when the water in the tank reaches the desired height, it raises the ball which lifts the plug, thus allowing the water to run off, leaving the prints in the tank. As the water lowers, the plug is replaced, and the tank is again filled and the operation repeated continuously.

CLEANING BOOTS.—Mr. G. H. Cable has patented an apparatus for cleaning boots. From a base projects a stand on which a boot can be placed to be cleaned. Also from the base extends upwards a bracket having a swan neck projecting over the heel part of the stand. Through a socket at the end of this neck passes a sliding bar which can be lowered or raised. When lowered it is pressed down by a lever fixed by a screw. The bar being fixed, a boot is placed on the stand, the bar is slid down, its foot pressing on the inside sole, and there fixed by the lever and screw. The boot is thus firmly held in position while being cleaned.

ELECTRIC LAMPS.—An electric lamp attachment has been patented by Mr. W. Hartnell. The object is to provide means for placing and retaining a reflector surrounding an electric lamp in different positions so as to throw the light accordingly. This is accomplished by supporting the reflector, and the lamp also when possible, [illegible]itable attachments such as will permit them to [illegible]on a transverse axis passing through the centre of gravity of the pieces to be moved, and at the same time leave the whole free to turn upon another axis at right angles to the first, provided on a fixed support. This removes any tendency which the reflector or other parts might otherwise have of gravitating into a new position.

PROJECTILE. — A projectile for ordnance has been patented by Mr. M. Gledhill. The projectile consists of a hollow cylinder, its penetrating end having an annular surface of impact; this surface is bevelled to give it a rather sharp edge, so that in striking an armour plate in a direction normal to the surface thereof, the action will be somewhat like that of a hollow punch, and except when the angle of the axis of the projectile with the surface is very acute, the glancing of the shot from this surface will be almost impossible. The rear end of the projectile is provided with a plug or cover which forms a surface on which the pressure of the gas generated by the explosion of the powder will be exerted. This plug drops from the projectile when it leaves the gun.

CARTRIDGE.—Mr. A. H. Walker has patented a sea-oiling cartridge. The cartridge consists of a shell containing powder in the rear part of its interior, and having another shell containing oil in the forward part of its interior, the latter being provided with a forward opening. When discharged, this shell is driven through the wall of the containing shell and out to the desired distance over the sea. During its flight the open end is kept forward by the rotation of the projectile on its axis, and the oil kept in by the pressure of the air. When it reaches the end of its range the projectile sinks base downward a little below the surface of the water. The oil then escapes, rises to the surface, and spreads into a film, thus stilling the waves.

POCKET COMBINATION TOOL.—A combination tool to be carried in the pocket has been patented by Mr. W. Body. This tool comprises a corkscrew, a piercer, a button-hook, and a seal. The appliance is constructed in two parts, one fitting in the other, to be carried in the pocket. The corkscrew portion is provided with a square flat top with a hole through it. The flat surface is used as the seal. When required as a corkscrew the portion comprising the piercer and button-hook is passed through the hole, thus forming a cross-piece for convenience in turning the screw. The piercer and button-hook consists of a round portion with one end sharpened as a piercer and the other end formed into a hook. The hook and piercer portion fits into the screw portion, and is thus carried in the pocket.

GRINDING ALMONDS.—An apparatus for grinding almonds has been patented by Mr. W. T. Oschwald. It consists essentially of a hollow perforated cylinder fitting into a cone and united with same at their lower open extremities. Partitions are provided and placed in the interior of the cone in a helical direction, so as to prevent the almonds rotating with the cylinder, and to cause them to be carried downwards and through the perforations as the cylinder revolves. The cylinder is revolved by a handle which passes through a top cross-piece connecting the parts together through the centre of the cylinder, and fixed to a cross-piece at the bottom of same. When rotated the cylinder grinds the almonds placed in the cone, causing them to pass through the perforations and fall into a receptacle placed beneath for that purpose.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

For sale, Brotherhood 3-cylinder Engine, 6 in. by 7 in., £7. (London).—Address, S., 45, Clarendon Road, Southsea.

For sale, double Launch Engine, by Plenty, 5½ in. by 5 in. £20.—S., 45, Clarendon Road, Southsea.

Greenhouse Stoves, portable, require no chimney, no fixing, cheap, and effective.—PETERS, BARTSCH, AND CO., Derby.

A number of Microscope Objectives, Opera and Field Glasses, Thermometers, for sale cheap.—List on application to A. DANCER, 3, Monton Street, Greenheys, Manchester.

Set 50, coloured Photographic Lantern Slides of London, 6d. each, sample 9d.—5, Hanover Buildings, Southampton.

Field Glass, by Steward, Strand, nearly new, cost 90s., bargain, 35s.—HOLMES, 13, Hollis Street, Leeds.

Proctor's "Star Atlas," and "Universe of Stars," 8s. free.—R. ROWLEY, 45, Camden Street, Derby.

Astronomical Telescope, 3¼ by Wray, 4 powers, finder, tripod stand, 240s. Cost £25.—GOAMAN, Bridgeland, Bideford.

Amateur Mechanics supplied with Lathes, Drilling, Planing Machines, Castings, etc. Cash, or easy payments.—Britannia Company, 100, Houndsditch, London.

Britannia Co. *Bona-fide* makers of 300 varieties of lathes, and other engineers' tools. Prize medals. Makers to the British Government.

Wanted, by two experienced Mechanics, Model Work to do at home (Mechanical or Electrical). Specialities and ideas worked out to drawings, scale, or size. Good workmanship guaranteed. Moderate terms.—P. R., 40, Westbury Street, S.W.

Do your own Electro Plating and Gilding. System inexpensive. Particulars one stamp.—PERKS, 47, Alexandra Road, Richmond, Surrey.

Steel Name Stamps, 3d. per letter. Figures (set), 2s. 4d. Post free.—F. BALDWIN, Tuffley, Gloucester.

Meerschaum and Briar Pipes Repaired, Mounted, or Cased, ambers fitted.—W. GEORGE, 324, Essex Road, Islington, London.

Minerals, Fossils, Cretaceous, Liassic, Carboniferous, Silurian. 12 named specimens, 2s. 6d. free—CHAS. WARDINGLEY, Blackwood Crescent, Edinburgh.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate Sixpence for the first twenty-four words, and Threepence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Grand pair of coupled high-class model Beam Engines, bright and complete, fitted with pumps, governors, throttle valve, made regardless of cost by Lord Scarsdale's engineer, and made for work as well as show. Bargain. Half cash, half exchange.—295, St. Philip's Road, Sheffield.

New powerful Microscope, case, tongues, object-glass. Exchange for 3 in. Electric bell, new, or offers.—JOHN COLLINGE, John Street, off Cross Street, Middleton, near Manchester.

Splendid Solar Microscope, in case, by Nairne, six powers. Exchange photographic apparatus.—RIDOUT, Sunbury Common.

100 Geological Specimens, named. Exchange, 10s. Approval.—HOLDEN, Hoyland Nether, Barnsley.

I offer Lawn Mower, 52-inch Bicycle, Lockstitch Sewing Machine, or Fret-Saw and Lathe, cost £5 5s., in exchange for Lathe.—Wellesley House, Colchester.

SELECTED BOOKS.

The Frog. An Introduction to Anatomy, Histology, and Embryology. Third edition revised, with a new chapter on Development added. By A. M. Marshall. London: Smith, Elder. Price 6s.

Scientific Romances. No. 7. On the Education of the Imagination. No. 8. Many Dimensions. By C. H. Hinton. London: S. Sonnenschein. Price 1s.

Handbook of the Amaryllideæ. Including the Alstrœmerieæ and Agaveæ. By J. G. Baker, F.R.S., F.L.S., First Assistant in the Herbarium of the Royal Gardens, Kew. London: Bell and Co. Price 5s.

Electro-Plating. A Practical Handbook on the Deposition of Copper, Silver, Nickel, Gold, Aluminium, Brass, Platinum, etc., with descriptions of the Chemicals, Materials, Batteries, and Dynamo Machines used in the Art. By J. W. Urquhart, C.E. Second Edition. London: Crosby, Lockwood and Sons. Price 5s.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, August 20th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	54·2 degs., being 3·9 degs. below average.	6·5 ins., being 0·1 ins. above average.	361 hrs., being 19 hrs. below average.
England, N.E.	53·8 " " 4·5 " " "	7·9 " " 2·1 " " "	266 " " 113 " " "
England, East	57·0 " " 4·2 " " "	8·5 " " 3·1 " " "	291 " " 161 " " "
Midlands ...	56·0 " " 4·1 " " "	7·6 " " 1·5 " " "	291 " " 117 " " "
England, South	56·6 " " 3·2 " " "	8·1 " " 3·3 " " "	294 " " 158 " " "
Scotland, West	56·0 " " 1·8 " " "	8·2 " " 0·2 " " "	380 " " 5 " " "
England, N.W.	55·7 " " 3·5 " " "	9·3 " " 1·4 " " "	336 " " 48 " " "
England, S.W.	56·6 " " 3·3 " " "	9·0 " " 1·6 " " "	370 " " 95 " " "
Ireland, North	55·4 " " 2·7 " " "	9·4 " " 2·2 " " "	349 " " 43 " above "
Ireland, South	56·7 " " 2·1 " " "	8·1 " " 0·8 " " "	384 " " 25 " " "
The Kingdom...	55·8 " " 3·3 " " "	8·3 " " 1·6 " " "	332 " " 65 " below "

The above period represents the mean temperature for the Midsummer period of 1888; over the whole ten weeks, the mean loss of heat for the kingdom is shown to have been 3·3 degrees for each day. Rainfall is drawing nearer the normal, its distribution very equal; but the distribution of solar favours is becoming remarkably unequal.

Scientific News
FOR GENERAL READERS.

Vol. II. FRIDAY, SEPTEMBER 7, 1888. No. 10.

CONTENTS.

NOTICE.

We have pleasure in announcing that a Special Supplement of the Scientific News in connection with the British Association Meeting at Bath, will be published on the morning of Monday, 10th September, 1888. Arrangements have been made to give a *resumé* of each day's proceedings, as well as abstracts of papers interesting to general readers. Copies of Scientific News, as well as of the Special Supplement, can be obtained at the principal bookstalls and newsagents in Bath, or will be sent by post on sending 3½d. in stamps to the Publisher, 138, Fleet Street, London, E.C.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

In my last I referred to a visit to Agassiz, on the Aar Glacier, in 1842, which was remarkably instructive.

The nearest ordinary habitation to the glacier is the Hospice of the Grimsel, where I had already spent one day and met some of the Neufchatel glacier-students. We started for the day's excursion very jovially, all singing the "Rans des Vaches," and walked up a glaciated valley for about three-quarters of an hour, then climbed up a heap of rock fragments. This was a part of the *terminal moraine* of the glacier, the material carried by the ice in the manner presently to be described, and pitched down at the end, or foot, of the glacier.

We next mounted a tall, long ridge which appeared to be built up of similar material only. This, however, was not the case, for on removing the superficial fragments, ice was seen below. We were already on the glacier, but the ice was completely hidden. This ridge was the *medial moraine*, or *gufferlinie*, one of unusually large dimensions, especially as regards its height and width, and the magnitude of some of the blocks of stone that cover it.

But what is a gufferlinie or medial moraine ?

As the accumulated overflow of ice which constitutes a glacier travels down its valley-trough path it receives on each side, or shore, more or less of fragments which fell from the rocks immediately above.

Every such block of stone that has any considerable thickness shelters the ice on which it falls from the direct rays of the sun, and thus while the ice all round is lowered in level by the summer thawing the protected portion remains relatively higher. By such action each shore or lateral termination of the glacier becomes an elevated ridge of ice, clothed with a protective covering of rock fragments. These are the *lateral moraines*.

But it commonly happens in the upper glacial regions of the high Alps that two of these glacier valleys meet at their lower part, and spread out to fill a single still lower valley. The two glaciers thus become confluent, like rivers or their tributaries that similarly meet. It is evident that in such case the moraines of the inner shores of each glacier—*i.e.*, of those shores which meet at the confluence—must unite. They do so, and now instead of being on the shores of each of their former respective glaciers, they meet in the middle of the wider stream of ice, and thus form the medial moraine, or gufferlinie.

There are two upper branches of the Aar Glacier, the Finsteraar and the Lauteraar Glaciers—the dark and the clear glaciers. By their union they form the main lower glacier, and this medial moraine along which we walked In some places rises fully 80 feet above the general level of the naked ice, a ridge of clear ice hidden by its covering, as above described. Of its length some idea may be formed from the fact that although we walked at a good pace, we were more than three hours travelling continuously along it before we reached the great block on which was the edifice of loose stones designated, as we learned by the inscription on a big flag, the "Hôtel des Neufchatelois." This was situated a short distance below the projecting spur or promontory of rock *Im Abschwung*, at the foot of which the confluence occurs.

We were hospitably received, supplied with coffee, bread-and-cheese, and wine, and then invited to inscribe our names in the visitors' book. The leaves of this book were the facets of the great boulder on which the "hotel" was erected, and the pen and ink were a paint-brush and a pot of red ochre paint. The signatures were inscribed in characters varying from three or four inches to a foot in length.

I mention this particularly, as those names thus painted have subsequently acquired an historical scientific interest. In 1844 the block split into two pieces, and since that the frost has rent it into a mere heap of *débris*. Forty years after the first rupture—*i.e.*, in 1884—M. Forel was able to identify this heap by the vestiges of the paint-pot still remaining on some of the fragments.

It had then travelled a distance of 2,400 mètres (7,874 feet) from its position in 1840, showing that this great mass of ice on which it rested had been flowing down the valley at a mean rate of 179 feet per annum, a slower speed than usual, owing to the fact that the downward incline of this glacier is very small, so small that it appears in most parts nearly level.

This movement of glaciers is the most important element of the whole subject in reference to their work in the sculpture of the earth, and this medial moraine of the Aar Glacier is classic ground in reference to it, as it was here in the early days of glacier research that a very striking and demonstrative discovery was made. Agassiz knew that in 1827 Hugi had built a sort of refuge or shelter on the moraine, and also knew particulars concerning its position. In 1839 Agassiz, with some companions, trying to find some traces of it, spent four hours in the search, and were returning, when suddenly they came upon a solidly-built hut, but could not believe that it was Hugi's, which they knew was at the confluence of the Finsteraar and Lauteraar Glaciers, close to the Im Abschwung promontory of rock, from which they were now at a considerable distance. The hut was in good condition, even some of the hay and straw remaining on the roof. They examined the inside, and there found a bottle containing papers. One was in Hugi's handwriting, stating that he had revisited the hut in 1830, and found that it had moved about 100 paces from its original position. A second paper described a third visit in 1836, when he found that it had travelled 2,200 feet from the rock against which he built it. A third paper stated that some naturalists from Berne and Basle had at about this time repaired the hut and used it as a shelter while weather-bound in attempting to cross the glacier to Grindelwald.

Agassiz measured the distance from the original place and found that it then amounted to 4,400 feet, and therefore the hut had travelled in the three years between 1836 and 1839 as far as in the nine years from 1827 to 1836. Another measurement, in 1840, showed a progress of 200 feet in the year. These measurements he recorded in the visitors' book of the Grimsel Hospice, with an appeal to future visitors to continue the investigation.

Making due allowance for Hugi's rough measurements by stepping, a remarkable acceleration is here apparent, and is explained by subsequent observations, which show that the middle of the glacier, like the middle of a river, flows more rapidly than its sides. Hugi's hut was at first at the spot where the right and left banks of the confluent glaciers meet, but as it advanced it came out into mid-stream, and its pace was accelerated accordingly. The maximum thickness of the ice was reached at about 1836. This diminished downwards by combined action of sun-heat on the upper surface and earth-heat and friction below.

Other curious results of "ablation," or thinning down, of glaciers are peculiarly well shown on the Aar Glacier, and we examined them under expert guidance. I will describe them in my next.

ANCIENT OPINIONS AND PRE-SCIENTIFIC FANCIES CONCERNING THE INTERIOR OF THE EARTH.

MANY ages before the rise of geology, the human imagination had set itself to work, and philosophers, basing upon some notions more or less vague gleaned here and there, or setting out with the observation of a few local phenomena, had forged systems more bold and ingenious than probable or logical, with the object of explaining the structure of the earth's core. Subsequently these old paradoxes were forgotten in proportion as more serious hypotheses cropped up. Still in the year 1678 savants were far from being agreed on this mysterious question, and the margin left for dreamers was still ample.

Aristoteles proved, or believed that he had proved by means of a syllogism, which has remained famous as a specimen of a vicious circle, that the centre of the earth coincided with the centre of the visible universe. Indeed if we adopt the old astronomical notions, it would be difficult to admit that the pivot of the heavens was placed eccentrically with reference to the celestial sphere. Almost all imaginable suppositions were put forward in antiquity and in modern times when it was required to conceive the physical condition of the earth's interior. The bowels of the earth, according to Pythagoras, Empedocles, and Plato, are on fire.

Their opinion, maintained afterwards with more authority by Descartes and Leibnitz, still prevails in France, strenuously advocated by such eminent champions as Daubrée, Faye, and De Lapparent. On the contrary, according to Anaxagoras and Democritus, followed long afterwards by Woodward, we walk upon a sphere filled with water, encased in a thin coating of earth, like the shell of an egg. Buffon avowed his ignorance, but he did not favour the central fire. We do not know who first gave us a nucleus of iron. Could he return to the earth he might perceive with satisfaction that his view, far from being forgotten is still sustained, among others, by Professor Nordenskiöld. Even the very existence of terrestrial magnetism constitutes a strong argument. A certain number of more mystical thinkers supposed beneath our feet a vast void in which there circulated a sun, a moon, and planets, inhabited by plants, animals, and rational beings of a very special nature. Others affirmed that the world is perforated by a long tunnel, opening at the two poles. Less daring speculators were content to imagine the existence of great internal seas, communicating with the superficial oceans.

A very minute description of the earth's interior is given by the celebrated Father Athanasius Kircher in a work in two folio volumes, entitled *Mundus Subterraneus.* The treatise of this learned Jesuit merits the name of an encyclopædia, for we find here condensed the principles or the applications of all the sciences which are closely or remotely connected with the main question: geography, astronomy, mechanics, physics, chemistry, and natural history.

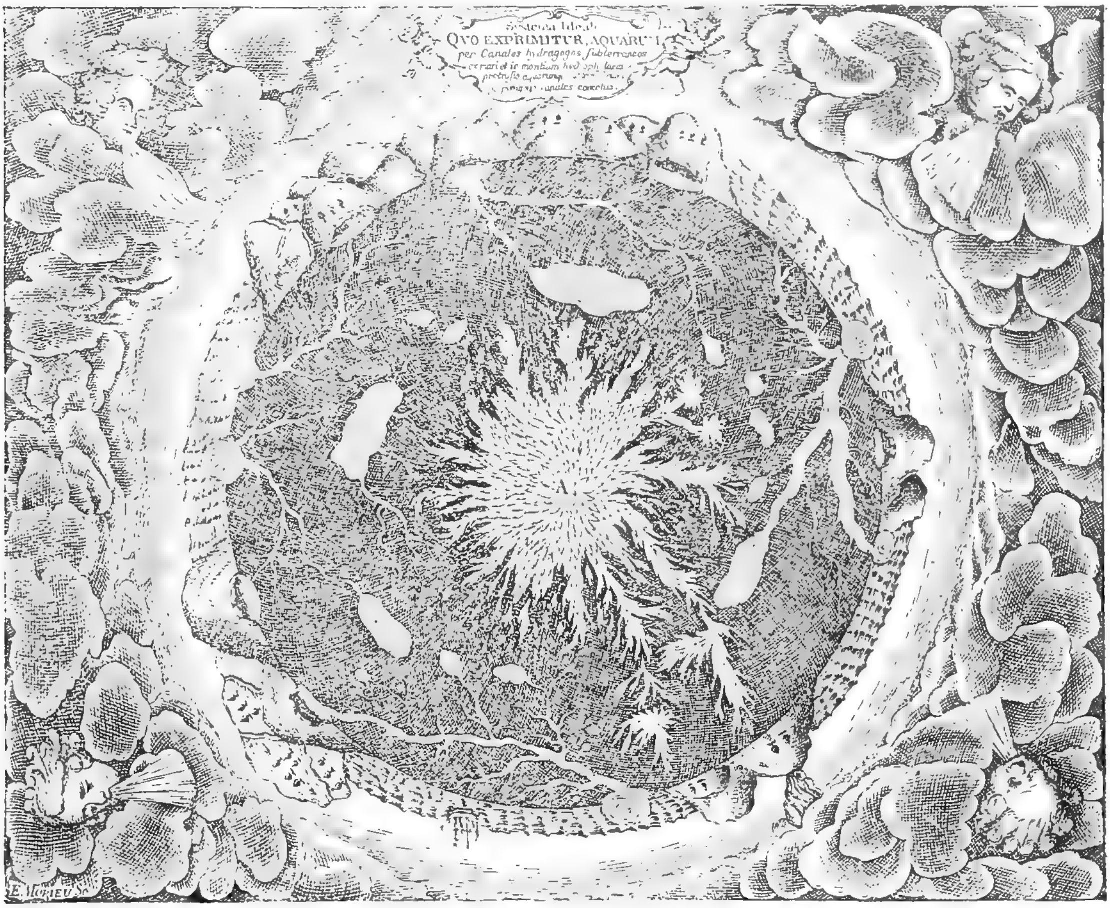
The subjoined figure which we borrow from *La Nature* is taken from an engraving in Kircher's great work, published in 1678. It is an ideal section of the earth, showing the central fire, A, and the internal circulation of the waters.

Kircher's fundamental idea is a parallelism between the human body or *microcosm* and the earth, *geocosm.*

The inmost nucleus of the latter is in a state of ignition, but the constitution of the mean and higher strata is most heterogeneous. To our intestines, there correspond subterranean canals and abysses of water (*hydrophylacia*), which feed the springs, and through them communicate with all the seas. A central fire radiates through innumerable veins (*pyrophylacia*), which vivify and warm the globe, feeding the volcanoes and heating the hot springs. In our body, the vital spirits (*sanguis spirituosus*) acts in a similar manner. How is the globe to respire without the *aërophylacia*, vast hollow reservoirs corresponding to the lungs and filled with air? The air of the *aërophylacia* escapes through branching conduits, and serves firstly to maintain the combustion of the igneous masses which would otherwise be extinguished; but besides, a certain number of pipes vent into superficial caverns, thus occasioning the winds. We must not forget that the baseless matter here propounded is mixed with sound, accurate nations which our modern geologists do not reject. Father Kircher was not merely a traveller and a compiler; he had travelled and observed, and had made many experiments.

An analogy between the heavenly bodies and men or animals is still accepted by certain speculators. In a work published six years ago, and bearing the modest title, "The Perfect Way," we are told that the planets are persons, and even possess memory. Father Kircher makes a much more frugal use of his imagination.

We must never forget that our positive acquaintance with the earth's interior amounts to nothing. We have not penetrated to the depth of five miles, which is as if we had explored a body 133 feet in thickness to the depth of one inch! Surely such knowledge is too literally superficial.



IDEAL SECTION OF THE EARTH (AFTER KIRCHER).

ON THE GEOLOGY OF BATH AND THE NEIGHBOURHOOD.

(*Continued from p.* 198.)

WE now pass to the Secondary or Mezozoic rocks, which rest on the upturned edges of the Palæozoic strata, or, as it should be more properly expressed, rest unconformably. The explanation of this is that at the close of the Carboniferous Period some of the strata which had formed was raised above sea-level, and became land. When this was accomplished, the land was subjected to denudation, and by this process other rocks were originated.

The sub-systems of the Mesozoic Period, with which this article is concerned, are the Permian, Trias, and Jurassic. The Permians form a debatable ground between the Carboniferous and Trias, but into the merits of the arguments we need not enter.

The Trias formation as typically developed on the Continent of Europe, consists of the following divisions:—

3. Keuper.
2. Muschelkalk.
1. Bunter.

In England the Muschelkalk has not been clearly proved to be represented, but we have the equivalents of the Bunter and Keuper. The Bunter series are not developed in the neighbourhood of Bath, but there are some beds which may correspond with the Keuper, and these are of considerable interest. They are locally known as the Dolomite or Magnesian Conglomerate, so-called from dolomite (carbonate of lime and magnesia) forming a cementing matrix, by which the boulders and pebbles which occur in the rock are held together. The Dolomitic Conglomerate may be seen to advantage at Clifton, on the left-hand side of the "New Road" leading from Clifton to the Hot Wells.*

Among the varied life of the Trias Period reptiles were very abundant, which, indeed, is a feature of the secondary strata, and hence it has sometimes been called the "Age of Reptiles."

The only inference that can be drawn from the blocks of Carboniferous limestone constituting the Conglomerate is, that the limestone must have undergone denudation. The Dolomitic Conglomerate is probably a consolidated beach; if we compare its appearance with what we see on the beaches around our coasts and islands, the similarity is at once apparent. Sir H. De la Beche says, in reference to the origin of the conglomerate, "Standing on any high ground or the Mendip Hills, it is interesting to consider how exactly the masses occur as they should do, under the supposition that they have been beaches among islands, raised above the sea of the times."

The Trias period is also represented by the New Red Marl, which, however, is not of much interest. The various localities at which it is exposed may be readily seen by reference to the Geological Survey map of the district around Bath. The Trias period was brought to a close by the formation of a series of beds, known on the Continent as the Rhœtic. The equivalent strata in this country are typically represented at Penarth near Cardiff, and they are therefore sometimes known as the Penarth Beds. In England they occupy the position of passage beds between the Trias and Lias formations.

At the base of the Rhœtic beds in this country we get a series of green and red marls, which represent the last of the Trias rocks. Then a well-marked physical change is indicated by a very interesting bed, in which the shell *Avicula contorta* is numerous, and this suggested to Dr. Wright that it should be called the *Avicula contorta* bed. Then follow black shales in one of which, the "Bone Bed," fish and reptilian remains are especially abundant. Then another change is indicated by a cream-coloured limestone, named by William Smith, in 1815, the White Lias. Now, the *Avicula contorta* zone and the White Lias are well-defined geological landmarks, and hence Mr. Charles Moore* has included in the Rhœtic series the strata between those two horizons.

Near the base of the White Lias is a well-known ornamental limestone, known as the "Landscape Marble," which is about one foot thick. One of the best exposures of the White Lias is to be seen just outside Bath, near the Weston station on the Midland Railway.

We now enter upon the Jurassic rock, on which Bath rests, and of which the hills surrounding the city are built up. The Jurassic period of the earth's history is typically represented in the Jura Mountains, and hence the name Jurassic. In this country there are two distinctive series, namely, the Lias and Oolitic. It is the former of these which overlie the White Lias of the Rhœtic, and are clearly distinguished by the blue colour of the limestone, and dark intervening shales. According to Sir H. De la Beche, the term Lias originated with the Somersetshire quarrymen, and by them was applied to distinguish argillaceous limestone forming a part of the succession of strata now all included under the name. Of the reptiles which inhabited the Lias seas, estuaries, rivers, and land we have some most wonderful combinations of structure. Three groups are found—the *Enaliosaurians*, or marine reptiles, the *Pterodactylians*, or aerial reptiles, and the *Teleosaurians*, or river and land reptiles.

The most prominent group are the *Enaliosaurs*, or Sea-Lizards, the two groups of which are represented respectively by the *Ichthyosaurus* and *Plesiosaurus*. Good specimens may be seen in the Bath Museum, and some of the best ever obtained have been found in the Lower Lias of Street in Somersetshire. The *Ichthyosaurus* was indeed a wonderful creature. In size it was sometimes as much as 24 feet in length; it had the skull of a crocodile, the eye fashioned like a bird and a turtle. It had the backbone of a fish, the paddle of a whale, and the scapular arch of a *Platypus*.

The *Plesiosaurus* was hardly less remarkable. It was distinguished by its long neck, resembling that of a swan united to the trunk of a quadruped, with ribs like a chameleon.

There is another reptile that appears for the first time in the Lias, which has a unique history, seeing that nothing approaching to it is found either in living or extinct natural forms. This is the *Pterodactyle*, a flying reptile, whose skeleton was modified and adapted to an aerial life. It had some resemblance to bats and birds, but was widely different from both. In bats the whole anterior extremity is elongated to form a framework of a wing, but in the *Pterodactyle* it was only the little finger that was lengthened and strengthened to become a rod for supporting a membrane, whilst the other parts of the hand, the thumb, and three inner fingers retain their normal size. Like birds, the long bones of the arm were hollow cylinders, and it differed from birds in having the skull of Reptilia. Its jaws were armed with long teeth implanted in distinct sockets.

The Teleosaurians, or land reptiles, appear in the Upper Lias. Several examples of small specimens have been found in the fish-bed of Dumbledon, and in the same formation in Somersetshire as well as in Yorkshire.

English geologists divide the Lias, as represented in this country, into three divisions, namely, Lower, Upper, and Middle, and each one is marked by palæontological

* The Dolomite Conglomerate is also well shown at Tytherington.

* "Quart. Jour. Geol. Soc.," vol. xvii., p. 495, 1861.

and lithological differences. These divisions are further distinguished by zones of life—that is to say, that at certain periods during the progress of this formation certain creatures lived more abundantly than at others, or lived only during the time that certain strata were forming, and then disappeared. Many of these forms of life remain as fossils, and hence it is that we are enabled to make out certain horizons or zones which characterise the Lias. In marking these zones the Ammonites are the chief indicators. Thus the Lower Lias is marked by seven Ammonite zones, the Middle Lias by five, and the Upper by three.

Before referring further to the life of the Jurassic period it may be well to say something more respecting the rocks. The Upper Lias beds pass up into yellow sandy strata, which are typically represented at Midford, near Bath, and were therefore at first named the Midford Sands. Above the sands we get a very interesting bed, called by Dr. Wright the *Cephalopoda* bed, because of the number of Ammonites and Belemnites which occur in it; and it is here that some geologists draw the line between the lias and succeeding oolitic formations.

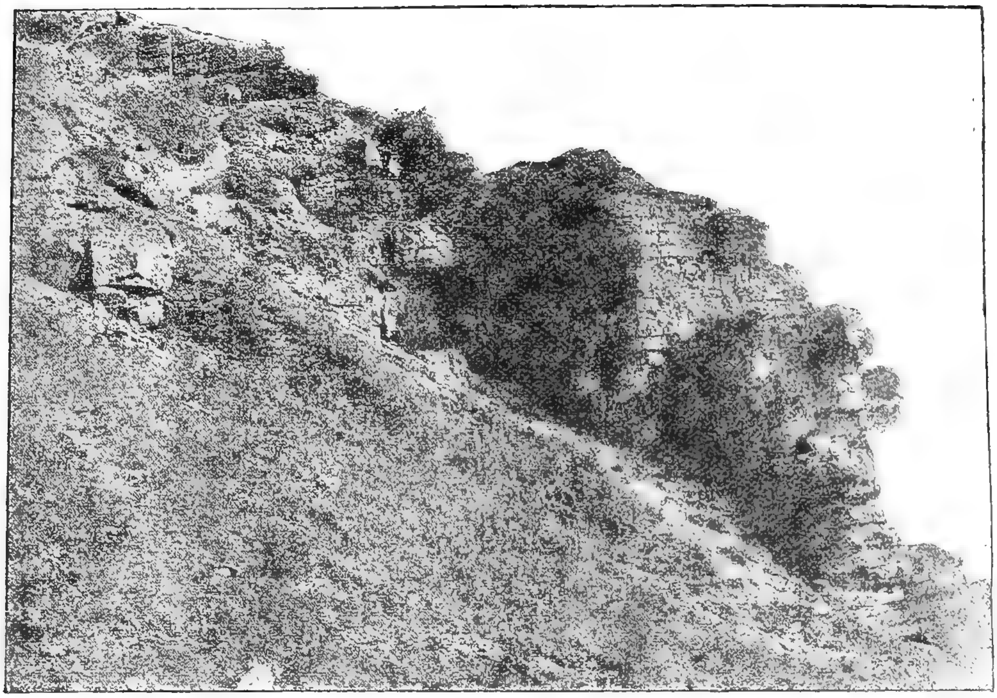


FIG. 5.—THE PEA GRIT AS EXPOSED AT CLEEVE HILL, NEAR CHELTENHAM.

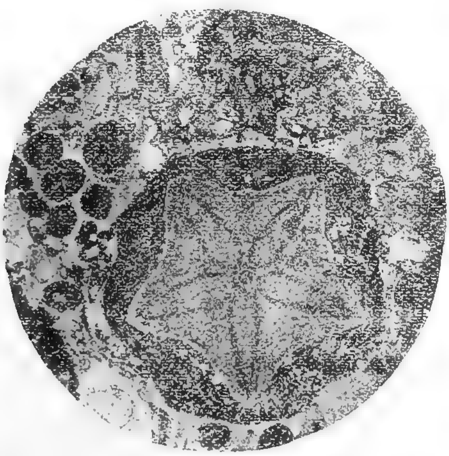

FIG. 6.—MICRO-PHOTOGRAPH OF A SECTION OF THE PEA GRIT, FROM CLEEVE HILL, NEAR CHELTENHAM. (Enlarged.)

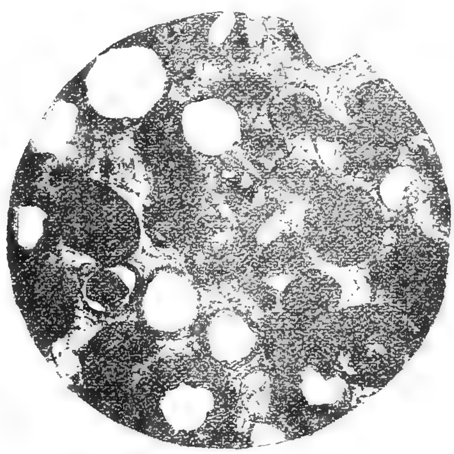

FIG. 7.—MICRO-PHOTOGRAPH OF A SECTION OF BATH STONE (GREAT OOLITE.) (× 22 diams.)

The term Oolite is from the Greek *oon*, an egg, and *lithos*, a stone. The name is suggested from the structure of a large portion of the rock, which is made up of minute granules resembling somewhat the roe of an egg. The Oolitic formation is divided as follows :—

Upper Oolitic	Purbeck Beds.
	Portland Beds.
	Kimeridge Clays.
Middle Oolitic	Coralline Beds.
	Oxford Clay and Kelloway Rock.
Lower Oolitic	Great Oolite Series.
	Inferior Oolite.

The inferior Oolite is extensively developed in the Cotswold Hills, especially near Cheltenham, where it is about 236 ft. thick, but thins out in the direction of Bath, where it is represented by about 25 ft. Near the base of the inferior Oolite at Cheltenham a remarkable series of beds known as the Pea Grit occur (fig. 5.) The name appears to be suggested from the resemblance of the granules to peas, which they do in size and shape. Fig. 6 is a micro-photograph of a section of this rock from Cleeve Hill, near Cheltenham, and illustrates the structure and mode of formation of Oolitic strata. The rock is seen to be made up of oval and round granules, the largest of them measuring a little over one-eighth of an inch in diameter, and the smallest ·014. In each of the granules there is a nucleus around which layers of carbonate of lime have formed. This is best seen in the large type of granule, which is known as Pisolite, to distinguish it from the smaller or Oolitic grains. In the case of the Pisolite granule in fig. 6 the nucleus is that of a joint of a Pentacrinite, and is shown in section. These crinoids were allied to the Encrinites to which we referred when describing the Carboniferous Limestone, but in the case of the Pentacrinus the joints are five-sided. These creatures were numerous in the Jurassic Sea, and have contributed to the strata in the same way, though less extensively, that the Encrinites did to the Carboniferous Limestone. The smaller granules in the Oolite have a variety of objects, as nuclei; sometimes a portion of a spine of an Echinus, a fragment of shell, a foraminifera or grain of sand.

Fig. 8.—Micro-Photograph of a Section of Forest Marble. (× 22 diams.)

The Inferior Oolite terminates at the horizon of the Fuller's Earth, a material well known for its use in commerce. The maximum thickness of the formation is about 400 ft., which includes clays, marls, and nodules of earthy limestone. At Bath, however, it is not more than 150 ft., and continues to decrease in thickness until on reaching the Valley of the Windrush it dies out, so that in the country round Burford the inferior Oolite and great Oolite series are in contact.

The great Oolite series are thus divided by Mr. H. B. Woodward, in his "Geology of England and Wales :—

3. Cornbrash.
2. Forest Marble and Bradford Clay.
1. Great Oolite { Upper zone. / Lower zone, Stonesfield slate.

The name Stonesfield Slate was taken from the village of Stonesfield. The formation appears to be that of an estuarine deposit, for among the fossils which it contains are those of plants, consisting of Algæ, Ferns, and Conifers. The conditions under which the Stonesfield Slate formed extended over an extensive area in East Gloucestershire, but is not represented around Bath nearer than at Stroud. Some of the beds yield slabs which are worked for roofing purposes, and hence the term slate, as applied to this rock.

Above the Stonesfield Slate comes the Bath or Great Oolite, which is extensively quarried on the hills around Bath and mined at Box. Visitors to Bath should endeavour to visit one of these mines, for they will see a sight which they will never forget. At Bath the Great Oolite is 150 feet thick, and consists of limestone made up of shell *débris*, tough calcareous rocks mixed with clay and fine oolitic limestones, the latter being the typical "Bath Stone."

Of the Bath Stone it is very difficult to get a thin section suitable for examination under a microscope, owing to the oolitic granules being so loosely held together. Directly we begin to grind down a piece of the rock the granules fall out. Fig. 7 is a photograph of a section in which a number of granules remain, but they are not thin enough to show the nuclei. In the figure the spaces between the granules are seen to be filled with infilling calcite, which affords a good example of the process by which limestone has become compact. The white oval spaces have been made by the falling out of granules.

At the close of the Great Oolite period there followed conditions which were not favourable to the formation of limestones, and a deposit of clay took place known as the Bradford Clay, the name being taken from Bradford, in Wiltshire, where the clay is best developed.

Then there was another change of conditions, and limestone-forming organisms again appeared, and their calcareous remains collecting on the sea floor gave rise to a shelly limestone known as the forest marble. Fig. 8 is a micro-photograph of this rock, which shows it to be chiefly made up of fragments of shells and some oolitic granules; but in the photograph the places occupied by the granules are represented by circular holes, the granules having dropped out during the grinding down of the section.

On the other members of the Jurassic system we must not enter, but the mode of formation and structure differs little from those already referred to.

The life of the Oolitic period resembled that of the Lias, but we find some fresh genera and species. Corals were numerous; in the inferior Oolite of the Cotswold Hills there are three fossil coral reefs. Oolitic limestone is at the present day formed in the coral seas, and it is therefore possible, even likely, that the carbonate of lime which formed around the nuclei of oolitic granules may have been derived from that source. Visitors to the Bath Stone quarries should have no difficulty in obtaining good specimens of the coral *Halamophyllia radiata*, which is most numerous in the upper beds.

[We regret that by an unfortunate mistake figures 2 and 3 on page 197 were transposed.]

General Notes.

STRANDED WHALES.—A large whale, which had stranded on the east coast near Snettisham, was last week towed to Hunstanton. It is about 30 ft. long. A smaller whale was also stranded at Heacham, near Hunstanton.

THE DEEPEST WELL IN THE WORLD.—A well of the depth of 3,000 to 6,000 yards is to be sunk in the United States if Congress can be prevailed upon to vote the necessary funds. The results of this enterprise, if carried out, will doubtless prove exceedingly instructive.

NATIVE GOLD IN LIMESTONE.—At a meeting of the Philadelphia Academy of Natural Sciences, Professor Leidy exhibited a fragment of metamorphic limestone from Eldorado county, California, having on its surface a spot of native gold—the first instance he had seen of gold occurring in limestone.

DISCOVERY OF MINERALS IN RUSSIA.—The Russian *Journal of Metallurgical Industries* states that large deposits of silver and lead have just been discovered in the upper part of the Kouban and on the banks of its affluents, the Douot and Outchkolan. Some oil springs have also been found in the same quarter.

DISTINCTIONS BETWEEN COLOURS.—We may have colours which if illuminated by daylight or gaslight seem perfectly identical, but if illuminated by a monochromatic light, such as that of sodium, will appear different, unless the chemical composition of the colouring matters is absolutely identical. In this manner cheques and other documents which have been fraudulently altered may sometimes be detected.

SHIP-CANAL ACROSS ITALY.—A canal is projected intersecting Italy from west to east. It will begin near Castro, on the Tuscan coast, and terminate at Fano, in the Adriatic. The length will be 283 kilomètres, its mean width 100 yards, and its depth 12 yards. It will be used to effect the desiccation of the lakes of Bolsena and Thrasimenæ. The expense is estimated at 500 million francs.

DETERIORATION OF HANDWRITING.—The *Journal of the Franklin Institute*, noticing a circular issued by the French Geographical Society calling an "International Geographical Congress" for 1889, remarks that of all the signatures to this document "but one is clearly legible, and two are absolutely illegible. It seems as if all over the world the legibility of handwriting is decreasing. There are few of the smooth and unmistakable handwritings of a century ago." A parallel fact is the deterioration of style, especially to be noted in English writers.

PHOTOGRAPHS OF LIGHTNING.—M. Ch. Mousette, in a communication to the Paris Academy of Sciences, suggests that the peculiarities observed in the photographs of lightning may be principally due to vibrations imparted to the apparatus by tremors of the soil, by the wind, or by the rolling of the thunder. In support of this view, he executed in black on white a design consisting of points and lines variously inclined, and has then photographed it, firstly keeping the camera free from all vibrations, and secondly exposing it to slight shocks. In the second case the proofs present the form of a striated band.

NEW APPLIANCE FOR FISHING BY THE ELECTRIC LIGHT.—A paragraph in *Cosmos* states that experiments have been made on board the steamer *President Herweg* in the North Sea to test a new apparatus for submarine electric lighting, devised by an engineer of the name of Pellenz. The results have been very satisfactory; the lamp acted without accident at the bottom of the sea, the depth being 100 fathoms, giving a light of 100 candles, whilst the vessel was steaming at the rate of four miles per hour. The fishes, attracted by the light, floated to the apparatus. This is said to have been the first experiment of the kind made in the open sea.

MORTALITY DUE TO LEAD.—According to *Cosmos*, Dr. Carter, of the Board of Health at Baltimore, advances the opinion that the use of drinking-water holding lead in solution is a predisposing cause of scarlatina and diphtheria. During the fifty-four years from 1830 to 1883 the average annual mortality from scarlet fever in that city has been 225, and in the last year of the term 334. On January 1st, 1884, a new law concerning plumbing work came into force, and the deaths have since been—1884, 104; 1885, 68; 1886, 32; and 1887, 36; or a yearly mean of 60. The mean yearly death-rate from diphtheria prior to 1884 was 469, but since that date it has sunk to 234.

THE MINING INSTITUTE OF SCOTLAND.—This institute held its annual summer meeting at Dalkeith, on the 23rd ult. The first part of the programme consisted of a visit to Newbattle and Arniston Collieries. The members were received at Newbattle Colliery by Mr. Morison, when an examination was made of the works above ground and under ground, the same programme being carried out as at the visit of the Iron and Steel Institute. Afterwards they proceeded to Arniston Collieries, where they were received by Mr. Clark, and, after seeing the works there, left by special train for Dalkeith. In the afternoon a general meeting was held, and the election of new members took place. Mr. James Hastie was elected to the office of vice-president, and Mr. Wallace Thorneycroft to the office of councillor.

THE ADULTERATION OF SHERRY.—In the last issue of the United States Consular Reports the Consuls at Cadiz and Jerez de la Frontera return to the subject of the adulteration of sherry, on which they recently reported most unfavourably. Mr. Ingraham, of Cadiz, sends a translation of a circular from the Spanish Minister of the Interior to the civil governors of the provinces, directing prosecutions against the makers and vendors of adulterated wines, in accordance with a Royal decree against adulteration. Adulterated wines are thus defined in the decree—(1) Natural wines which contain impure industrial alcohol and alcohol from husks (*cascara*), if they are not rectified and purified; (2) salicylic acid and other antiseptic substances; (3) foreign coloured substances, those derived from the products of pit coal (*sic*), as well as of vegetable or other origin; (4) artificial glucose, sugar from flour, or new wine; (5) glycerine.

BOOKS AS TRANSMITTERS OF INFECTION.—According to the *Lancet*, the municipal authorities of Dresden have instituted an experimental inquiry into the probability of the transmission of zymotic disease by the medium of library-books. A number of volumes from the town library which had been in frequent use were taken for experiment. The dust from the leaves and covers was sown in nutrient solutions, and cultivations were reared. But there appeared no disease germs, the dust being of a non-organised character. Next some of the dirtiest leaves were rubbed first with a dry, and then with a wet finger. On the dry finger scarcely any microbia were found; on the wet finger there were many, but all of a non-infectious character. In particular the bacilli of tubercle were absent. The conclusion drawn was that the danger of infection through books from circulating libraries is very slight, but it is recommended to dust such volumes well before reading, and never to wet the finger in the mouth in order to turn over the leaves.

An "In Memoriam" Tablet to Charles Darwin, at Edinburgh.—A report was published in a recent issue of this paper, stating that it was the intention of some people to put up an "In memoriam" tablet at 11, Lothian Street, Edinburgh, where Charles Darwin resided with his brother during some part, or mayhap the whole of the session 1825-6. This is certainly a praiseworthy object, but it should be pointed out that it would probably have been accomplished nearly three months ago by another set of people than those at present interested, had they not been directly asked by Mr. Francis Darwin, the son of the late Charles Darwin, not to proceed in the matter until further investigations had been made; the reason of postponement being to allow Mr. Darwin to find out whether his father had remained any length of time at Lothian Street or had removed elsewhere, and until this point had been settled those formerly interested in the matter determined to do nothing. It may therefore be as well to wait until Mr. Francis Darwin has settled this point, as he is likely soon to do, having lately heard of some early letters of his father which may throw light on the Edinburgh life.

Lead-poisoning by Home-made Wines.—The *Sanitary Record* has drawn attention to the danger of lead-poisoning by wines made in the ordinary glazed earthenware pans, such glaze containing sometimes 50 or 60 per cent. of red or white lead. In his last report on the Alcester rural sanitary district, Dr. Fosbroke, the medical officer of health, records some cases that came under his notice. Members of two families residing at Inkberrow were attacked by unmistakable symptoms of lead-poisoning. On inquiring Dr. Fosbroke ascertained that the persons affected had partaken of some home-made wine, though not by any means in large quantities. This wine, he learnt, was made from black currants and plums, which in the course of preparation were allowed to ferment in a glazed earthenware washing pan. This pan showed signs of corrosion, and there seems no doubt that the lead which is used in the "glaze" had been taken up by the wine and imbibed by the sufferers. As the manufacture of home-made wine is more common among the labouring classes than it used to be, it should be borne in mind that the fermentative process required for its manufacture should be carried out in wooden vessels, and the ordinary glazed earthenware pans be specially avoided.

A Destroyed Island.—Dr. Treub, the director of the Botanical Garden at Buitenzorg, Java, has published his experience with regard to the reappearance of vegetation upon the Island of Kraketoa, which partly sank, and was wholly overwhelmed by the ashes and pumice-stone from its volcano during the violent outbreak of 1883. Three years after this day, Dr. Treub (on 26th June, 1886) visited the island, and as he approached it he found that it was covered with vegetation to the very summit of the mountain. The plants could not have grown from the roots or seeds of those existing before the great eruption, for the toughest organism must have been destroyed by the excessive volcanic heat. The whole island was covered with a layer of ashes and pumice-stone from 3 ft. to 240 ft. thick. Nor could the vegetation, Dr. Treub thinks, have been introduced by man, for the island is uninhabited and difficult of access. It must have been by means of seeds carried thither by birds, the wind, or the currents of the sea that the new vegetation arose. It consists for the most part of ferns, of which eleven different varieties were found, and of single specimens of blossoming herbs, such as are found on coral reefs that have lately risen above the level of the sea. Dr. Treub has, however, found that the ferns were not the first living plants that had found nourishment on the destroyed island. Almost everywhere there were signs that the ashes and pumice-stone had been covered by a thin layer of algæ, which rendered the surface of the soil soft and capable of absorbing water. These microscopic algæ prepared the way for the ferns, and the latter, in their turn, for the blossoming herbs.—*Daily News*.

The Public Health.—The Registrar-General's return for the week ending August 25th shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 18·1 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The five healthiest places were Bristol, Brighton, Derby, Sunderland, and Birmingham. In London 2,401 births and 1,438 deaths were registered. Allowance made for increase of population, the births were 300 and the deaths 115 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 15·9, 18·0, and 16·2 in the three preceding weeks, rose again last week to 17·5. During the first eight weeks of the current quarter the death-rate averaged 16·2 per 1,000, and was 4·7 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,438 deaths included 47 from measles, 21 from scarlet fever, 17 from diphtheria, 28 from whooping-cough, 7 from enteric fever, 192 from diarrhœa and dysentery, 7 from cholera and choleraic diarrhœa, and not one from small-pox, typhus, or ill-defined forms of continued fever; thus, 319 deaths were referred to these diseases, being 36 below the corrected average weekly number. In Greater London 3,167 births and 1,821 deaths were registered, corresponding to annual rates of 29·9 and 17·2 per 1,000 of the population. In the outer ring 58 deaths from diarrhœa, 13 from measles, and 8 from diphtheria were registered. The fatal cases of diarrhœa included 15 in Tottenham, 9 in West Ham, and 6 in Enfield sub-districts. Three deaths from measles were returned in Croydon, in Willesden, and in Tottenham sub-districts; and the fatal cases of diphtheria included 2 in Edmonton and 2 in Walthamstow sub-districts.

Natural History.

THE GORGONA ANTELOPE.

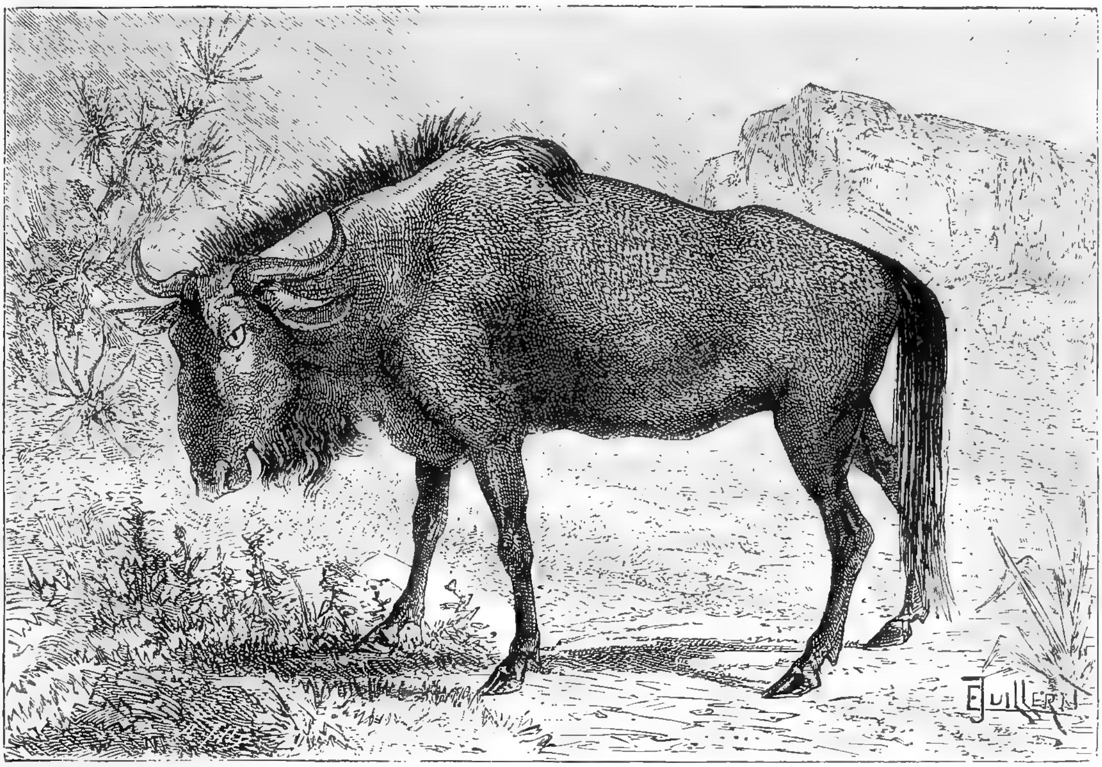
AMONG the numerous and varied family of the antelopes, there is one group differing widely in appearance from the rest, and presenting at first sight almost the characters of a monstrosity. This group belongs to the southern part of the African continent, and includes the common and the brindled gnu (*Catoblepas gnu* and *Catoblepas gorgon*), or gorgona, which we are about to describe. Both these species have a head and neck like those of a bull, joined to the hind-quarters and the tail of a horse. All the species of *Catoblepas*, though natives of a hot climate, are able to live in Europe in the open air, and to multiply in captivity. The horns of the gnu are expanded at the base, so as to form a kind of shield at the top of the head. This shield does not exist in the gorgona, or blue wildebeest as it is called by the European settlers in South Africa. Its horns, though very thick at the root, remain separate, turning outwards and curving upwards only at the extremity.

The physiognomy of the animal, like that of the gnu, is sinister, and its temper is exceedingly uncertain. Indeed, it must be remarked that all the larger antelopes, like the deer, are very unsafe as pets. Contrary to the common belief, they are much less to be trusted when domesticated than are carnivorous animals. The gorgona has not a trace of the tuft of black hair which grows along the middle of the nose of the gnu. As in the latter species, however, the chin is ornamented with a beard which falls back upon the throat. The upper side of the neck supports a stiff, bristly mane, extending backwards to the withers.

The skin of the gorgona differs in colour from that of the gnu. It is of an iron-grey, passing to reddish on the lower parts of the body, and it appears marked on the neck and on the flanks by perpendicular stripes. But these stripes, which are by no means very distinct, are not produced as in the zebra and the tiger by differences of colour; they are due merely to the arrangement of the hair, which diverges, and the tips of which meet in lines which are very regular. The mane and the beard are strongly shaded with black, as well as the tail, which reaches down to the ground.

According to Dr. Kirk, the well-known explorer, the gorgona antelope is called *kokong* by the Bechuanas, and *nyumbo* by the Manganjas and the tribes inhabiting the banks of the Zambeze. It is, or rather was, very common in all this region of South Africa, especially in Batokoland and on the borders of Lake Shirwa. Here it associates in numerous bands with the zebras, ostriches, and giraffes. The natives hunt it very eagerly, not for its flesh, which is tough and of an unpleasant taste, but for its tail. This appendage passes among these savages as a wonderful talisman, capable of ensuring success in their warlike expeditions.

In the month of November the old males separate from their herds and wander through the country, always ready to pick a quarrel with any other males which they may meet. If alarmed, they generally make one or two wide circuits before taking to flight. Our figure is taken from *La Nature*.



THE GORGONA ANTELOPE.

Speed of Carrier Pigeons.—According to *La Nature*, four pigeons belonging to Count Karolyi, flew, in 1884, from Paris to Buda-Pesth in seven hours. Their speed must, therefore, have been nearly 185 kilometres per hour, or nearly 115 miles.

Formation of Vegetable Mould.—According to *La Nature*, Dr. M. C. Keller, of the University of Zurich, has recently published his researches on this subject, conducted in Madagascar. He fully confirms the results of Darwin. In Madagascar an earth-worm more than a yard in length (*Geophagus Darwini*) plays the principal part in the formation of soil.

Localisation of the Cerebral Centre of Visual Perception.—Mr. Alexandre Vitzon, in a communication laid before the Academy of Sciences, concludes that, in dogs at least, the integrity of sight is connected with the integrity of the occipital lobes of the brain, the destruction of this part of the brain occasioning immediate, complete and permanent blindness in both eyes.

A Train Stopped by Locusts.—*Cosmos* figures and describes a recent scene of this kind in Algeria. The crushed insects formed an oily paste upon the rails, so that the wheels turned round without advancing. An account has reached us of a train in Australia being obliged, in order to force its way through a marching column of caterpillars, to go back for upwards of a mile, and then return at the highest possible speed.

Ravages of Ferocious Animals in India.—According to the *Quarterly Review*, the number of human beings killed by wild beasts in 1886 was 2,707: by wild elephants, 57; by tigers, 928; by leopards, 194; by bears, 113; by wolves, 222; by hyaenas, 24; by other animals (doubtless chiefly death-snakes), 1,169. The number of wild animals destroyed was, elephants, 7; tigers, 1,464; leopards, 4,051; bears, 1,668; wolves, 6,725; hyaenas, 1,650; other animals, 6,852.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

EXPANSION OF INDIA-RUBBER.

In the very interesting paper on "Mechanical Refrigeration" (in Scientific News, August 3rd, p. 100) there is a statement which, left unexplained, might lead the general reader into a misunderstanding of the properties of india-rubber. To the correct remark, "Most substances expand when they are heated, and contract when they are cooled; and, conversely, when they are compressed their temperature rises, and it falls when they are allowed to expand," the author appends this doubtful note:—"India-rubber is an exception. If an elastic band be suddenly extended while it is touching the lips, it will feel warm, and when it is relaxed it will feel colder." Now, in the extension of the elastic band, there is no expansion, and in the relaxation there is no compression. There is merely a change of form. The cubic contents of the material are the same in all the cases. If you compress cork, heat is generated; in this case the compression diminishes the cubic contents of the cork. It is quite different with india-rubber. This can be tested practically. If a cylindrical metal tube be completely filled with a piece of india-rubber, and both ends be tightly closed; if pressure be applied to make the cylinder change its shape and become elliptical in section instead of circular, what is the result? It is well known that with the circular section the cylinder's contents are a maximum; and any change of form would therefore diminish the contents. But with the india-rubber the pressure does not alter the shape of the cyclinder; strike it with a hammer, and the effect is, as it were, on a piece of solid iron. Pressure does not, then, compress india-rubber, it only produces a change of form. It is different with cork. Fit cork into the circular cylinder and close the ends. Put on a pressure, and the form of the cylinder is easily changed, because the cork is compressible, with the additional exceptional property of elasticity which enables it to recover its shape when the pressure is removed.

A COBRA'S REVENGE.

In your issue of the 24th ult. was a cutting sent by G. G., bearing this title, so thinking the subject of some interest, I send you the enclosed cuttings from the *Madras Mail*:—

"Sir,—Under the above heading there appeared in your issue of 7th inst. an account of the death of engine-driver A. Fischer, at Pennar, an employé in the Madras Railway Co's service. The author of the account must have drawn deeply on his imagination to concoct so tragic a tale out of the meagre facts at his disposal. About 5 a.m. on the 3rd inst., while asleep in his quarters, Mr. Fischer was bitten on the hand, by a rat as he supposed at the time. At 6 a.m. he went to work, but feeling unwell, obtained leave from duty at 7.30, and reported himself to the apothecary. The symptoms, as described to me, might have been caused by a cobra's bite, and in spite of treatment, he rapidly got worse, and died at 2.45 p.m. No one had seen a cobra in the compound for a month previous to the occurrence, but a snake was killed in a tree in Fischer's compound the day after his death, and shown to me on the 5th inst. It was not a cobra. There is no evidence to prove that driver Fischer died from the effects of snake-bite, and it is to be regretted that an autopsy was not held upon the body. Unfortunately, I did not appear upon the scene until after the funeral.—*H. Leslie Ansted* (*Medical Officer, Madras Railway Co.*)."

"Sir,—The account in the *Madras Mail* of the 7th inst. of the death of Mr. Andrew Fischer, of the Madras Railway Co., at the Pennar Bridge Works, from cobra-bite, with the remarks of 'Kellayan,' reminds me of a story which I have heard repeated oftener than once by Major George Proudfoot, late military secretary to H.H. the Nizam. When he lived at Bowen Pillay, part of the cantonment of Secunderabad, where the native cavalry regiment is quartered, he saw, one evening as he went in his gate, a cobra hastening across the large grassy compound towards a hedge. He gave it chase, and seeing that he would not be able to overtake it before it reached the hedge, he flung at it the heavy walking-stick he carried in his hand, but missed it. Immediately the cobra turned round, and when the Major made off in the direction of his house it pursued him. The affair might have had a tragic ending for him if his syces had not observed it from the stables, and come to his rescue with bamboos, torn from the stables' verandah, with which they despatched the cobra. On the theory of the superior wisdom of the serpent, one wonders why the cobra, when it knew that its pursuer had parted with his weapon of offence, did not carry out its original intention and quietly take refuge in its hole in the hedge. On the theory of the revengeful nature of the cobra, as stated by 'Kellayan,' the action of this particular member of the species in following after its pursuer with deadly intent is explained.—*J.*"

M. H. L.

STRANGE ACTION OF A BEETLE.

Referring to the curious behaviour of a beetle (Scientific News, Aug. 17th), it occurs to me that the insect may have been injured in *one* eye, and that, seeing only with the other, it may have thought it was progressing in a straight line, when in reality it was describing a circle.

Althorne, West Bournemouth. C. Carus-Wilson.

The British Association.

BATH, SEPT. 5.

THE 58th annual meeting of the British Association opened to-day with the usual meeting of the council at 1 o'clock, under the presidency of Sir Henry Roscoe. The meeting of the general committee was held at the Guildhall under the presidency of Sir Henry Roscoe.

The minutes of the Manchester meeting having been read by Mr. Atchison,

Sir Douglas Galton read the report of the council, which notified the election of a large number of corresponding members and the nomination of Archdeacon Browne as a vice-president of the meeting. The report further stated that invitations for the year 1890 would be presented from Leeds and Cardiff, and from Edinburgh for the year 1891, and continued,

"The council have received the following report from a committee of the council appointed to consider the question of grants to marine biological stations in this country, together with a letter from Professor E. Ray Lankester, secretary of the Marine Biological Association, suggesting that the British Association should complete its donations to the funds of that association so as to make up the sum given to the amount of £500, thereby securing certain rights:

"The British Association has up to the present time granted altogether £300 to the Marine Biological Association, and by a further grant of £200 the British Association would be entitled to nominate a representative on the council of the Marine Biological Association. The committee are of opinion that the council should recommend the general committee to grant the £200, and appoint a member to represent them on the council of the Marine Biological Association.

"With reference to the grants to marine biological stations generally, the committee are of opinion that in all these cases it is desirable that grants in future should be made to individuals for specific researches rather than for the general maintenance of institutions; and with reference to the Scottish stations they would further call the attention of the council to the fact that the Scotch Fishery Board has a Parliamentary grant of £2,000 per annum for scientific investigations, the whole of which, it appears from the appropriation accounts, is not at present expended."

The council, having received the above report, have forwarded it, together with the letter of Professor Ray Lankester, to the committee of Section D.

In accordance with the regulations, the five retiring members of the council will be Professor W. Boyd Dawkins, F.R.S., Professor J. Dewer, F.R.S., Professor W. H. Flower, C.B., Dr. J. H. Gladstone, and Professor H. N. Moseley. The council recommend the re-election of the other ordinary members of council, with the addition of the following gentlemen:—Dr. Gamgee, Dr. A. Geikie, Professor Liveing, Mr. W. H. Preece, and Professor Rucker.

On the motion of the President the report was adopted. Dr. Williamson read the financial statement, which showed a total income for the year of £8,441. The grants made amounted to £1,511. The balance at the bank was £239. The investment account showed a total of £12,839 10s. 5d. The accounts were adopted. Mr. Atchinson presented a list of officers of sections, and the recommendations committee having been appointed, the meeting adjourned till Monday.

In the evening Professor Sir Henry Roscoe, the retiring president, took the chair in the large drill-hall, and was cordially received. He addressed the assembly as follows:—

My Lords, Ladies, and Gentlemen,—Four-and-twenty eventful years in the history of science have passed away since the British Association last visited the city of Bath. Those of us who were present here in 1864 will not soon forget that memorable meeting. It was presided over, as you all will remember, by that veteran geologist, that great forerunner of a new science of life, Sir Charles Lyell, of beloved and venerated memory. Yes, ladies and gentlemen, it was he who prepared the way by his recognition of the true history of our globe for the even more illustrious Darwin. It was he who pointed out that the causes which have modified the earth's crust in the past are for the most part those which are now changing the face of nature. Lyell was a typical example of the expositor of nature's most secret processes. His work was that of an investigator of science pure and undefiled, and as such his life and labours stand for ever as an example to all those who love science for her own sake. But the far-seeing founders of this our British Association were as fully alive to the fact as we, in perhaps our more utilitarian age, can be that, just as man does not live by bread alone, so it is not only by purely scientific discovery that the nations progress or that science advances. They knew as well as we do that to benefit humanity the application of the results of scientific research to the great problems of everyday life is a necessity. Hence our founders, while acknowledging that the basis of our Association can only be securely laid upon the principles of pure science in its various branches, recognised the importance of the application of those principles in the establishment of a section which should represent one of the most remarkable outcomes of the activity and force of the nation—a section of engineering. It is therefore meet and right that, in due proportion, this great department of our scientific edifice, a department which, perhaps, more than any other, has effected a revolution in our modern social systems, should be represented in our presidential chair. Twenty-four years ago it was pure science that we honoured in Sir Charles Lyell: to-day it is applied science to which we show our respect in the person of Sir Frederick Bramwell. It would ill become me, engaged as I have been in the study of subjects far removed from those which fill the life of an active and successful engineer, to venture on this occasion on a eulogium upon the work of my successor; still less is it in my mind to draw any comparison as to the relative importance to be attached to the work of the investigator such as Lyell, and to that of him who applies the researches of others to the immediate wants of mankind. It is enough for me, as I am sure it will be for you, to remember that both classes of men are needed for the due advancement of science, and to rejoice that as in former years the names of Fairbairn, of Armstrong, and of Hawkshaw have adorned our list of Presidents, so in the present instance this branch of science, which represents lines of human activity rendered illustrious by the labours of many great Englishmen, is to-day represented by our eminent President. I have the honour of requesting Sir Frederick Bramwell to take the chair, and to favour us with the Presidential address.

ADDRESS BY SIR FREDERICK BRAMWELL, D.C.L., F.R.S., M.INST.C.E., PRESIDENT.

THE late Lord Iddesleigh delighted an audience, for a whole evening, by an address on "Nothing." Would that I had his talents, and could discourse to you as charmingly as he did to his audience, but I dare not try to talk about "Nothing." I do, however, propose, as one of the two sections of my address, to discourse to you on the importance of the "Next-to-nothing." The other section is far removed from this microscopic quantity, as it will embrace the Eulogy of the Civil Engineer, and will point out the value to science of his works.

I do not intend to follow any system in dealing with these two sections. I shall not even do as Mr. Dick, in "David Copperfield," did—have two papers, to one of which it was suggested he should confine his memorial and his observations as to King Charles's head. The result is, you will find, that the importance of the next-to-nothing and the laudation of the Civil Engineer will be mixed up in the most illogical and haphazard way, throughout my Address. I will leave to such of you as are of orderly minds the task of rearranging the subjects as you see fit, but I trust—arrangement or no arrangement—that by the time I have brought my address to a conclusion I shall have convinced you that there is no man who more thoroughly appreciates the high importance of the "next-to-nothing" than the Civil Engineer of the present day, the object of my eulogy this evening.

If I may be allowed to express the scheme of this Address in modern musical language, I will say that the "next-to-nothing" "motive" will commonly usher in the "praise-song" of the Civil Engineer, and it seems to me will do this very fitly, for in many cases it is by the patient and discriminating attention paid to the effect of the "next-to-nothing" that the Civil Engineer of the present day has achieved some of the labours of which I now wish to speak to you.

An Association for the Advancement of Science is necessarily one of such broad scope in its objects, and is so thoroughly catholic as regards science, that the only possible way in which it can carry out those objects at all, is to segregate its members into various subsidiary bodies, or sections, engaged on particular branches of Science. Even when this division is resorted to, it is a hardy thing to say that every conceivable scientific subject can be dealt with by the eight Sections of the British Association. Nevertheless, as we know, for fifty-seven years the Association has carried on its labours under Sections, and has earned the right to say that it has done good service to all branches of Science.

Composed, as the Association is, of a union of separate Sections, it is only right and according to the fitness of things that, as time goes on, your Presidents should be selected, in some sort of rotation, from the various Sections. This year it was felt, by the Council and the Members, that the time had once more arrived when Section G—the Mechanical Section—might put forward its claim to be represented in the Presidency; the last time on which a purely engineering Member filled the chair having been at Bristol in 1875, when that position was occupied by Sir John Hawkshaw. It is true that at Southampton, in 1882, our lamented friend Sir William Siemens was President, and it is also true that he was a most thorough engineer and representative of Section G; but all who knew his great scientific attainments will probably agree that, on that occasion, it was rather the Physical Section A which was represented, than the Mechanical Section G.

I am aware it is said Section G does not contribute much to pure Science by original research, but that it devotes itself more to the application of Science. There may be some foundation for this assertion, but I cannot refrain from the observation, that when Engineers, such as Siemens, Rankine, Sir William Thomson, Fairbairn, or Armstrong make a scientific discovery, Section A says it is made, not in the capacity of an Engineer, and, therefore, does not appertain to Section G, but in the capacity of a Physicist, and therefore appertains to Section A—an illustration of the danger of a man's filling two positions, of which the composite Prince-Bishop is the well-known type. But I am not careful to labour this point, or even to dispute that Section G does not do much for *original* research. I don't agree it is a fact, but for the purposes of this evening I will concede it to be so. But what then? This Association is for the "Advancement of Science"—the *Advancement*, be it remembered; and I wish to point out to you, and I trust I shall succeed in establishing, that for the *Advancement* of Science it is absolutely necessary there should be the *Application* of Science, and that, therefore, the Section, which as much as any other (or, to state the fact more truly, which more than any other) in the Association *applies* Science is doing a very large share of the work of *advancing* Science, and is fully entitled to be periodically represented in the Presidency of the whole Association.

I trust also I shall prove to you that applications of Science and discoveries in pure Science act and react the one upon the other. I hope in this to carry the bulk of my audience with me, although there are some, I know, whose feelings, from a false notion of respect for Science, would probably find vent in the "toast" which one has heard in another place—this "toast" being attributed to the Pure Scientist—"Here's to the latest scientific discovery: may it never do any good to anybody!"

To give an early illustration of this action and reaction, which I contend occurs: take the well-worn story of Galileo, Torricelli, and the pump-maker. It is recorded that Galileo first, and his pupil Torricelli afterwards, were led to investigate the question of atmospheric pressure, by observing the failure of a pump to raise water by "suction" above a certain level. Perhaps you will say the pump-maker was not applying science, but was working without science. I answer, he was unknowingly applying it, and it was from that which arose in this unconscious application that the mind of the Pure Scientist was led to investigate the subject, and thereupon to discover the primary fact, of the pressure of the atmosphere, and the subsidiary facts which attend thereon. It may appear to many of you that the question of the exercise of pressure by the atmosphere should have been so very obvious, but little merit ought to have accrued to the discoverer; and that the statement, once made, must have been accepted almost as a mere truism. This was, however, by no means the case. Sir Kenelm Digby, in his "Treatise on the Nature of Bodies," printed in 1658, disputes the proposition altogether, and says, in effect, he is quite sure, the failure of the pump to raise water was due to imperfect workmanship of some kind or description, and had nothing to do with the pressure of the air, and that there is no reason why a pump should not suck up water to any height. He cites the boy's sucker, which, when applied to a smooth stone will lift it, and he says the reason why the stone follows the sucker is this: Each body must have some other body in contact with it. Now, the stone being in contact with the sucker, there is no reason why that contact should be broken up for the mere purpose of substituting the contact of another body, such as the air. It seems pretty clear, therefore, that even to an acute and well-trained mind, such as that of Sir Kenelm Digby, it was by no means a truism, and to be forthwith accepted when once stated, that the rise of water on the "suction side" of a pump was due to atmospheric pressure. I hardly need point out that the pump-maker should have been a member of "G." Galileo and Torricelli, led to reflect by what they saw, should have been members of "A" of the then "Association for the Advancement of Science."

But passing away from the question of the value of the application of science of a date some two and a half centuries ago, let us come a little nearer to our own times.

Electricity—known in its simplest form to the Greeks by the results arising from the friction on amber, and named therefrom; afterwards produced from glass cylinder machines, or from plate machines; and produced a century ago by the "Influence" machine—remained, as did the discoveries of Volta and Galvani, the pursuit of but a few, and even the brilliant experiments of Davy did not suffice to give very great impetus to this branch of physical science.

Ronalds, in 1823, constructed an electric telegraph. In 1837 the first commercial use was made of the telegraph, and from that time electrical science received an impulse such as it had never before experienced. Further scientific facts were discovered; fresh applications were made of these discoveries. These fresh applications led to renewed vigour in research, and there were the action and reaction of which I have spoken. In the year 1871 the Society of Telegraph Engineers was established. In the year 1861 our own Association had appointed a Committee to settle the question of electrical standards of resistance, which Committee, with enlarged functions, continued its labours for twenty years, and of this Committee I had the honour of being a member. The results of the labours of that Committee endure (somewhat modified, it is true), and may be pointed to as one of the evidences of the value of the work done by the British Association. Since Ronald's time, how vast are the advances which have been made in electrical communication of intelligence, by land lines, by submarine cables all over the world, and by the telephone! Few will be prepared to deny the statement that pure electrical science has received an enormous impulse, and has been advanced by the commercial application of electricity to the foregoing, and to purposes of lighting. Since this latter application, scores, I may say hundreds, of acute minds have been devoted to electrical science, stimulated thereto by the possibilities and probabilities of this application.

In this country, no doubt, still more would have been done if the lighting of districts from a central source of electricity had not been, since 1882, practically forbidden by the Act passed in that year. This Act had in its title the facetious statement that it was "to facilitate Electrical Lighting," although it is an Act which, even modified as it has been this year, is still a great discouragement of free enterprise, and a bar to progress. The other day a member of the House of Commons was saying to me, "I think it is very much to our discredit in England that we should have allowed ourselves to be outrun in the distribution of electric lighting to houses, by the inhabitants of the United States, and by those of other countries." Looking upon him as being one of the authors of the "facetious" Act, I thought it pertinent to quote the case of the French parricide, who, being asked what he has to say in mitigation of punishment, pleads, "Pity a poor orphan"—the parricide and the legislator being both of them authors of conditions of things which they affect to deplore. I will say no more on this subject, for I feel that it would not be right to take advantage of my position here to-night to urge Political Economy views, which should be reserved for Section F. I will merely, and as illustrative of my views of the value of the application of Science to Science itself, say there is no branch of physics pursued with more zeal and with more happy results than that of electricity, with its allies, and there is no branch of Science towards which the public looks with greater hope of practical benefits; a hope that, I doubt not, will be strengthened after we have had the advantage of hearing one of the ablest followers of that science, Professor Ayrton, who, on Friday next, has been good enough to promise to discourse on "The Electrical Transmission of Power."

One of the subjects which, as much as (or probably more than) any other, occupies the attention of the engineer, and therefore of Section G, is that of (the so-called) Prime Movers, and I will say boldly that, since the introduction of printing by the use of movable type, nothing has done so much for civilisation as the development of these machines. Let us consider these prime movers—and, first, in the comparatively humble function of replacing that labour which might be performed by the muscular exertion of human beings, a function which at one time was looked upon by many kindly but short-sighted men as taking the bread out of the mouth of the labourer (as it was called), and as being therefore undesirable. I remember revisiting my old schoolmaster, and his saying to me, shaking his head:—"So you have gone the way I always feared you would, and are making things of iron and brass, to do the work of men's hands."

It must be agreed that all honest and useful labour is honourable, but when that labour can be carried out without the exercise of any intelligence, one cannot help feeling that the result is likely to be intellectually lowering. Thus it is a sorry thing to see unintelligent labour, even although that labour be useful. It is but one remove from unintelligent labour which is not useful; that kind of labour generally appointed (by means of the tread-wheel or the crank) as a punishment for crime. Consider even the honourable labour (for it is useful, and it is honest) of the man who earns his livelihood by turning the handle of a crane, and compare this with the labour of a smith, who, while probably developing more energy by the use of his muscles, than is developed by the man turning the crane-handle, exercises at the same time the powers of judgment, of eye, and of hand in a manner which I never see without my admiration being excited. I say that the introduction of prime movers as a mere substitute for unintelligent manual labour is in itself a great aid to civilisation and to the raising of humanity, by rendering it very difficult, if not impossible, for a human being to obtain a livelihood by unintelligent work—the work of the horse in the mill, or of the turnspit.

But there are prime movers and prime movers—those of small dimensions, and employed for purposes where animal power or human power might be substituted, and those which attain ends that by no conceivable possibility could be attained at all by the exertion of muscular power.

Compare a galley—a vessel propelled by oars—with the modern Atlantic liner; and first let us assume that prime movers are non-existent and that this vessel is to be propelled galley-fashion. Take her length as some 600 feet, and assume that place be found for as many as 400 oars on each side, each oar worked by three men, or 2,400 men; and allow that six men under these conditions could develop work equal to one horse-power: we should have 400 horse-power. Double the number of men, and we should have 800 horse-power, with 4,800 men at work, and at least the same number in reserve, if the journey is to be carried on continuously. Contrast the puny result thus obtained with the 19,500 horse-power given forth by a large prime mover of the present day, such a power requiring, on the above mode of calculation, 117,000 men at work and 117,000 in reserve; and these to be carried in a vessel less than 600 feet in length. Even if it were possible to carry this number of men in such a vessel, by no conceivable means could their power be utilised so as to impart to it a speed of twenty knots an hour.

This illustrates how a prime mover may not only be a mere substitute for muscular work, but may afford the means of attaining an end, that could not by any possibility be attained by muscular exertion, no matter what money was expended or what galley-slave suffering was inflicted.

Take again, the case of a railway locomotive. From 400 to 600 horse-power developed in an implement which, even including its tender, does not occupy an area of more than 50 square yards, and that draws us at sixty miles an hour. Here again, the prime mover succeeds in doing that which no expenditure of money or of life could enable us to obtain from muscular effort.

To what, and to whom, are these meritorious prime movers due? I answer: to the application of science, and to the labours of the Civil Engineer, using that term in its full and proper sense, as embracing all engineering other than military. I am, as you know, a Civil Engineer, and I desire to laud my profession and to magnify mine office; and I know of no better means of doing this than by quoting to you the definition of "civil engineering" given in the Charter of the Institution of Civil Engineers, namely, that it is "the art of directing the great sources of power in Nature for the use and convenience of man." These words are taken from a definition or description of engineering given by one of our earliest scientific writers on the subject, Thomas Tredgold, who commences that description by the words above quoted, and who, having given various illustrations of the civil engineer's pursuits, introduces this pregnant sentence:—

"This is, however, only a brief sketch of the objects of civil engineering, the real extent to which it may be applied is limited only by the progress of science; its scope and utility will be increased with every discovery in philosophy, and its resources with every invention in mechanical or chemical art, since its bounds are unlimited, and equally so must be the researches of its professors."

"The art of directing the great sources of power in Nature for the use and convenience of man." Among all secular pursuits, can there be imagined one more vast in its scope, more beneficent, and therefore more honourable, than this? There are those, I know—hundreds, thousands—who say that such pursuits are not to be named as on a par with those of literature; that there is nothing ennobling in them; nothing elevating; that they are of the earth, earthy; are mechanical, and are unintellectual, and that even the mere bookworm, who, content with storing his own mind, neither distributes those stores to others nor himself originates, is more worthily occupied than is the civil engineer.

I deny this altogether, and, while acknowledging, with gratitude, that, in literature, the masterpieces of master minds have afforded, and will afford, instruction, delight, and solace for all generations, so long as civilisation endures, I say that the pursuits of civil engineering are worthy of occupying the highest intelligence, and that they are elevating and ennobling in their character.

Remember the kindly words of Sir Thomas Browne, who said, when condemning the uncharitable conduct of the mere bookworm, "I make not, therefore, my head a grave, but a treasure of knowledge, and study not for mine own sake only, but for those who study not for themselves." The engineer of the present day finds that he must not make his "head a grave," but that, if he wishes to succeed, he must have, and must exercise scientific knowledge; and he realises daily the truth that those who are to come after him must be trained in science, so that they may readily appreciate the full value of each scientific discovery as it is made. Thus the application of science by the engineer not only stimulates those who pursue science, but adds him to their number.

Holding, as I have said I do, the view that he who displaces unintelligent labour is doing good to mankind, I claim for the unknown engineer who, in Pontus, established the first water-wheel of which we have a record, and for the equally unknown engineer who first made use of wind for a motor, the title of pioneers in the raising of the dignity of labour, by compelling the change from the non-intelligent to the intelligent.

With respect to these motors—wind and water—we have two proverbs which discredit them—"Fickle as the wind," "Unstable as water."

Something more trustworthy was needed—something that we were sure of having under our hands at all times. As a result, Science was applied, and the "fire" engine, as it was first called, the "steam" engine, as it was renamed, a form of "heat" engine, as we now know it to be, was invented.

Think of the early days of the steam-engine—the pre-Watt days. The days of Papin, Savory, Newcomen, Smeaton! Great effects were produced, no doubt, as compared with no fire-engine at all; effects so very marked as to extort from the French writer, Belidor, the tribute of admiration he paid to the "fire" engine erected at the Fresnes Colliery by English engineers. A similar engine worked the pumps in York-place (now the Adelphi) for the supply of water to portions of London. We have in his work one of the very clearest accounts, illustrated by the best engravings (absolute working drawings), of the engine which had excited his admiration. These drawings show the open-topped cylinder, with condensation taking place below the piston, but with the valves worked automatically.

It need hardly be said that, noteworthy as such a machine was, as compared with animal power, or with wind or water motors, it was of necessity a most wasteful instrument as regards fuel. It is difficult to conceive in these days how, for years, it could have been endured that at each stroke of the engine the chamber that was to receive the steam at the next stroke was carefully cooled down beforehand by a water injection.

Watt, as we know, was the first to perceive, or, at all events, to cure, this fundamental error which existed prior to his time in the "fire" engine. To him we owe condensation in a separate vessel, the doing away with the open-topped cylinder, and the making the engine double-acting; the parallel motion; the governor; and the engine indicator, by which we have depicted for us the way in which the work is being performed within the cylinder. To Watt, also, we owe that great source of economic working—the knowledge of the expansive force of steam; and to his prescience we owe the steam jacket, without which expansion, beyond certain limits, is practically worthless. I have said "prescience"—foreknowledge—but I feel inclined to say that, in this case, prescience may be rendered "pre-Science," for I think that Watt *felt* the utility of the steam jacket, without being able to say on what ground that utility was based.

I have already spoken in laudatory terms of Tredgold, as being one of the earliest of our scientific engineering writers, but, as regards the question of steam jacketing, Watt's prescience was better than Tredgold's science, for the latter condemns the steam jacket, as being a means whereby the cooling surfaces are enlarged, and whereby, therefore, the condensation is increased.

I think it is not too much to say, that engineers who, since Watt's days, have produced machines of such marvellous power—and, compared with the engines of Watt's days, of so great economy—have, so far as principles are concerned, gone upon those laid down by Watt. Details of the most necessary character—necessary to enable those principles to be carried out—have, indeed, been devised since the days of Watt. Although it is still a very sad confession to have to make, that the very best of our steam-engines only utilises about one-sixth of the work which resides (if the term may be used) in the fuel that is consumed, it is, nevertheless, a satisfaction to know that great economical progress has been made, and that the 6 or 7 lbs. of fuel per horse-power per hour consumed by the very best engines of Watt's days, when working with the aid of condensation, is now brought down to about one-fourth of this consumption; and this in portable engines, for agricultural purposes, working without condensation—engines of small size, developing only 20 horse-power; in such engines the consumption has been reduced to as little as 1·85 lb. per brake horse-power per hour, equal to 1·65 lb. per indicated horse-power per hour, as was shown by the trials at the Royal Agricultural Society's meeting at Newcastle last year—trials in which I had the pleasure of participating.

In these trials, Mr. William Anderson, one of the Vice-Presidents of Section G, and I were associated, and, in making our report of the results, we adopted the balance-sheet system, which I suggested and used so long ago as 1873 (see vol. 52, pages 154 and 155, of the "Minutes of Proceedings of the Institution of Civil Engineers"), and to which I alluded in my address as President of G at Montreal.

I have told you that the engineer of the present day appreciates the value of the "next-to-nothings." There is an old housekeeping proverb that if you take care of the farthings and the pence, the shillings and the pounds will take care of themselves. Without the balance-sheet one knows that for the combustion of 1 lb. of coal, the turning into steam of a given quantity of water at a given pressure is obtained. It is seen, at once, that the result is much below that which should be had, but to account for the deficiency is the difficulty. The balance-sheet, dealing with the most minute sources of loss—the farthings and the pence of economic working—brings you face to face with these, and you find that improvement must be sought in paying attention to the "next-to-nothings."

Just one illustration. The balance-sheet will enable you at a glance to answer this, among many important questions. Has the fuel been properly burnt?—with neither too much air, nor too little.

At the Newcastle trials our knowledge as to whether we had the right amount of air for perfect combustion was got by an analysis of the waste gases, taken continuously throughout the whole number of hours' run of each engine, affording, therefore, a fair average. The analysis of any required portion of gases thus obtained was made in a quarter of an hour's time by the aid of the admirable apparatus invented by Mr. Stead, and, on the occasion to which I refer, manipulated by him. In one instance an excess of air had been supplied, causing a percentage of loss of 6·34. In the instance of another engine there was a deficiency of air, resulting in the production of carbonic oxide, involving a loss of 4 per cent. The various percentages of loss, of which each one seems somewhat unimportant, in the aggregate amounted to 28 per cent., and this with one of the best boilers. This is an admirable instance of the need of attention to apparently small things.

I have already said that we now know the steam-engine is really a heat-engine. At the York meeting of our Association I ventured to predict that, unless some substantive improvement were made in the steam-engine (of which improvement, as yet, we have no notion), I believed its days, for small powers, were numbered, and that those who attended the centenary of the British Association in 1931 would see the present steam-engines in museums, treated as things to be respected, and of antiquarian interest to the engineers of those days, such as are the open-topped steam cylinders of Newcomen and of Smeaton to ourselves. I must say I see no reason, after the seven years which have elapsed since the York meeting, to regret having made that prophecy or to desire to withdraw it.

The working of heat-engines, without the intervention of the vapour of water, by the combustion of the gases arising from coal, or from coal and from water, is now not merely an established fact, but a recognised and undoubted, commercially economical, means of obtaining motive power. Such engines, developing from 1 to 40 horse power, and worked by the ordinary gas supplied by the gas mains, are in most extensive use in printing works, hotels, clubs, theatres, and even in large private houses, for the working of dynamos to supply electric light. Such engines are also in use in factories, being sometimes driven by the gas obtained from "culm" and steam, and are giving forth a horse power for, it is stated, as small a consumption as one pound of fuel per hour.

It is hardly necessary to remind you—but let me do it—that, although the saving of half a pound of fuel per horse power appears to be insignificant, when stated in that bald way, one realises that it is of the highest importance when that half-pound turns out to be 33 per cent. of the whole previous consumption of one of those economical engines to which I have referred.

The gas-engine is no new thing. As long ago as 1807, a M. de Rivaz proposed its use for driving a carriage on ordinary roads. For anything I know he may not have been the first proposer. It need hardly be said that in those days he had not illuminating gas to resort to, and he proposed to employ hydrogen. A few years later, a writer in *Nicholson's Journal*, in an article on "flying machines," having given the correct statement that all that is needed to make a successful machine of this description is to find a sufficiently light motor, suggests that the direction in which this may be sought is the employment of illuminating gas, to operate by its explosion on the piston of an engine. The idea of the gas-engine was revived, and formed the subject of a patent by Barnett in the year 1838. It is true this gentleman did not know very much about the subject, and that he suggested many things which, if carried out, would have resulted in the production of an engine which could not have worked; but he had an alternative proposition which would have worked.

Again, in the year 1861, the matter was revived by Lenoir, and in the year 1865, by Hugon, both French inventors. Their engines obtained some considerable amount of success and notoriety, and many of them were made and used; but in the majority of cases they were discarded as wasteful and uncertain. The Institution of Civil Engineers, for example, erected a Lenoir in the year 1868, to work the ventilating fan, but after a short time they were compelled to abandon it, and to substitute a hydraulic engine.

At the present time, as I have said, gas-engines are a great commercial success, and they have become so by the attention given to small things, in popular estimation—to important things, in fact, with which, however, I must not trouble you. Messrs. Crossley Brothers, who have done so much to make the gas-engine the commercial success that it is, inform me that they are prosecuting improvements in the direction of attention to detail, from which they are obtaining greatly improved results.

But, looking at the wonderful petroleum industry, and at the multifarious products which are obtained from the crude material, is it too much to say, that there is a future for motor engines, worked by the vapour of some of the more highly volatile of these products—true vapour—not a gas, but a condensable body, capable of being worked over and over again? Numbers of such engines, some of as much as 4 horse power, made by Mr. Yarrow, are now running, and are apparently giving good results; certainly excellent results as regards the compactness and lightness of the machinery; for boat purposes they possess the great advantage of being rapidly under way. I have seen one go to work within two minutes of the striking of the match to light the burner.

Again, as we know, the vapour of this material has been used as a gas in gas-engines, the motive power having been obtained by direct combustion.

Having regard to these considerations, was I wrong in predicting that the heat-engine of the future will probably be one independent of the vapour of water? And, further, in these days of electrical advancement, is it too much to hope for the direct production of electricity from the combustion of fuel?

As the world has become familiar with prime movers, the desire for their employment has increased. Many a householder could find useful occupation for a prime mover of $\frac{1}{4}$ or $\frac{1}{2}$ horse power, working one or two hours a day; but the economical establishment of a steam-engine is not possible until houses of very large dimensions are reached, where space exists for the engine, and where, having regard to the amount of work to be done, the incidental expenses can be borne. Where this cannot be, either the prime mover, with the advantages of its use, must be given up as a thing to be wished for, but not to be procured, or recourse must be had to some other contrivance—say to the laying on of power, in some form or another, from a central source.

I have already incidentally touched upon one mode of doing this, namely, the employment of illuminating gas, as the working agent in the gas-engine; but there are various other modes, possessing their respective merits and demerits—all ingenious, all involving science in their application, and all more or less in practical use—such as the laying-on of special high-pressure water, as is now being extensively practised in London, in Hull, and elsewhere. Water at 700 lbs. pressure per inch is a most convenient mode of laying on a large amount of power, through comparatively small pipes. Like electricity, where, when a high electro-motive force is used, a large amount of energy may be sent through a small conductor, so with water, under high pressure, the mains may be kept of reasonable diameters, without rendering them too small to transmit the power required through them.

Power is also transmitted by means of compressed air, an agent which, on the score of its ability to ventilate, and of its cleanliness, has much to recommend it. On the other hand, it is an agent which, having regard to the probability of the deposition of moisture in the form of "snow," requires to be worked with judgment.

Again, there is an alternative mode for the conveyance of power by the exhaustion of air, a mode which has been in practical use for over sixty years.

We have also the curious system pursued at Schaffhausen, where quick-running ropes are driven by turbines, these being worked by the current of the river Rhine; and at New York, and in other cities of the United States, steam is laid on under the streets, so as to enable domestic steam-engines to be worked, without the necessity of a boiler, a stoker, or a chimney, the steam affording also means of heating the house when needed.

Lastly, there is the system of transmitting power by electricity, to which I have already adverted. I was glad to learn, only the other day, that there was every hope of this power being applied to the working of an important subterranean tramway.

These distributions from central sources need, as a rule, statutory powers to enable the pipes or wires to be placed under the roads; and, following the deplorable example of the Electrical Facilities Act, it is now the habit of the enlightened corporation and the enterprising town clerk of most boroughs to say to capitalists who are willing to embark their capital in the plant for the distribution of power from a central source—for their own profit, no doubt, but also, no doubt, for the good of the community—"We will oppose you in Parliament, unless you will consent that, at the end of twenty-one years, we may acquire compulsorily your property, and may do so, it it turns out to be remunerative, without other payment than that for the mere buildings and plant at that time existing." This is the way English enterprise is met, and then English engineers are taunted, by Englishmen—often by the very men who have had a share in making this "boa-constrictor" of a "Facilities Act"—that their energy is not to be compared with that which is to found in the United States and other countries. Again, however, I must remember that I am not addressing Section F.

There is one application of science, by engineers, which is of extreme beauty and interest, and that cannot be regarded with indifference by the agriculturalists of this country. I allude to the Heat-withdrawing Engines (I should like to say "cold-producers," but I presume, if I did, I should be criticised), which are now so very extensively used for the importation of fresh meat, and for its storage when received here. It need hardly be said that that which will keep cool and sweet the carcases of sheep will equally well preserve milk, and many other perishable articles of food. We have in these machines daily instances that, if you wish to make a ship's hold cold you can do it by burning a certain quantity of coals—a paradox, if ever there was one.

In this climate of ours, where the summer has been said to consist of "three hot days and a thunderstorm," there is hardly need to make a provision for cooling our houses, although there is an undoubted need for making a provision to heat them. Nevertheless, these of us who have hot-water heating arrangements for use in the winter would be very glad indeed if, without much trouble or expense, they could turn these about, so as to utilise them for cooling their houses in summer. Mr. Loftus Perkins, so well known for his labours in the use of very high-pressure steam (600 to 1,000 lbs. on the inch), and also so well known for those most useful high-pressure warming arrangements which, without disfiguring our houses by the passage of large pipes, keep them in a state of warmth and comfort throughout the winter, has lately taken up the mode of—I will say it—producing "cold" by the evaporation of ammonia, and, by improvements in detail, has succeeded in making an apparatus which, without engine or pumps, produces "cold" for some hours in succession, and requires, to put it in action, the preliminary combustion of only a few pounds of coke or a few feet of gas.

As I have said, our climate gives us but little need to provide or employ apparatus to cool our houses, but one can well imagine that the Anglo-Indian will be glad to give up his punkah for some more certain, and less draughty, mode of cooling.

I now desire to point out how, as the work of the engineer grows, his needs increase. New material, or better material of the old kind, has to be found to enable him to carry out these works of greater magnitude. At the beginning of this century, stone, brick, and timber were practically the only materials employed for that which I may call standing engineering work—*i.e.*, buildings, bridges, aqueducts, and so on—while timber, cast iron, and wrought iron were for many years the only available materials for the framing and principal parts of moving machines and engines, with the occasional use of lead for the pipes and of copper for pipes and for boilers.

As regards the cast iron, little was known of the science involved (or that ought to be involved) in its manufacture. It was judged of by results. It was judged of largely by the eye. It was "white," it was "mottled," it was "grey." It was known to be "fit for refining," fit for "strong castings," or fit for castings in which great fluidity in the molten metal was judged to be of more importance than strength in the finished casting. With respect to wrought iron, it was judged of by its results also. It was judged of by the place of its manufacture—but when the works of the district were unknown, the iron, on being tested, was classed as "good fibrous," although some of the very best was "steel-like," or "bad," "hot-short," or "cold-short." A particular district would produce one kind of iron, another district another kind of iron. The ore, the flux, and the fuel were all known to have influence, but to what extent was but little realised; and if there came in a new ore, or a new flux, it might well be that for months the turn-out of the works into which these novelties had been introduced would be prejudiced. Steel again—that luxury of the days of my youth—was judged by the eye. The wrought bars, made into "blister" steel by "cementation," were broken, examined, and grouped accordingly. Steel was known, no doubt, to be a compound of iron and carbon, but the importance of exactness in the percentage was but little understood, nor was it at all understood how the presence of comparatively small quantities of foreign matter might necessitate the variation of the proportions of carbon. The consequence was that anomalous results every now and then arose to confound the person who had used the steel, and falsifying the proverb "true as steel," steel became an object of distrust. Is it too much to say that Bessemer's great invention of steel made by the "converter," and that Siemens's invention of the open-hearth process, reacted on pure science, and set scientific men to investigate the laws which regulate the union of metals and of metalloids?—and that the labours of these scientific men have improved the manufacture, so that steel is now thoroughly and entirely trusted? By its aid engineering works are accomplished which, without that aid, would have been simply impossible. The Forth Bridge, the big gun, the compound armour of the ironclad with its steel face, the projectile to pierce that steel face—all equally depend upon the "truth" of steel as much as does the barely visible hair-spring of the chronometer, which enables the longitude of the ship in which it is carried to be ascertained. Now, what makes the difference between trustworthy and untrustworthy steel for each particular purpose? Something which, until our better sense comes to our aid, we are inclined to look upon as ridiculously insignificant—a "next-to-nothing." Setting extraneous ingredients aside, and considering only the union of iron and carbon, the question whether there shall be added or deducted one-tenth of 1 per cent. (pardon my clumsy way of using the decimal system) of carbon is a matter of great importance in the resulting quality of the steel. This is a striking practical instance of how apparently insignificant things may be of the highest importance. The variation of this fraction of a percentage may render your boiler steel untrustworthy, may make the difference between safety in a gun and danger in a gun, and may render your armour-piercing projectile unable to pierce even the thinnest wrought-iron armour.

While thus brought incidentally to the subject of guns, let me derive from it another instance of the value of small things. I have in my hand a piece of steel ribbon. It is probable that only those who are near to me can see it. Its dimensions are one-fourth by one-sixteenth of an English inch, equal to an area of one sixty-fourth of a square inch. This mode of stating the dimensions I use for the information of the ladies. To make it intelligible to my scientific friends, I must tell them that it is approximately ·00637 of a metre, by approximately ·00159 of a metre, and that its sectional area is ·0000101283 (also approximately) of a square metre. This insignificant (and speaking in reference to the greater number of my audience), practically invisible piece of material—that I can bend with my hand, and even tie into knots, is, nevertheless, not to be despised. By it one reinforces the massive and important-looking A tube of a 9·2-inch gun, so that from that tube can be projected with safety a projectile weighing 380 lbs. at a velocity when leaving the muzzle of between one-third and one-half of a mile in a second, and competent to traverse nearly 12½ miles before it touches the ground. It may be said, "What is the use of being able to fire a projectile to a distance which commonly is invisible (from some obstacle or another) to the person directing the gun?" I will suggest to you a use. Imagine a gun of this kind placed by some enemy who, unfortunately, had invaded us, and had reached Richmond. He has the range-table for his gun; he, of course, is provided with our Ordnance maps, and he lays and elevates the gun at Richmond, with the object of striking, say, the Royal Exchange. Suppose he does not succeed in his exact aim. The projectile goes 100 yards to one side or the other, or it falls 250 yards short or passes 250 yards over; and it would be "bad shooting" indeed, in these days, if nearly every projectile which was fired did not fall somewhere within an area such as this. In this suggested parallelogram of 100,000 square yards, or some twenty acres, there is some rather valuable property; and the transactions which are carried on are not unimportant. It seems to me that business would not be conducted with that calmness and coolness which are necessary for success, if, say every five minutes, a 380 lbs. shell fell within this area, vomiting fire, and scattering its walls in hundreds of pieces, with terrific violence, in all directions. Do not suppose I am saying that similar effects cannot be obtained from a gun where wire is not employed. They can be. But my point is, that they can also be obtained by the aid of the insignificant thing which I am holding up at this moment—this piece of steel ribbon, which looks more suitable for the framework of an umbrella.

I have already spoken to you, when considering steel as a mere alloy of iron and carbon, as to the value of even a fraction of 1 per cent. of the latter; but we know that in actual practice steel almost always contains other ingredients. One of the most prominent of these is manganese. It had for years been used, in quantities varying from a fraction of 1 per cent. up to 2·5 per cent., with advantage as regards ductility, and as regards its ability to withstand forging. A further increase was found not to augment the advantage: a still further increase was found to diminish it: and here the manufacturer stopped, and, so far as I know, the pure scientist stopped, on the very reasonable ground that the point of increased benefit appeared to have been well ascertained, and that there could be no advantage in pursuing an investigation which appeared only to result in decadence. But this is another instance of how the application of science reacts in the interests of pure science itself. One of our steel manufacturers, Mr. Hadfield, determined to pursue this apparently barren subject, and in doing so discovered this fact—that, while with the addition of manganese in excess of the limit before stated, and up to as much as 7 per cent., deterioration continued, after this latter percentage was passed improvement again set in.

Again, the effects of the addition of even the very smallest percentages of aluminium upon the steel with which it may be alloyed are very striking and very peculiar, giving to the steel alloy thus produced a very much greater hardness, and enabling it to take a much brighter and more silver-like polish. Further, the one-twentieth part of 1 per cent. of aluminium, when added to molten wrought iron, will reduce the fusing-point of the whole mass some 500 degrees, and will render it extremely fluid, and thus enable wrought iron (or what are commercially known as "mitis"—castings of the most intricate character) to be produced.

No one has worked more assiduously at the question of the effect of the presence of minute quantities, even traces, of alloys with metals than Professor Roberts-Austen, and he appears by his experiments, to be discovering a general law, governing the effect produced by the mixture of particular metals, so that, in future, it is to be hoped, when an alloy is, for the first time, to be attempted, it will be possible to predict with reasonable certainty what the result wil be, instead of that result remaining to be discovered by experiment.

I have just, incidentally, mentioned aluminium. May I say that we engineers look forward, with much interest, to all processes tending to bring this metal, or its alloys, within possible commercial use?

One more instance of the effect of impurities in metals. The engineer engaged in electrical matters is compelled, in the course of his daily work, frequently to realise the importance of the "next-to-nothing." One striking instance of this is afforded by the influence which an extremely minute percentage of impurity has on the electrical conductivity of copper wire: this conductivity being in some cases reduced by as much as 50 per cent, in consequence of the admixture of that which, under other circumstances, would be looked upon as insignificant.

Reverting to the question of big guns. According to the present mode of manufacture, after we have rough-bored and turned the "A" tube (and perhaps I ought to have mentioned that by the "A" tube is meant the main piece of the gun, the innermost layer, if I may so call it, that portion which is the full length of the gun, and upon which the remainder of the gun is built up)—after, as I have said, we have rough-bored and turned this "A" tube, we heat it to a temperature lying between certain specified limits, but actually determined by the behaviour of samples previously taken, and then suddenly immerse it perpendicularly into a well some 60 feet deep, full of oil, the oil in this well being kept in a state of change by the running into it, at the bottom, of cold oil conveyed by a pipe proceeding from an elevated oil tank. In this way the steel is oil-hardened, with the result of increasing its ultimate tensile strength, and also with the result of raising its so-called elastic limit. In performing this operation it is almost certain that injurious internal strains will be set up: strains tending to produce self-rupture of the material. Experiments have been carried out in England, by Captain Andrew Noble, and by General Maitland of the Royal Gun Factory, by General Kalakoutsky, in Russia, and also in the United States, to gauge what is the value, as represented by dimensions, of these strains, and we find that they have to be recorded in the most minute fractions of an inch, and yet, if the steel be of too "high" a quality (as it is technically called), or if there has been any want of uniformity in the oil-hardening process, these strains, unless got rid of or ameliorated by annealing, may, as I have said, result in the self-rupture of the steel.

I have spoken of the getting rid of the strains by annealing, a process requiring to be conducted with great care, so as not to prejudice the effects of the oil-hardening. But take the case of a hardened steel projectile, hardened so that it will penetrate the steel face of compound armour. In that case annealing cannot be resorted to, for the extreme hardness of the projectile must not be in the least impaired. The internal strains in these projectiles are so very grave, that for months after they are made there is no security that they will not spontaneously fracture. I have here the point of an 8-inch projectile, which projectile weighs 210 lbs., this with others was received from the makers as long ago as March of this year, and remained an apparently perfect and sound projectile until about the middle of August—some five months after delivery, and, of course, a somewhat longer time since manufacture—and between August 6th and 8th this piece which I hold in my hand, measuring $3\frac{3}{4}$ inches by $3\frac{1}{2}$ inches, spontaneously flew off from the rest of the projectile, and has done so upon a surface of separation which, whether having regard to its beautiful regularity, or to the conclusions to be drawn from it as to the nature of the strains existing, is of the very highest scientific interest. Many other cases of self-rupture of similar projectiles have been recorded.

Another instance of the effect of the "next-to-nothing" is the hardening and tempering or annealing of steel. As we know, the iron and the carbon (leaving other matters out of consideration) are there. The carbon is (even in tool-steel) a very small proportion of the whole. The steel may be bent, and will retain the form given to it. You heat it and plunge it in cold water; you attempt to bend it and it breaks; but if, after the plunging in cold water, you temper it by carefully reheating it, you may bring it to the condition fit either for the cutting-tool for metal, or for the cutting-tool for wood, or for the watch-spring; and these important variations of condition which are thus obtained depend upon the "next-to-nothing" in the temperature to which it is reheated, and therefore in the nature of the resulting combination of the ingredients of which the steel is composed.

Some admirable experiments were carried out on this subject by the Institution of Mechanical Engineers, with the assistance of one of our Vice-Presidents, Sir Frederick Abel, and the subject has also been dealt with by an eminent Russian writer.

There is, to my mind, another and very striking popular instance (if I may use the phrase) of the importance of attention to detail—that is, to the "next-to-nothing." Consider the bicycles and tricycles of the present day—machines which afford the means of healthful exercise to thousands, and which will, probably within a very short time, prove of the very greatest possible use for military purposes. The perfection to which these machines have been brought is almost entirely due to strict attention to detail; in the selection of the material of which the machines are made; in the application of pure science (in its strictest sense) to the form and to the proportioning of the parts, and also in the arrangement of these various parts in relation the one to the other. The result is that the greatest possible strength is afforded with only the least possible weight, and that friction in working has been reduced to a minimum. All of us who remember the hobby-horse of former years, and who contrast that machine with the bicycle or tricycle of the present day, realise how thoroughly satisfactory is the result of this attention to detail—this appreciation of the "next-to-nothing."

Let me give you another illustration of the importance of small things, drawn from gunnery practice.

At first sight one would be tempted to say that the density of the air on the underside of a shot must, notwithstanding its motion of descent, be so nearly the same as that of the air upon the upper side as to cause the difference to be unworthy of consideration, but we know that the projectiles from rifled guns tend to travel sideways as they pass through the air, and that the direction of their motion, whether to the right or to the left, depends on the "hand" of the rifling. We know also, that the friction against liquid or against gaseous bodies varies with the densities of these bodies, and it is believed that, minute as is the difference in density to which I have referred, it is sufficient to determine the lateral movement of the projectile. This lateral tendency must be allowed for, in these days of long ranges, in the sighting and laying of guns, if we desire accuracy of aim, at those distances at which it is to be expected our naval engagements will have to be commenced, and perhaps concluded. We can no longer afford to treat the subject as Nelson is said to have treated it, in one of his letters to the Secretary of the Admiralty, who had requested that an invention for laying guns more accurately should be tried. Nelson said he would be glad to try the invention, but that, as his mode of fighting consisted in placing his ship close alongside that of his enemy, he did not think the invention, even if it were successful, would be of much use to him.

While upon the question of guns, I am tempted to remark upon that which is by no means a small thing (for it is no less than the rotation of the earth), which in long-distance firing may demand attention, and that to an extent little suspected by the civilian.

Place the gun north and south, say in the latitude of London, and fire a 12-mile round such as I have mentioned, and it will be found that, assuming the shot were passing through a vacuum, a lateral allowance of more than 200 feet must be made to compensate for the different velocity of the circumference of the earth at 12 miles north or south of the place where the gun was fired, as compared with the velocity of the circumference of the earth at that place itself—the time of flight being, in round numbers, one minute.

At the risk of exciting a smile, I am about to assert that engineering has even its poetical side. I will ask you to consider with me whether there may not be true poetry in the feelings of the engineer who solves a problem such as this: Consider this rock, never visible above the surface of the tide, but making its presence known by the waves which rise around it: it has been the cause of destruction to many a noble vessel which had completed, in safety, its thousands of leagues of journey, and was, within a few score miles of port; then dashed to pieces upon it. Here is this rock. On it build a lighthouse. Lay your foundations through the water, in the midst of the turmoil of the sea; make your preparations; appear to be attaining success, and find the elements are against you and that the whole of your preliminary works are ruined or destroyed in one night; but again commence, and then go on and go on until at last you conquer; your works rise above ordinary tide-level; then upon these sure foundations, obtained, it may be, after years of toil, erect a fair shaft, graceful as a palm and sturdy as an oak; surmount it with a light, itself the produce of the highest application of science; direct that light by the built-up lens, again involving the highest application of science; apply mechanism, so arranged that the lighthouse shall from minute to minute reveal to the anxious mariner its exact name and its position on the coast. When you have done all this, will you not be entitled to say to yourself, "It is I who have for ever rendered innocuous this rock which has been hitherto a dread source of peril"! Is there no feeling, do you think, of a poetical nature excited in the breast of the engineer who has successfully grappled with a problem such as this?

Another instance: The mouth of a broad river, or, more properly speaking, the inlet of the sea, has to be crossed at such a level as not to impede the passage of the largest ships. Except in one or two places the depth is profound, so that multiple foundations for supporting a bridge become commercially impossible, and the solution of the problem must be found by making, high in the air, a flight of span previously deemed unattainable. Is there no poetry here? Again, although the results do not strike the eye in the same manner, is there nothing of poetry in the work, that has to be thought out and achieved, when a wide river or an ocean-channel has to be crossed by a subterranean passage? Works of great magnitude of this character have been performed with success, and to the benefit of those for whose use they were intended. One of the greatest and most noble of such works, encouraged, in years gone by by the Governments of our own country and of France, has lately fallen into disfavour with an unreasoning public, who have not taken the pains to ascertain the true state of the case.

Surely it will be agreed that the promotion of ready intercourse and communication between nations constitutes the very best, and most satisfactory guarantee for the preservation of peace; when the peoples of two countries come to know each other intimately, and when they, therefore, enter into closer business relations, they are less liable to be led away by panic or by anger, and they hesitate to go to war the one with the other. It is in the interests of both that questions of difference which may arise between them should be amicably settled, and having an intimate knowledge of each other, they are less liable to misunderstand, and the mode of determination of their differences is more readily arranged. Remember, the means of ready intercourse and of communication, and the means of easy travel, are all due to the application of science by the engineer. Is not, therefore, his profession a beneficent one?

Further, do you not think poetical feeling will be excited in the breast of that engineer who will in the near future solve the problem (and it certainly will be solved when a sufficiently light motor is obtained) of travelling in the air—whether this solution be effected by enabling the self-suspended balloon to be propelled and directed, or perhaps, better still, by enabling not only the propulsion to be effected and the direction to be controlled, but by enabling the suspension in the air itself to be attained by mechanical means?

Take other functions of the civil engineer, functions which, after all, are of the most important character, for they contribute directly to the prevention of disease, and thereby not only prolong life, but do that which is probably more important, afford to the population a healthier life while lived.

In one town, about which I have full means of knowing, the report has just been made that in the year following the completion of a comprehensive system of sewerage, the deaths from zymotic diseases had fallen from a total of 740 per annum to a total of 372, practically one-half. Has the engineer no inward satisfaction who knows such results as these have accrued from his work?

Again, consider the magnitude and completeness of the water-supply of a large town, especially a town that has to depend upon the storing-up of rain-water: the prevision which takes into account, not merely the variation of the different seasons of the year, but the variation of one year from another; that, having collated all the stored-up information, determines what must be the magnitude of the reservoirs to allow for at least three consecutive dry years, such as may happen; and that finds the sites where these huge reservoirs may be safely built.

All these, and many other illustrations which I could put before you if time allowed, appear to me to afford conclusive evidence that, whether it be in the erection of the lighthouse on the lonely rock at sea; whether it be in the crossing of rivers, or seas, or arms of seas by bridges or by tunnels; whether it be the cleansing of our towns from that which is foul; whether it be the supply of pure water to every dwelling, or the distribution of light or of motive power; whether it be in the production of the mighty ocean steamer, or in the spanning of valleys, the piercing of mountains, and affording the firm, secure road for the express train; or whether it be the encircling of the world with telegraphs—the work of the Civil Engineer is not of the earth, earthy, is not mechanical to the exclusion of science, is not unintellectual; but is of a most beneficent nature, is consistent with true poetical feeling, and is worthy of the highest order of intellect.

ABSTRACT OF THE ADDRESS TO THE MATHEMATICAL AND PHYSICAL SECTION OF THE BRITISH ASSOCIATION,

By Professor G. F. Fitzgerald, M.A., F.R.S., President of the Section.

In a presidential address on the borderlands of the known delivered from this chair, the great Clerk Maxwell spoke of as an undecided question whether electro-magnetic phenomena are due to a direct action at a distance or are due to the action of an intervening medium. The year 1888 will be ever memorable as the year in which this great question has been experimentally decided by Hertz in Germany and, I hope, by others in England. It has been decided in favour of the hypothesis that these actions take place by means of an intervening medium. Although there is nothing new about the question, and although most workers at it have long been practically satisfied that electro-magnetic actions are due to an intervening medium, I have thought it worth while to try and explain to others who may not have considered the problem what the problem is and how it has been solved.

An illustrative example may make the question itself clearer, and so lead you to understand the answer better. In colloquial language we may say that balloons, hot air, etc., rise because they are light. In old times this was stated more explicitly, and therefore much more clearly. It was said that they possessed a quality called "levity." "Levity" was opposed to "heaviness." Heaviness made things tend downwards, levity made things tend upwards. It was a sort of action at a distance. At least it would have required such a hypothesis if it had survived until it was known that heaviness was due to the action of the earth. I expect levity would have been attributed to the direct action of heaven. It was comparatively recently in the history of mankind that the rising of hot air, flames, etc., was attributed to the air. Everybody knew that there was air, but it was not supposed that the upward motion of flames was due to it. We now know that this and the rising of balloons are due to the difference of pressure at different levels in the air. In a similar way we have long known that there is an ether, an all-pervading medium, occupying all known space. Its existence is a necessary consequence of the undulatory theory of light. People who think a little but not much sometimes ask me, "Why do you believe in the ether? What's the good of it?" I ask them, "What becomes of light for the eight minutes after it has left the sun and before it reaches the earth?" When they consider that they observe how necessary the ether is. If light took no time to come from the sun there would be no need of the ether. That it is a vibratory phenomenon, that it is affected by matter it acts through—these could be explained by action at a distance very well. The phenomena of interference would, however, require such complicated and curious laws of action at a distance as practically to put such a hypothesis out of court or else be purely mathematical expressions for wave propagation. In fact, anything except propagation in time is explicable by action at a distance. It is the same in the case of electro-magnetic actions. There were two hypotheses as to the causes of electro-magnetic actions. One attributed electric attraction to a property of a thing called electricity, to attract at a distance, the other attributed it to a pull exerted by means of the ether, somewhat in the way that air pushes balloons up. We do not know what the structure of the ether is by means of which it can pull, but neither do we know what the structure of a piece of india-rubber is by means of which it can pull, and we might as well ignore the indiarubber, though we know a lot about the laws of its action, because we do not know its structure, as to ignore the ether because we do not know its structure. Anyway, what was wanted was an experiment to decide between the hypothesis of direct action at a distance and of action by means of a medium. At the time that Clerk Maxwell delivered his address no experiment was known that could decide between the two hypotheses. Specific inductive capacity, the action of intervening matter, the delay in telegraphing, the time propagation of electro-magnetic actions by means of conducting material—these were known, but he knew that they could be explained by means of action at a distance, and had been so explained. Waves in a conductor do not necessarily postulate action through a medium such as the ether. When we are dealing with a conductor and a thing called electricity running over its surface, we are, of course, postulating a medium on or in the conductor, but not outside it, which is the special point at issue. Clerk Maxwell *believed* that just as the same air that transmits sound is able by differences of pressure—*i.e.*, by means of its energy per unit volume—to move bodies immersed in it, so the same ether that transmits light causes electrified bodies to move by means of its energy per unit volume. He believed this, but there was no experiment known then to decide between this hypothesis and that of direct action at a distance. As I have endeavoured to impress upon you, no *experimentum crucis* between the hypotheses is possible except an experiment proving propagation in time either directly, or indirectly by an experiment exhibiting phenomena like those of the interference of light. A theorist may speak of propagation of actions in time without talking of a medium. This is all very well in mathematical formulæ, but, as in the case of light, we must consider what becomes of it after it has left the sun and before it reaches the earth, so every hypothesis assuming action in time really postulates a medium whether we talk about it or not. There are some difficulties surrounding the complete interpretation of some of Hertz's experiments. The conditions are complicated, but I confidently expect that they will lead to a decision on most of the outstanding questions on the theory of electro-magnetic action. However, there is no doubt that he has observed the interference of electro-magnetic waves quite analogous to those of light, and that he has proved that electro-magnetic actions are propagated in air with the velocity of light. By a beautiful device Hertz has produced rapidly alternating currents of such frequency that their wave length is only about two mètres. I may pause for a minute to call your attention to what that means. These waves are propagated three hundred thousand kilomètres in a second. If they vibrated three hundred thousand times a second the waves would be each a kilomètre long. This rate of vibration is much higher than the highest audible note, and yet the waves are much too long to be manageable. We want a vibration about a thousand times as fast again with waves about a mètre long. Hertz produced such vibrations, vibrating more than a hundred million times a a second. That is, there are as many vibrations in one second as there are seconds—in a day? No, far more. In a week? No, more even than that. The pendulum of a clock ticking seconds would have to vibrate for four months before it would vibrate as often as one of Hertz's vibrators vibrates in one second. And how did he detect the vibrations and their interference? He could not see them; they are much too slow for that; they should go about a million times as fast again to be visible. He could not hear them; they are much too quick for that. If they went a million times more slowly they would be well heard. He made use of the principle of resonance. You all understand how by a succession of well-timed small impulses a large vibration may be set up. It explains many things, from speech to spectrum analysis. It is related that a former Marquess of Waterford used the principle to overturn lamp-posts; his ambition soared above knocker-wrenching. So that it is a principle known to others besides scientific men. Hertz constructed a circuit whose period of vibration for electric currents was the same as that of his generating vibrator, and he was able to see sparks, due to the induced vibration, leaping across a small air-space in this resonant circuit. The well-timed electrical impulses broke down the air-resistance just as those of my Lord of Waterford broke down the lamp-post. The combination of a vibrating generating circuit with a resonant-receiving circuit is one that I spoke of at the meeting of the British Association at Southport as one by which this very question might be studied. At the time I did not see any feasible way of detecting the induced resonance; I did not anticipate that it could produce sparks. By its means, however, Hertz has been able to observe the interference between waves incident on a wall and the reflected waves. He placed his generating vibrator several wave lengths away from a wall, and placed the receiving resonant circuit between the generator and the wall, and in this air-space he was able to observe that at some points there were hardly any induced sparks, but at other and greater distances from his generator they reappeared to disappear again in regular succession at equal intervals between his generator and the wall. It is exactly the same phenomenon as what are known as Lloyd's bands in optics, which are due to the interference between a direct and a reflected wave. It follows hence that, just as Young's and Fresnell's researches on the Interference of Light prove the undulatory theory of optics, so Hertz's experiment proves the ethereal theory of electro-magnetism. It is a splendid result. Henceforth I hope no learner will fail to be impressed with the theory—hypothesis no longer—that electro-magnetic actions are due to a medium pervading all known space, and that it is the same medium as the one by which light is propagated, that non-conductors can, and probably always do, as Professor Poynting has taught us, transmit electro-magnetic energy. By means of variable currents energy *is* propagated into space with the velocity of light. The rotation of the earth is being slowly stopped by the diurnal rotation of its magnetic poles. This seems a hopeful direction in which to look for an explanation of the secular precession of terrestrial magnetism. It is quite different from Edlund's curious hypothesis that free space is a perfect conductor. If this were true, there would be a pair of great antipoles outside the air, and terrestrial magnetism would not be much like what it is, and I think the earth would have stopped rotating long ago. With alternating currents we *do* propagate energy through non-conductors. It seems almost as if our future telegraph cables would be pipes. Just as the long sound waves in speaking tubes go round corners, so these electro-magnetic waves go round corners if they are not too sharp. Professor Lodge will probably have something to tell us on this point in connection with lightning conductors. The silvered glass-bars used by surgeons to conduct light are exactly what I am describing. They are a glass, a non-conducting, and therefore transparent, bar surrounded by a conducting, and therefore opaque, silver sheath, and they transmit the rapidly alternating currents we call light. There would not be the same difficulty in utilising the energy of these electro-magnetic waves as in utilising radiant heat. Having all the vibrations of the same period we might utilise Hertz's resonating circuits, and in any case the second law of thermodynamics would not trouble us when we could practically attain to the absolute zero of these, as compared with heat, long period vibrations.

We seem to be approaching a theory as to the structure of the ether. There are difficulties from diffusion in the simple theory that it is a fluid full of motion, a sort of vortex sponge. There were similar difficulties in the wave theory of light owing to wave propagation round corners, and there is as great a difficulty in the jelly theory of the ether arising from the freedom of motion of matter through it. It may be found that there is diffusion or it may be found that there are polarised distributions of fluid kinetic energy which are not unstable when the surfaces are fixed; more than one such is known. Osborne Reynolds has pointed out another, though in my opinion less hopeful, direction in which to look for a theory of the ether. Hard particles are abominations. Perhaps the impenetrability of a vortex would suffice. Olive Lodge speaks confidently of a sort of chemical union of two opposite kinds of elements forming the ether. The opposite sides of a vortex ring might perchance suit, or maybe the ether, after all, is but an atmosphere of some infra-hydrogen element; these two latter hypotheses may both come to the same thing. Anyway we are learning daily what sort of properties the ether must have. It must be the means of propagation of light; it must be the means by which electric and magnetic forces exist; it should explain chemical actions, and, if possible, gravity.

On the vortex-sponge theory of the ether there is no real difficulty by reason of complexity why it should not explain chemical actions. In fact, there is every reason to expect that very much more complex actions would take place at distances comparable with the size of the vortices than at the distances at which we study the simple phenomena of electro magnetism. Indeed, if vortices can make a small piece of a strong elastic solid we can make watches and build steam engines and any amount of complex machinery, so that complexity can be no essential difficulty. Similarly the instantaneous propagation of gravity, if it exists, is not an essential difficulty, for vortices each occupy all space, and they act on one another simultaneously everywhere. The theory that material atoms are simple vortex rings in a perfect liquid otherwise unmoving is insufficient, but with the innumerable possibilities of fluid motion it seems almost impossible but that an explanation of the properties of the universe will be found in this conception. Anything purporting to be an explanation founded on such ideas as "an inherent property of matter to attract," or building up big elastic solids out of little ones, is not of the nature of an ultimate explanation at all; it can only be a temporary stopping place. There are metaphysical grounds, too, for reducing matter to motion and potential to kinetic energy.

These ideas are not new, but it is well to enunciate them from time to time, and a presidential address in Section A is a fitting time. Besides all this it has become the fashion to indulge in quaint cosmical theories and to dilate upon them before learned societies and in learned journals. I would suggest, as one who has been bogged in this quagmire, that a successor in this chair might well devote himself to a review of the cosmical theories propounded within the last few years. The opportunities for piquant criticism would be splendid.

Returning to the sure ground of experimental research let us for a moment contemplate what is betokened by this theory that in electro-magnetic engines we are using as our mechanism the ether, the medium that fills all known space. It was a great step in human progress when man learnt to make material machines, when he used the elasticity of his bow and the rigidity of his arrow to provide food and defeat his enemies. It was a great advance when he learnt to use the chemical action of fire; when he learnt to use water to float his boats and air to drive them; when he used artificial selection to provide himself with food and domestic animals. For two hundred years he has made heat his slave to drive his machinery. Fire, water, earth, and air have long been his slaves, but it is only within the last few years that man has won the battle lost by the giants of old, has snatched the thunderbolt from Jove himself and enslaved the all-pervading ether.

ABSTRACT OF THE ADDRESS TO THE CHEMICAL SECTION OF THE BRITISH ASSOCIATION.

By Professor William A. Tilden, D.Sc. Lond, F.R.S., F.C.S., President of the Section.

The fact that at the last meeting of the Association a Committee was appointed to inquire into the methods at present adopted for teaching chemistry suggested that, as I had not been able to accept an invitation to join this Committee, I might make use of this opportunity for contributing to the discussion. The first report of the Committee will be received with much interest by the Section. As might be expected, it embodies the expression of many varieties of opinion.

The existence of chemistry as a department of science not merely requiring the observation of facts that are to be made useful, but seeking in the accumulated stores of observation to discover law, is a thing of comparatively recent growth. How chemistry arose out of alchemy I need not remind you, but the connection between the study of chemistry and that of medicine, and the maintenance of this connection down to even the present generation, is illustrated by the fact that a large number of men who have become eminent as chemists began their career in the surgery or the pharmacy. Black, Davy, Berzelius, Wollaston, Wöhler, Wurtz, Andrews, and W. A. Miller began by the study of medicine, whilst Scheele, H. Rose, and the great names of Liebig and Dumas are to be found in the long roll of those who received their earliest notions of chemistry in the pharmaceutical laboratory. Chemistry has been gradually emancipated from these associations with enormous advantage to both sides. So long as technical purposes alone were held in view a scientific chemistry could not exist, but no sooner did the study take an independent form and direction than multitudes of useful applications of the facts discovered became apparent.

In the old time such instruction in chemistry as was given in the universities and mining or technical schools seems to have taken the form of lectures read by the Professor, and access to a laboratory for practical manipulation seems to have been a high privilege, accorded only under exceptional circumstances to the few. We are told, for example, that when Liebig went to Paris in 1823 he applied to Gay-Lussac for practical instruction at first without success, and that admission to the laboratory of the Ecole Polytechnique was ultimately granted him only through the intervention of Von Humboldt.

Doubtless, therefore, the recollection of his own early difficulties when seeking instruction contributed largely to influence Liebig in the establishment of the laboratory in the University of Giessen, and in the adoption of the principles which guided his teaching there. For the first time in the history of chemistry, students met not merely to listen to the discourse of a professor concerning his own experiments and conclusions, but to examine for themselves the basis of the theories taught, to learn the processes of analysis, and by independent investigation to extend the boundaries of existing knowledge.

The fame of the new school spread fast and far, and soon men from every part of the civilised world assembled to share in the advantages offered. The influence of the new method can be estimated when we reflect that nearly all the now passing generation of chemists in England and America obtained the greater part of their training in Liebig's laboratory; and as a large number of them have been teachers, it may be assumed that they transplanted into their own countries the methods they had learnt from the great German master.

It was not till 1846, long after the school at Giessen had risen into fame, that in England a sense of our deficiencies in respect to provision for teaching chemistry was felt strongly enough to lead to the establishment of a college of chemistry. At that time the Professor of Chemistry at Oxford was also Professor of Botany. At Cambridge it was thought praise and boast enough that the occupant of the chair of chemistry had, during more than thirty years, frequently resided at the University, and every year gave a course of lectures. The Jacksonian professorship was not then, as now, in the possession of a chemist. University College, London, had at this period a very distinguished man in the chair of chemistry, but it was only in 1848 that a commodious laboratory was provided by public subscription, raised in commemoration of the services of Dr. Birkbeck in promoting popular education. In that year Fownes was appointed to co-operate with Graham in the work of teaching, though his premature death soon after left but little time for the fulfilment of the rich promise of his earlier days. At Manchester John Owens had died in 1846, leaving the bulk of his estate for the purpose of establishing a university in Manchester, but as yet the Owens College was not.

The foundation of the College of Chemistry in 1846 was therefore an event of supreme importance in the history of chemical teaching in this country.

Since then the means of instruction in science in England have multiplied enormously. In University College, London, founded in 1828, and in Owens College, Manchester, founded in 1851, not only have chairs of chemistry existed from the first, but they have been occupied by a succession of chemists of the highest eminence. But long after 1846 the whole of the serious teaching of scientific chemistry was accomplished at the College of Chemistry, and it was nigh upon twenty years before the Manchester school began to attract considerable notice.

In 1872-3 the movement set in which has resulted in the erection of colleges for higher instruction at a number of important English and Welsh towns. These, together with the pre-existent Queen's Colleges in Ireland and the Universities of more ancient foundation in the three kingdoms, are for the most part provided with pretty good laboratories and a competent staff. We have also the Normal School of Science and the Institute raised by the City and Guilds of London at South Kensington, and its Associate College at Finsbury. England is therefore at the present time as well provided with *places* of instruction for the study of chemistry as any country in the world.

It is nevertheless true that increased opportunities for study, a considerable supply of capable teachers, and an enormous body of students have not produced such an amount of original investigation, or even of accurate analytical work, as might reasonably be expected. A full and complete explanation of all the influences which contribute to this result would be difficult; but I think the apparent inactivity of the chemical schools in this country is not generally the fault of the professors, but is chargeable in the main to the ignorance, and partly to the indifference, of the public.

In the case of chemistry the absence of sentiment in favour of concentration and thoroughness, and the demand for superficiality, if only it can be had wholesale, tells in a variety of ways. The governing bodies who control the various colleges and universities, and the public generally, cannot understand that good and useful work is being done unless it can be shown in the form of passes at examinations. Though I most firmly believe in the necessity for examinations, serious mischief begins when they are regarded as the end itself, and not as mere incidents in the student's career towards the end, which should be knowledge.

Reflect also upon the fact that there are only two or three colleges in this country which can boast of more than one professor of chemistry. In nearly all cases one man is called upon to discharge the duty of teaching classes both elementary and advanced, in pure and applied chemistry, inorganic and organic, theoretical and practical. This is a kind of thing which kills specialism, and without specialists we can have not only no advance, but no efficient teaching of more than rudiments.

That teachers ought to engage in research at all is by no means clear to the public and to those representatives of the public who are charged with the administration of these new institutions. Without going far into the discussion of the general question, which is a large one, I may perhaps be allowed to offer a few remarks for the consideration of any of my audience who may perchance incline towards that opinion.

It is only when a teacher occupies himself with research that the most complete guarantee is given that he is interested in his subject and that he is a learner. A popular mistake consists in regarding a professor as a living embodiment of science—complete, infallible, mysterious; whereas in truth he is, or ought to be, only a senior student who devotes the greater part of his time to extending and consolidating his own knowledge for the benefit or those who come to learn of him, not only what lies within the boundaries of the known, but how to penetrate into the far greater region of the unknown. Moreover, the man who has no intellectual independence and simply accepts other people's views without challenge is pretty certain to make the stock of knowledge with which he sets out in life do service to the end. That one may be fitted to form a sound judgment concerning new theories he must be familiar with the methods by which progress is accomplished. The work of investigation then reacts beneficially upon the work of teaching; that is why teachers should be encouraged, nay even required, to investigate, and not because their discoveries may haply prove to be practically useful.

Of course it may be said that there have been distinguished investigators who could not teach, but the converse is not true; every teacher who has attained to eminence as a teacher, who has drawn men after him, who has founded a school of thought, and has left his mark upon his generation, has been an industrious worker in research of some kind. All teachers cannot be expected to reach the same high standard, but this is the ideal after which all must strive, or fail utterly.

The fact that there is as yet little demand among schoolmasters for high attainments in chemistry is another reason why so little is accomplished in the chemical schools. Here again the public is really to blame. It is disgraceful that in all classes of schools, even where chemistry is supposed to be taught, there are but few places where serious employment is found for the well trained chemist. I could point to several schools which claim the position of first-rate, where chemistry is taught by masters who have never studied the subject at all, but who are, I suppose, allowed the traditional "ten minutes' start" with the book. Would the head-masters of such places dare to employ a person to teach mathematics who did not know the four first rules of arithmetic, or another to teach Latin who had not even got through the accidence? I fancy not. This, however, is without exaggeration the exact parallel of the position in which chemistry is placed in the majority of schools.

There is an opportunity at the present time of correcting some of these mistakes, but no advantage is being taken of it. I refer now to the "technical schools" which are springing up everywhere. There may be a few competent teachers of chemistry employed in some of them, but I find it difficult to think of many examples. The sort of person who is put in charge of these places is usually a schoolmaster, who is allowed, sometimes even after his appointment, to get a short course of qualitative analysis in order to enable him to obtain a certificate which will entitle him to earn grants from the Science and Art Department.

Three years has hitherto been regarded as the normal period for study. The question arises, can a young man, previously well educated, expect to become an accomplished chemist, competent to apply his knowledge usefully, by giving the whole of his time to study during *three years*? I believe not.

By reason of the enormous development of the science the position of the student of chemistry is nowadays very different from what it was thirty years ago. Since that time we have not only got a few new elements, a matter of small importance in itself, but new views of the nature of the elements and of their mutual relations. This could hardly have come about but for the recognition of the law of Avogadro as a fundamental principle, upon which we rely as the ultimate criterion by which the true distinction between so-called equivalent weights and molecular ratios has been established. By the gradual evolution of ideas having reference successively to the electro-chemical relations of elements and compounds, the theory of types, and atomicity or valency, we have arrived at notions of chemical constitution based upon the hypothesis of the orderly linking together of atoms. Thirty years ago isomerism had scarcely attracted notice, and carbon compounds were only just beginning to be arranged in homologous series. The general use at the present day of the language of the molecular kinetic theory shows how deeply this theory influences our ideas of the internal constitution of matter. Within the period referred to, dissociation has been studied, and a vast body of thermo-chemical data have been accumulated. And although the larger portion of the results of this work still await interpretation, dynamical ideas of chemical action are now generally accepted. We have also new methods of investigation, including spectroscopic analysis with all its vast train of results.

It has always been thought essential that a student of chemistry should have some knowledge of physics. It is now more than ever necessary that this knowledge should be extensive, sound, and based upon a good foundation of mathematics. Thirty years ago a hundred pages of Fownes contained all that was thought necessary, but no one nowadays could be satisfied with that. It is now asserted that a young chemist who expects to find a career in industrial chemistry should also have learnt drawing, and more important still that he should have a good general knowledge of mechanics, steam, and building construction. I suppose everyone will agree in adding French and especially German. You see how the requirements expand.

The inference from all this is that it now takes longer to make a chemist than formerly. This is a point of considerable practical importance.

My estimate that a well-educated and intelligent young man will now require five years for the study of chemistry and accessory subjects before he is likely to be of much use will not appear extravagant.

Here one may remark that in order to become a chemist it is before all things necessary to study chemistry. If the greater part of a student's time is to be taken up with other things it is not very clear how this is to be done.

A reform all round is wanted. The mathematics, modern languages, and drawing properly belong to the antecedent school period, and I believe the Institute of Chemistry would greatly promote the interests of the profession, if it would impose upon candidates for the Associateship not only a three years' course of training with an examination in practical chemistry at the end, but a severe examination in mathematics, in the English, French, and German languages, and perhaps drawing before matriculation or registration.

A consideration of the present position of the student of chemistry leads naturally to a review of the methods of teaching the subject. Speaking broadly, I suppose nearly all professional chemists who have had the advantage of systematic training have, up to the present time, passed through very much the same kind of course. This consists, as everybody knows, very largely of analytical work, qualitative and quantitative, preceded or followed by the preparation of a number of definite chemical compounds, besides practice in certain very necessary physical determinations, *e.g.*, relative density of solids, liquids, and gases, melting points, boiling points, and so forth. There seems now to be a disposition in some quarters to depart from this time-honoured curriculum in favour of a course in which the student is early engaged in some semblance of investigation, and in which he is encouraged to attack difficult problems, which from their fundamental importance offer considerable temptation. I venture to express a hope that this will not be carried too far. Already we are in danger of losing the art of accurate analysis. One constantly meets with young chemists who are ready enough to discuss the constitution of benzene, but who cannot make a reliable combustion. And according to my own experience, attempts at research among inexperienced chemists become abortive more frequently in consequence of deficient analytical skill than from any other cause.

But though it does not appear to me to be wise to encourage beginners, without sufficient experience or manipulative skill, to attempt original work, one of the best possible exercises preparatory to original work is to select suitable memoirs, and not only to read them but to work conscientiously through the whole of the preparations and analyses described, following the instructions given. Many of Dr. Hofmann's papers afford excellent examples. So also do the writings of Dr. Perkin and Dr. Frankland, besides those of many other chemists which could easily be selected by the teacher.

An intelligent student, possessing the requisite preliminary knowledge, would obtain much instruction by repeating the work contained in such papers as the following, for example:—Emerson Reynolds, on the "Missing Sulphur Urea" ("J. Chem. Soc.," 1869—i.); Fittig and Tollens, on the "Synthesis of Hydrocarbons of the Benzol Series" (Liebig's "Annalen," 1864, cxxxi. 303); L. Claisen and Pupils, on the "Introduction of Acid Radicles into Ketones," etc. ("Berichte," xx.); Lawson and Collie, on the "Action of Heat on Salts of Tetramethyl-Ammonium" ("J. Chem. Soc.," June, 1888); Thorpe and Hambly, on "Manganic Trioxide" ("J. Chem. Soc.," March, 1888); besides many others, including papers on analytical processes. To such as these there might subsequently be added the determination of an atomic weight on the model of one of the best masters, as a discipline which could not fail to be impressive, and full of instruction.

A number of papers, pamphlets and text-books have lately appeared, professing to teach the principles of the science practically and by new methods. Most of these turn out, upon inspection, to be very old methods indeed, but there is a small residue of distinctly original character, which are sure to attract, as they deserve, considerable attention. The systems I refer to provide a series of problems which the pupils are called upon to solve. According to this plan the student is not allowed peaceably to examine the properties of oxygen or sulphur which he now sees for the first time. He must weigh, and measure, and observe, and then infer. All this coming at once upon the head of a beginner seems to me to be well fitted to drive him to despair.

I well remember the first experiment in chemistry I ever made. It consisted in dissolving zinc in diluted sulphuric acid in an evaporating dish, lighting with a match the bubbles of hydrogen as they rose, and afterwards leaving the solution to crystallise. I was about sixteen, and the bubbles of gas as well as the crystals I afterwards got interested me very much. If at that time I had been made to weigh the zinc and acid, and measure the hydrogen with the object of answering some question about the composition of zinc and hydrogen sulphates, I should have been pretty much in the position of a boy ignorant of geometry shut up with the propositions of Euclid and ordered to give the demonstrations.

I think when we recall such a fact as that Priestley, who discovered oxygen in 1774, failed to the end of his days to understand the process of combustion, and actually wrote, in 1800, a pamphlet in defence of "phlogiston," we ought not to be surprised when young people, though born a century later, fail to perceive at once the full significance of facts to which they are introduced for the first time. At the outset you cannot reasonably expect a young student both to observe accurately and infer justly. These two things must be kept separate at first, and for this reason among others I believe that attempts to make young students verify for themselves the fundamental propositions of chemistry will not be successful. One has only to trace the origin of one's own convictions in reference to any important fact or principle to perceive that they very seldom spring into existence suddenly, but almost always commence in vagueness and hesitation, acquiring consistency and solidity only as the result of accumulated experience.

I will not pretend to determine what may be included within the wide circle of the functions of the British Association; but I think I cannot be mistaken in assuming that the advancement of science is dependent in no small degree upon the provision for the efficient teaching of science. I have traced an outline of what has been done in the past, and have endeavoured to show in what respects I think we are deficient at the present time. No matter how ardent may be the aspirations, how earnest the endeavours of the few, progress will be slow unless they are sustained by the sympathy of the many. On one principle the public must surely insist, that only those shall be allowed to teach who know.

ABSTRACT OF THE ADDRESS TO THE GEOLOGICAL SECTION OF THE BRITISH ASSOCIATION,

By W. Boyd Dawkins, M.A., F.R.S., F.G.S., F.S.A., Professor of Geology and Paleontology in Owens College, President of the Section.

Our science has made great strides during the last twenty-four years, and she has profited much from the great development of her sisters. The microscopic analysis of the rocks has opened out a new field of research, in which physics and chemistry are in friendly rivalry, and in which fascinating discoveries are being made almost day by day as to metamorphism, and the crushing and shearing forces brought to bear upon the cooling and contracting crust while the earth was young. The deep-sea explorations have revealed the structure and the deposits of the ocean abysses, and the depths supposed to be without life, like the fabled deserts in the interior of Africa, are now known to teem with varied forms glowing with the richest colours. From a comparison of these deposits with the stratified rocks we may conclude that the latter are marginal, and deposited in depths not greater than 1,000 fathoms, or the shore end of the Globigerina ooze, and most of them at a very much less depth, and that consequently there is no proof in the geological record of the ocean depths having ever been in any other than their present places.

In North America the geological survey of the Western States has brought to light an almost unbroken series of animal remains, ranging from the Eocene down to the Pleistocene Age. In these we find the missing links in the pedigree of the Horse, and sufficient vidence of transitional forms to cause Professor Flower to restore o its place in classification the order Ungulata of Cuvier. These may be expected to occupy the energies of our kinsmen on the other side of the Atlantic for many years, and to yield further proof of the truth of the doctrine of evolution. The use of this word reminds me how much we have grown since 1864, when evolution was under discussion, and when biological, physical, and geological laboratories could scarcely be said to have existed in this country. Truly may the scientific youth of to-day make the boast—

Ἡμεῖς μὲν πατέρων μέγ' ἀμείνονες εὐχόμεθ' εἶναι—

"We are much better off than our fathers were," while we, the fathers, have the poor consolation of knowing that when they are fathers their children will say the same of them. There is reason to suppose that our science will advance more swiftly in the future than it has in the past, because it has more delicate and precise methods of research than it ever had before, and because its votaries are more numerous than they ever were.

In 1864 the attention of geologists was mainly given to the investigations of the later stages of the Tertiary Period. The bent of my pursuits inclines me to revert to this portion of geological inquiry, and to discuss certain points which have arisen during the last few years in connection with the classificatory value of fossils, and the mode in which they may be best used for the co-ordination of strata in various parts of the world.

The principle of homotaxy, first clearly defined by Professor Huxley, has been fully accepted as a guiding principle in place of synchronism or contemporaneity, and the fact of certain groups of plants and animals succeeding one another in a definite order, in countries remote from each other, is no longer taken to imply that each was living in the various regions at the same time, but rather, unless there be evidence to the contrary, that they were not. While, however, there is a universal agreement on this point among geologists, the classificatory value of the various divisions of the vegetable and animal kingdoms is still under discussion, and, as has been very well put by my predecessor in this chair at Montreal, sometimes the evidence of one class of organic remains points in one direction, while the evidence of another class points in another and wholly different direction as to the geological horizon of the same rock. The Flora, put into the witness-box by the botanist, says one thing, while the Mollusca or the Vertebrata say another thing in the hands of their respective counsel. There seems to be a tacit assumption that the various divisions of the organic world present the same amount of variation in the rocks, and that consequently the evidence of every part of it is of equal value.

The cryptogamic flora of the later Primary rocks shows but slight evidence of change. The forests of Britain and of Europe generally, and of North America, were composed practically of the same elements—Sigillaria, Calamites, and conifers allied to the Ginkho—throughout the whole of the Carboniferous (16,336 feet in thickness in Lancashire and Yorkshire) and Devonian rocks, and do not present greater differences than those which are to be seen in the existing forests of France and Germany. They evidently were continuous both in space and time, from their beginning in the Upper Silurian to their decay and ultimate disappearance in the Permian Age.

The forests of the Secondary Period, consisting of various conifers and cycads, also present slight differences as they are traced upwards through the Triassic and Jurassic rocks, while remarkable and striking changes took place in the fauna, which mark the division of the formations into smaller groups. As the evidence stands at present, the cycads of the Lias do not differ in any important character from those of the Oölites or the Wealden, and the *Salisburia* in Yorkshire in the Liassic Age is very similar to that of the Island of Mull in the Early Tertiary, and to that (*Salisburia adiantifolia*) now living in the open air in Kew Gardens.

Nor do we find evidence of greater variation in the dicotyledonous forests, from their first appearance in the Cenomanian stage of the Cretaceous rocks of Europe and America, through the whole of the Tertiary Period down to the present time. In North America the flora of the Dakota series so closely resembles the Meiocene of Switzerland that Dr. Heer had no hesitation in assigning it in the first instance to the Meiocene Age.

In the Tertiary Period there is an unbroken sequence in the floras, as Mr. Starkie Gardner has proved, when they are traced over many latitudes, and most of the types still survive at the present day, but slightly altered. If, however, Tertiary floras of different ages are met with in one area, considerable differences are to be seen, due to progressive alterations in the climate and altered distribution of the land. As the temperature of the Northern Hemisphere became lowered the tropical forests were pushed nearer and nearer to the equator, and were replaced by plants of colder habit from the northern regions, until ultimately, in the Pleistocene Age, the Arctic plants were pushed far to the south of their present habitat. In consequence of this Mr. Gardner concludes that "it is useless to seek in the Arctic regions for Eocene floras as we know them in our latitudes, for during the Tertiary Period the climatic conditions of the earth did not permit their growth there. Arctic fossil floras of temperate and therefore Meiocene aspect are in all probability of Eocene age, and what has been recognised in them as a newer or Meiocene facies is due to their having been first studied in Europe in latitudes which only became fitted for them in Meiocene times. When stratigraphical evidence is absent or inconclusive, this unexpected persistence of plant types or species throughout the Tertiaries should be remembered, and the degrees of latitude in which they are found should be well considered before conclusions are published respecting their relative age."

This view is consistent with that held by the leaders in botany, Hooker, Dyer, Saporta, Dawson, and Asa Gray—whose recent loss we so deeply deplore—that the North Polar region is the centre of dispersal, from which the Dicotyledons spread over the Northern Hemisphere. If it be true—and I, for one, am prepared to accept it—it will follow that for the co-ordination of the subdivisions of the Tertiary strata in various parts of the world the plants are uncertain guides, as they have been shown to be in the case of the Primary and Secondary rocks. In all cases where there is a clash of evidence, such as in the Laramie lignites, in which a Tertiary flora is associated with a Cretaceous fauna, the verdict in my opinion must go to the fauna. They are probably of the same geological age as the deposit at Aix-la-Chapelle.

I would remark further, before we leave the floras behind us, that the migration of new forms of plants into Europe and America took place before the arrival of the higher types in the fauna, after the break-up of the land at the close of the Carboniferous period, and after the great change in geography at the close of the Neocomian. The Secondary plants preceded the Secondary vertebrates by the length of time necessary for the deposit of the Permian rocks, and the Tertiary plants preceded the Tertiary vertebrates by the whole period of the Upper Cretaceous.

Let us now turn to the fauna.

Professor Huxley, in one of his many addresses which have left their mark upon our science, has called attention to the persistence of types revealed by the study of Palæontology, or, to put it in other words, to the singularly little change which the ordinal groups of life have undergone since the appearance of life on the earth. The species, genera, and families present an almost endless series of changes, but the existing orders are for the most part sufficiently wide, and include the vast series of fossils without the necessity of framing new divisions for their reception. The number of these extinct orders is not equally distributed through the animal kingdom. Taking the total number of orders at 108, the number of extinct orders in the Invertebrata amounts only to 6 out of 88, or about 7 per cent., while in the Vertebrates it is not less than 12 out of 40, or 30 per cent. These figures imply that the amount of ordinal change in the fossil Vertebrates stands to that in the Invertebrata in the ratio of 30 to 7. This disproportion becomes still more marked when we take into account that the former had less time for variation than the latter, which had the start by the Cambrian and Ordovicean Periods. It follows also that as a whole they have changed faster.

The distribution of the extinct orders in the animal kingdom, taken along with their distribution in the rocks, proves further that some types have varied more than others, and at various places in the geological record. In the Protozoa, Porifera, and Vermes there are no extinct orders; among the Cœlenterates one: the Rugosa; in the Echinodermata three: Cystideans, Edriasterida, and Blastoidea; in the Arthropoda two: the Trilobita and Eurypterida. All these, with the solitary exception of the obscure order Rugosa, are found only in the Primary rocks. Among the Pisces there are none; in the Amphibia one; the Labyrinthodonts ranging from the Carboniferous to the Triassic Age. Among the Reptilia there are at least six of Secondary age: Plesiosauria, Ichthyosauria, Dicynodontia, Pterosauria, Theriodontia, Deinosauria; in the Aves two: the Saururæ and Odontornithes, also Secondary. In the Mammalia the Amblypoda, Tillodontia, Condylarthra, and Toxodontia represent the extinct orders—the three first Early Tertiary, and the last Pleistocene. It is clear therefore that, while the maximum amount of ordinal variation is presented by the Secondary Reptilia and Aves, all the extinct orders in the Tertiary are Mammalian.

If we turn from the extinct orders to the extinct species, it will also be found that the maximum amount of variation is presented by the plants, and all the animals, excepting the Mammalia, in the Primary and Secondary Periods.

The general impression left upon my mind by these facts is that, while all the rest of the animal kingdom had ceased to present important modifications at the close of the Secondary Period, the Mammalia, which presented no great changes in the Secondary rocks, were, to quote a happy phrase of Professor Gaudry, "en pleine évolution" in the Tertiary Age. And when, further, the singular perfection of the record allows us to trace the successive and gradual modifications of the Mammalian types from the Eocene to the close of the Pleistocene Age, it is obvious that they can be used to mark subdivisions of the Tertiary Period, in the same way as the reigns of kings are used to mark periods in human history. In my opinion they mark the geological horizon with greater precision than the remains of the lower members of the animal kingdom, and in cases such as that of Pikermi, where typical Meiocene forms, such as Deinotheria, are found in a stratum above an assemblage of marine shells of Pleiocene age, it seems to me that the Mammalia are of greater value in classification than the Mollusca, some of the species of which have been living from the Eocene down to the present day.

Yet another important principle must be noted. The fossils are to be viewed in relation to those forms now living in their respective geographical regions. The depths of the ocean have been where they are now since the earliest geological times, although continued geographical changes have been going on at their margins. In other words, geographical provinces must have existed even in the earlier geological periods, although there is reason to believe that they did not differ so much from each other as at the present day. It follows from this that the only just standard for comparison in dealing with the fossils, and especially of the later rocks, is that which is offered by the fauna and flora of the geographical province in which they are found. The non-recognition of this principle has led to serious confusion. The fauna, for example, of the Upper Sivalik Formation has been very generally viewed from the European standpoint and placed in the Meiocene, while, judged by the standpoint of India, it is really Pleiocene. A similar confusion has followed from taking the Meiocene flora of Switzerland as a standard for the Tertiary flora of the whole of the Northern Hemisphere.

It now remains for us to see how these principles may be applied to the co-ordination of Tertiary strata in various parts of the world. In 1880 I proposed a classification of the European Tertiaries, in which, apart from the special characteristic fossils of each group, stress was laid on the gradual approximation of various groups to the living Mammalia. The definitions are the following:—

DIVISIONS.	CHARACTERISTICS.
1. Eocene, or that in which the higher Mammalia (Eutheria) now on the earth were represented by allied forms belonging to existing orders and families.	Extinct orders. Living orders and families. No living genera.
Oligocene.	
2. Meiocene, in which the alliance between fossil and living Mammals is closer than before.	Living genera. No living species.
3. Pleiocene, in which living species of Mammals appear.	Living species few. Extinct species predominant.
4. Pleistocene, in which living species of Mammals preponderate.	Living species abundant. Extinct species present. Man present.
5. Prehistoric, or that period outside history in which Man has multiplied exceedingly on the earth and introduced the domestic animals.	Man abundant. Domestic animals present. Wild Mammals in retreat. One extinct Mammal.
6. Historic, in which the events are recorded in history.	Records.

These definitions are of more than European significance. The researches of Leidy, Marsh, and Cope prove that they apply equally to the Tertiary strata of North America.

It may be objected to the Prehistoric and Historic divisions of the Tertiary period that neither the one nor the other properly fall within the domain of geology. It will, however, be found that in tracing the fauna and flora from the Eocene downwards to the present day there is no break which renders it possible to stop short at the close of the Pleistocene. The living plants and animals were in existence in the Pleistocene age in every part of the world which has been investigated. The European mollusca were in Europe in the Pleiocene age. The only difference between the Pleistocene fauna, on the one hand, and the Prehistoric, on the other, consists in the extinction of certain of the mammalia at the close of the Pleistocene age in the Old and New Worlds, and in Australia. The Prehistoric fauna in Europe is also characterised by the introduction of the ancestors of the present domestic animals, some of which, such as the Celtic shorthorn *(Bos longifrons)*, sheep, goat, and domestic hog, reverted to a feral condition, and have left their remains in caves, alluvia and peat-bogs over the whole of the British Isles and the Continent. These remains, along with those of man in the neolithic, bronze, and iron stages of culture, mark off the Prehistoric from the Pleistocene strata. There is surely no reason why a cave used by palæolithic man should be handed over to the geologist, while that used by men in the Prehistoric age should be taken out of his province, or why he should be asked to study the lower strata only in a given section, and leave the upper to be dealt with by the archæologist. In these cases the ground is common to geology and archæology, and the same things, if they are looked at from the standpoint of the history of the earth, belong to the first, and, if from the standpoint of the history of man, to the second.

If, however, there be no break of continuity in the series of events from the Pleistocene to the Prehistoric ages, still less is there in those which connect the Prehistoric with the period embraced by history. The historic date of a cave or of a bed of alluvium is as clearly indicated by the occurrence of a coin as the geological position of a stratum is defined by an appeal to a characteristic fossil. The gradual unfolding of the present order of things from what went before compels me to recognise the fact that the Tertiary period extends down to the present day. The Historic period is being recorded in the strata now being formed, exactly in the same way as the other divisions of the Tertiary have left their mark in the crust of the earth, and history is incomplete without an appeal to the geological record. In the masterly outline of the destruction of Roman civilisation in Britain the historian of the English Conquest was obliged to use the evidence, obtained from the upper strata, in caves which had been used by refugees from the cities and villas; and among the materials for the future history of this city there are, to my mind, none more striking than the proof, offered by the silt in the great Roman bath, that the resort of crowds had become so utterly desolate and lonely in the ages following the English Conquest as to allow of the nesting of the wild duck.

I turn now to the place of man in the geological record, a question which has advanced but little since the year 1864. Then, as now, his relation to the glacial strata in Britain was in dispute. It must be confessed that the question is still without a satisfactory answer, and that it may well be put to "a suspense account." We may, however, console ourselves with the reflection that the river-drift man appears in the Pleistocene strata of England, France, Spain, Italy, Greece, Algiers, Egypt, Palestine, and India along with Pleistocene animals, some of which were pre-glacial in Britain. He is also proved to have been post-glacial in Britain, and was probably living in happy, sunny, southern regions, where there was no ice, and therefore no glacial period, throughout the Pleistocene age.

It may further be remarked that man appears in the geological record where he might be expected to appear. In the Eocene the Primates were represented by various Lemuroids (*Adapis*, *Necrolemur*, and others) in the Old and New Worlds. In the Meiocene the Simiadæ (*Dryopithecus*, *Pliopithecus*, *Oreopithecus*) appear in Europe, while man himself appears, along with the living species of Mammalia, in the Pleistocene age, both in Europe and in India.

The question of the antiquity of Man is inseparably connected with the further question, "Is it possible to measure the lapse of geological time in years?" Various attempts have been made, and all, as it seems to me, have ended in failure. Till we know the rate of causation in the past, and until we can be sure that it has been invariable and uninterrupted, I cannot see anything but failure in the future. Neither the rate of the erosion of the land by sub-aërial agencies, nor its destruction by oceanic currents, nor the rate of the deposit of stalagmite, or of the movement of the glaciers have as yet given us anything at all approaching a satisfactory date. We only have a sequence of events recorded in the rocks, with intervals the length of which we cannot measure. We do not know the exact duration of any one geological event. Till we know both, it is surely impossible to fix a date, in terms of years, either for the first appearance of Man, or for any event outside the written record. We may draw cheques upon "the bank of force" as well as "on the bank of time."

Two of my predecessors in this chair, Dr. Woodward and Professor Judd, have dealt with the position of our science in relation to biology and mineralogy. Professor Phillips in 1864 pointed out that the later ages in geology and the earlier ages of mankind were fairly united together in one large field of inquiry. In these remarks I have set myself the task of examining that side of our science which looks towards history. My conception of the aim and results of geology is that it should present a universal history of the various phases through which the earth and its inhabitants have passed in the various periods, until ultimately the story of the earth, and how it came to be what it is, is merged in the story of man and his works in the written records. Whatever the future of geology may be, it certainly does not seem likely to suffer in the struggle for existence in the scientific renascence of the nineteenth century.

ABSTRACT OF THE ADDRESS TO THE BIOLOGICAL SECTION OF THE BRITISH ASSOCIATION,

By W. T. Thiselton-Dyer, C.M.G., M.A., B Sc., F.R.S, F.L.S., President of the Section.

As the head of one of the great national establishments of the country devoted to the cultivation of systematic botany, I need hardly apologise for devoting a few words to the present position of that branch of the science. Of its fundamental importance I have myself no matter of doubt. But as my judgment may seem in such a matter not wholly free from bias, I may fortify myself with an opinion which can hardly be minimised in that way. The distinguished chemist Professor Lothar Meyer, perhaps the most brilliant worker in the field of theoretical chemistry, finds himself, like the systematic botanist, obliged to defend the position of descriptive science. And he draws his strongest argument from biology. "The physiology of plants and animals," he tells us, "requires systematic botany and zoology, together with the anatomy of the two kingdoms: each speculative science requires a rich and well-ordered material, if it is not to lose itself in empty and fruitless fantasies."

At present the outlook for systematic botany is somewhat discouraging. France, Germany, and Austria no longer possess anything like a school in the subject, though they still supply able and distinguished workers. That these are, however, few, may be judged from the fact that it is difficult to fill the place of the lamented Eichler in the direction of the Botanic Garden and Herbarium at Berlin. Outside our own country, Switzerland is the most important seat of general systematic study, to which three generations of De Candolles have devoted themselves. The most active centres of work at the moment are, however, to be found in our own country, in the United States, and in Russia. And the reason is, in each case, no doubt the same. The enormous area of the earth's surface over which each country holds sway brings to them a vast amount of material which peremptorily demands discussion.

No country, however, affords such admirable facilities for work in systematic botany as are now to be found in London. The Linnean Society possesses the Herbarium of Linnæus; the Botanical Department of the British Museum is rich in the collections of the older botanists; while at Kew we have a constantly increasing assemblage of material, either the results of travel and expeditions or the contributions of correspondents in different parts of the empire. A very large proportion of this has been worked up. But I am painfully impressed with the fact that the total of our available workers bears but a small proportion to the labour ready to their hands.

This is the more a matter of concern because for the few official posts which are open to botanists at home or abroad a practical knowledge of systematic botany is really indispensable. For suitable candidates for these one naturally looks to the Universities. And so far, I am sorry to say, in great measure one looks in vain. It would be, no doubt, a great impulse to what is undoubtedly an important branch of national scientific work if fellowships could occasionally be given to men who showed some aptitude for it. But these should not be mere prizes for undergraduate study, but should exact some guarantee that during the tenure of the fellowship the holder would seriously devote himself to some definite piece of work. At present, undoubtedly, the younger generation of botanists show a disposition to turn aside to those fields in which more brilliant and more immediate results can be attained. Their neglect of systematic botany brings to some extent its own Nemesis. A first principle of systematic botany is that a name should denote a definite and ascertainable species of plant. But in physiological literature you will find that the importance of this is entirely overlooked. Names are employed which are either not to be found in the books or they are altogether misapplied. I call to mind the case of an English physiologist who wrote a highly ingenious paper on the movement of water in plants. He was content to refer to the plant upon which he experimented as the "bay-laurel." I ascertained that the plant he really used was the cherry-laurel. Now, the bay is truly a laurel, while the cherry-laurel is a plum. Anyone repeating his experiments would therefore be led wholly astray. But if proper precautions are taken to ascertain the accurate botanical name of a plant no botanist throughout the civilised world is at a loss to identify it.

But precision in nomenclature is only the necessary apparatus of the subject. The data of systematic botany, when properly dis-discussed, lend themselves to very important generalisations. Perhaps those which are yielded by the study of geographical distribution are of the most general interest. The mantle of vegetation which covers the surface of the earth, if only we could rightly unravel its texture, would tell us a good deal about geological history. The study of geographical distribution, rightly handled, affords an independent line of attack upon the problem of the past distribution of land and sea. It would probably never afford sufficient data for a complete independent solution of the problem; but it must always be extremely useful as a check upon other methods. Here, however, we are embarrassed by the enormous amount of work which has yet to be accomplished. And unfortunately this is not of a kind which can be indefinitely postponed. The old terrestrial order is fast passing away before our eyes. Everywhere the primitive vegetation is disappearing as more and more of the earth's surface is brought into cultivation or, at any rate, denuded of its forests.

A good deal, however, has been done. We owe to the indomitable industry of Mr. Bentham and of Sir Ferdinand Mueller a comprehensive flora of Australia, the first large area of the earth's surface of which the vegetation has been completely worked out. Sir Joseph Hooker, in his retirement, has pushed on within sight of completion the enormous work of describing so much of the vast Indo-Malayan flora as is comprised within British possessions. To the Dutch botanists we owe a tolerably complete account of the Malayan flora proper. But New Guinea still remains botanically a *terra incognita*, and till within the last year or two the flora of China has been an absolute blank to us. A committee of the British Association (whose report will be presented to you) has, with the aid of a small grant of money, taken in hand the task of gathering up the scanty data which are available in herbaria and elsewhere. This has stimulated European residents in China to collect more material, and the fine collections which are now being rapidly poured in upon us will, if they do not overwhelm us by their very magnitude, go a long way in supplying data for a tentative discussion of the relations of the Chinese flora to that of the rest of Asia. I do not doubt that this will in turn explain a good deal that is anomalous in the distribution of plants in India. The work of the committee has been practically limited to Central and Eastern China. From the west, in Yunnan, the French botanists have received even more surprising collections, and these supplement our own work in the most fortunate manner. I have only to add for Asia Boissier's "Flora Orientalis," which practically includes the Mediterranean basin. But I must not omit the invaluable report of Brigade-Surgeon Aitchison on the collections made by him during the Afghan Delimitation Expedition. This has given an important insight into the vegetation of a region which had never previously been adequately examined. Nor must I forget the recent publication of the masterly report by Professor Bayley Balfour on the plants collected by himself and Schweinfurth in Socotra, an island with which the ancient Egyptians traded, but the singularly anomalous flora of which was almost wholly unknown up to our time.

The flora of Africa has been at present but imperfectly worked up, but the materials have been so far discussed as to afford a tolerably correct theory of its relations. The harvest from Mr. Johnston's expedition to Kilmanjaro was not as rich as might have been hoped. Still, it was sufficient to confirm the conclusions at which Sir Joseph Hooker had arrived on very slender data, as to the relations of the high-level vegetation of Africa generally. The flora of Madagascar is perhaps, at the moment, the most interesting problem which Africa presents to the botanist. As the rich collections for which we are indebted to Mr. Baron and others, are gradually worked out it can hardly be doubted that it will be necessary to modify in some respects the views which are generally received as to the relation of the island to the African continent, My colleague Mr. Baker communicated to the York meeting of the Association the results which, up to that time, he had arrived at, and these subsequent materials had not led him to modify. The flora as a whole presents a large proportion of endemic genera and species, pointing to isolation from a very ancient date. The tropical element is, however, closely allied to that of Tropical Africa and of the Mascarene Islands, and there is a small infusion of Asiatic types which do not extend to Africa. The high-level flora, on the other hand, exhibits an even closer affinity with that temperate flora the ruins of which are scattered over the mountainous regions of Central Africa, and which survives in its greatest concentration at the Cape.

The American botanists at Harvard are still systematically carrying on the work of Torrey and Gray in the elaboration of the flora of Northern America. The Russians are, on their part, continually adding to our knowledge of the flora of Northern and Central Asia. The whole flora of the North Temperate Zone can only be regarded substantially as one. The identity diminishes southwards, and increases in the case of the Arctic and Alpine regions. A collection of plants brought us from high levels in Corea by Mr. James might, as regards a large proportion of the species, have been gathered on one of our own Scotch hills.

We owe to the munificence of two English men of science the organisation of an extensive examination of the flora and fauna of Central America and the publication of the results. The work, when completed, can hardly be less expensive than that of the results of the *Challenger* voyage, which has severely taxed the liberality of the English Government. The problems which geographical distribution in this region present will doubtless be found to be of a singularly complicated nature, and it is impossible to over-estimate the debt of gratitude which biologists of all countries must owe to Messrs. Godman and Salvin, when their arduous undertaking is completed. I am happy to say that the botanical portion, which has been elaborated at Kew, is all but finished.

In South America I must content myself with referring to the great "Flora Brasiliensis," commenced by Martius half a century ago, and still slowly progressing under the editorship of Professor Urban at Berlin. Little discussion has yet been attempted of the mass of material which is enshrined in the mighty array of volumes already published. But the travels of Mr. Ball in South America have led him to the detection of some very interesting problems. The enormous pluvial denudation of the ancient portions of the continent has led to the gradual blending of the flora of different levels with sufficient slowness to permit of adaptive changes in the process. The tropical flora of Brazil, therefore, presents an admixture of modified temperate types which gives to the whole a peculiar character not met with to the same degree in the tropics of the old world. On the other hand, the comparatively recent elevation of the southern portion of the continent accounts, in Mr. Ball's eyes, for the singular poverty of its flora, which we may regard, indeed, as still in progress of development.

The botany of the *Challenger* expedition, which was also elaborated at Kew, brought for the first time into one view all the available facts as to the floras of the older oceanic islands. To this was added a discussion of the origin of the more recent floras of the islands of the Western Pacific, based upon material carefully collected by Professor Moseley, and supplemented by the notes and specimens accumulated with much judgment by Dr. Guppy. For the first time we were enabled to get some idea how a tropical island was furnished with plants, and to discriminate the littoral element due to the action of oceanic currents from the interior forest almost wholly due to frugivorous birds. The recent examination of Christmas Island by the English Admiralty has shown the process of island flora-making in another stage. The plants collected by Mr. Lister prove, as might be expected, to be closely allied to those of Java. But the effect of isolation has begun to tell; and I learn from my colleague Professor Oliver that the plants from Christmas Island cannot be for the most part exactly matched with their congeners from Java, but yet do not differ sufficiently to be specifically distinguished. We have here, therefore, it appears to me, a manifest case of nascent species.

The central problem of systematic botany I have not as yet touched upon: this is to perfect a natural classification. Such a classification, to be perfect, must be the ultimate generalisation of every scrap of knowledge which we can bring to bear upon the study of plant affinity. In the higher plants experience has shown that we can obtain results which are sufficiently accurate for the present, without carrying our structural analysis very far. Yet even here the correct relations of the Gymnosperms would never have been ascertained without patient and minute microscopic study of the reproductive processes. Upon these, indeed, the correct classification of the Vascular Cryptogams wholly depends, and generally, as we descend in the scale, external morphology becomes more and more insecure as a guide, and a thorough knowledge of the minute structure and life history of each organism becomes indispensable to anything like a correct determination of its taxonomic position. The marvellous theory of the true nature of Lichens would never have been ascertained by the ordinary methods of examination which were held to be sufficient by lichenologists.

The final form of every natural classification—for I have no doubt that the general principles I have laid down are equally true in the field of zoology—must be to approximate to the order of descent. For the Theory of Descent became an irresistible induction as soon as the idea of a natural classification had been firmly grasped.

Interesting as are the problems which the structure, the functions, the affinity, or the geographical distribution of a plant may afford, the living plant in itself is even more interesting still. Every organ will bear interrogation to trace the meaning and origin of its form and the part it plays in the plant's economy. That there is here an immense field for investigation there can be no doubt Mr. Darwin himself set us the example in a series of masterly investigations. But the field is well-nigh inexhaustible. The extraordinary variety of form which plants exhibit has led to the notion that much of it may have arisen from indifferent variation. No doubt, as Mr. Darwin has pointed out, when one of a group of structures held together by some morphological or physiological *nexus* varies, the rest will vary correlatively. One variation then may, if advantageous, become adaptive, while the rest will be indifferent. But it appears to me that such a principle should be applied with the greatest caution, and from what I have myself heard fall from Mr. Darwin, I am led to believe that in the later years of his life he was disposed to think that every detail of plant structure had some adaptive significance, if only the clue could be found to it. As regards the forms of flowers an enormous body of information has been collected, but the vegetative organs have not yielded their secret to anything like the same extent. My own impression is that they will be found to be adaptive in innumerable ways which at present are not even suspected. At Kew we have probably a larger number of species assembled together than are to be found anywhere on the earth's surface. Here, then, is ample material for observation and comparison. But the adaptive significance will doubtless often be found by no means to lie on the surface. Who, for example, could possibly have guessed by inspection the purpose of the glandular bodies on the leaves of *Acacia sphærocephala* and on the pulvinus of *Cecropia peltata* which Belt in the one case and Fritz Müller in the other have shown to serve as food for ants? So far from this explanation being far-fetched, Belt found that the former "tree is actually unable to exist without its guard," which it could not secure without some attraction in the shape of food. One fact which strongly impresses me with a belief in the adaptive significance of vegetative characters is the fact that in almost identical forms they are constantly adopted by plants of widely different affinity. If the forms were without significance one would expect them to be infinitely varied. If, however, they are not so, it is intelligible that different plants should independently avail themselves of the same appliances and expedients.

Although this country is splendidly equipped with appliances for the study of systematic botany, our Universities and colleges fall far behind a standard which would be considered even tolerable on the Continent in the means of studying morphological and physiological botany or of making researches in these subjects. There is not at the moment anywhere in London an adequate botanical laboratory; and though at most of the Universities matters are not quite so bad, still I am not aware of any one where it is possible to do more than give the routine instruction or to allow the students, when they have passed through this, to work for themselves. It is not easy to see why this should be, because on the animal side the accommodation and appliances for teaching comparative anatomy and physiology are always adequate and often palatial. Still less explicable to me is the tendency on the part of those who have charge of medical education to eliminate botanical study from the medical curriculum, since historically the animal histologists owe everything to botanists. In the seventeenth century Hooke first brought the microscope to the investigation of organic structure, and the tissue he examined was cork. Somewhat later Grew, in his "Anatomy of Plants," gave the first germ of the cell theory. During the eighteenth century the anatomists were not merely on a hopelessly wrong tack themselves, but they were bent on dragging botanists into it also. It was not till 1837, a little more than fifty years ago, that Henle saw that the structure of epithelium was practically the same as that of the *Parenchyma plantarum* which Grew had described 150 years before. Two years later Schwann published his immortal theory, which comprised the ultimate facts of plant and animal anatomy under one view. But it was to a botanist, Von Mohl, that, in 1846, the biological world owed the first clear description of protoplasm, and to another botanist, Cohn (1851), the identification of this with the sarcode of zoologists.

Now the historic order in discovery is not without its significance. The path which the first investigators found most accessible is doubtless that which beginners will also find easiest to tread. I do not myself believe that any better access can be obtained to the structure and functions of living tissues than by the study of plants. However, I am not without hopes that the serious study of botany in the laboratory will be in time better cared for. I do not hesitate to claim for it a position of the greatest importance in ordinary scientific education. All the essential phenomena of living organisms can be readily demonstrated upon plants. The necessary appliances are not so costly, and the work of the class-room is free from many difficulties with which the student of the animal side of biology has to contend.

Those, however, who have seriously devoted themselves to the pursuit of either morphological or physiological botany need not now be wholly at a loss. The splendid laboratory on Plymouth Sound, the erection of which we owe to the energy and enthusiasm of Professor Ray Lankester, is open to botanists as well as to zoologists, and affords every opportunity for the investigation of marine plants, in which little of late years has been done in this country. At Kew we owe to private munificence a commodious laboratory, in which much excellent work has already been done. And this Association has made a small grant in aid of the establishment of a laboratory in the Royal Botanic Garden at Peradeniya, in Ceylon. It may be hoped that this will afford facilities for work of the same kind as has yielded Dr. Treub such a rich harvest of results in the Buitenzorg Botanic Garden, in Java.

Physiological botany, as I have already pointed out, is a field in which this country in the past has accomplished great things. It has not of late, however, obtained an amount of attention in any way proportionate to that devoted to animal physiology. In the interests of physiological science generally this is much to be deplored; and I believe that no one was more firmly convinced of this than Mr. Darwin. Only a short time before his death, in writing to Mr. Romanes on a book that he had recently been reading, he said that the author had made "a gigantic oversight in never considering plants; these would simplify the problem for him." This goes to the root of the matter. There is, in my judgment, no fundamental biological problem which is not exhibited in a simpler form by plants than animals. It is possible, however, that the distaste which seems to exist amongst our biologists for physiological botany may be due in some measure to the extremely physical point of view from which it has been customary to treat it on the Continent. It is owing in great measure to the method of Mr. Darwin's own admirable researches that in this country we have been led to a more excellent way. The work which has been lately done in England seems to me full of the highest promise. Mr. Francis Darwin and Mr. Gardiner have each in different directions shown the entirely new point of view which may be obtained by treating plant phenomena as the outcome of the functional activity of protoplasm. I have not the least doubt that by pursuing this path English research will not merely place vegetable physiology, which has hitherto been too much under the influence of Lamarckism, on a more rational basis, but that it will also sensibly react, as it has done often before, on animal physiology.

There is no part of the field of physiological botany which has yielded results of more interest and importance than that which relates to the action of ferments and fermentation; and I could hardly give you a better illustration of the purely biological method of treating it. I believe that these results, wonderful and fascinating as they are, afford but a faint indication of the range of those that are still to be accomplished. The subject is one of extreme intricacy, and it is not easy to speak about it briefly. To begin with, it embodies two distinct groups of phenomena which have in reality very little which is essential in common.

What are usually called ferments are perhaps the most remarkable of all chemical bodies, for they have the power of effecting very profound changes in the chemical constitution of other substances, although they may be present in very minute quantity; but, which is their most singular and characteristic property, they themselves remain unchanged in the process. It may be said without hesitation that the whole nutrition of both animals and plants depends on the action of ferments. The organism is incapable of using solid nutrient matter for the repair and extension of its tissues; it must be first brought into a soluble form before it can be made available, and this change is generally brought about by the action of a ferment. Animal physiology has long been familiar with the part played by these bodies, and it may be said that no small part of the animal economy is made up of organs required either for the manufacture of ferments or for the exposure of ingested food to their action. It may seem strange at first sight to speak of analogous processes taking place in plants, but it must be remembered that plant nutrition includes two very distinct stages. Certain parts of plants build up, as every one knows, from external inorganic materials substances which are available for the construction of new tissues. It might be supposed that these are used up as fast as they are formed. But it is not so; the life of the plant is not a continuous balance of income and expenditure. On the contrary, besides the general maintenance of its structure, the plant has to provide from time to time for enormous resources to meet such exhausting demands as the renewal of foliage, the production of flowers, and the subsequent maturing of fruit.

In such cases the plant has to draw on an accumulated store of solid food, which has rapidly to be converted into the soluble form in which alone it is competent to be drawn off through the tissues to the seat of consumption. And I do not doubt, for my part, that in such cases ferments are brought into play of the same kind and in the same way as in the animal economy. Take such a simple case as a potato tuber. This is a mass of cellular tissue, the cells of which are loaded with starch. We may either dig up the tuber and eat the starch ourselves or we may leave it in the ground, in which case it will be consumed in providing material for the growth of a potato-plant next year. But the processes by which the insoluble starch is made available for nutrition are, I cannot doubt, closely similar in either case.

When we inquire further about these mysterious and all-important bodies the answer we can give is extremely inadequate. It is very difficult to obtain them in amount sufficient for analysis or in a state of purity. We know, however, that they are closely allied to albuminoids, and contain nitrogen in varying proportion. Papain, which is a vegetable ferment derived from the fruit of the papaw, and capable of digesting most animal albuminoids, is said to have the same ultimate composition as the pancreatic ferment and of peptones, bodies closely allied to proteids; the properties of all three bodies are, however, very different. It seems clear, nevertheless, that ferments must be closely allied to proteids, and like these bodies, they are no doubt directly derived from protoplasm.

I need not remind you that, unlike other constituents of plant tissues, protoplasm, as a condition of its vitality, is in a constant state of molecular activity. The maintenance of this activity involves the supply of energy, and this is partly derived from the waste of its own substance. This "self-decomposition" of the protoplasm liberates energy, and in doing so gives rise to a number of more stable bodies than protoplasm. Some of these are used up again in nutrition; others are thrown aside and are never drawn again into the inner circle of vital processes. In the animal organism, where the strictest economy of bulk is a paramount necessity, they are promptly got rid of by the process of excretion. In the vegetable economy these residual products usually remain. And it is for this reason, I may point out, that the study of the chemistry of plant nutrition appears to me of such immense importance. The record of chemical change is so much more carefully preserved, and the probability of our being able to trace the changes it has followed is consequently far more likely to be attended with success.

This preservation in the plant of the residual by-products of protoplasmic activity no doubt accounts for the circumstance which otherwise is extremely perplexing—the profusion of substances which we meet with in the vegetable kingdom to which it is hard to attribute any useful significance. It seems probable that ferments in a great many cases belong to the same category. I imagine that it is in some degree accidental that some of them have been made use of, and thus the plant has been able to temporarily lock up accumulations of food, to be drawn upon in future phases of its life with the certainty that they would be available. Without the ferments the key of the storehouse would be lost irretrievably.

Plants, moreover, are now known to possess ferments, and the number will doubtless increase to which it is difficult to attribute any useful function. Papain, to which I have already alluded, abounds in the papaw, but it is not easy to assign to it any definite function; still less is it easy, on teleological grounds, to account for the rennet ferment contained in the fruits of an Indian plant, *Withania coagulans*, and admirably investigated by Mr. Sheridan Lea.

Having dwelt so far on the action of ferments, we may now turn to fermentation and that other kind of change in organic matter called "putrefaction," which is known to be closely allied to fermentation. Ferments and fermentation, as I have already remarked, have very little to do with one another; and it would save confusion and emphasise the fact if we ceased to speak of ferments, but used some of the alternative names which have been proposed for them, such as *zymases* or *enzymes*.

The classical case of fermentation, which is the root of our whole knowledge of the subject, is that of the conversion of sugar into alcohol. Its discovery has everywhere accompanied the first stages of civilisation in the human race. Its details are now taught in our text-books; and I should hardly hope to be excused for referring to it in any detail if it were not necessary for my purpose to draw your attention more particularly to one or two points connected with it.

Let us trace what happens in a fermenting liquid. It becomes turbid; it froths and effervesces; the temperature sensibly increases; this is the first stage. After this it begins to clear; the turbidity subsides as a sediment; the sugar which the fluid at first contained has in great part disappeared, and a new ingredient, alcohol, is found in its place.

It is just fifty years ago that the great Dutch biologist Schwann made a series of investigations which incontrovertibly demonstrated that both fermentation and putrefaction were due to the presence of minute organisms which live and propagate at the expense of the liquids in which they produce as a result these extraordinary changes. The labours of Pasteur have confirmed Schwann's results, and—what could not have been foreseen—have extended the possibilities of this field of investigation to those disturbances in the vital phenomena of living organisms themselves which we include under the name of "disease," and which, no one will dispute, are matters of the deepest concern to every one of us.

Now, at first sight, the conversion of starch into sugar by means of diastase seems strikingly analogous to the conversion of sugar into alcohol. It is for this reason that the phenomena have been so long associated. But it is easy to show that they are strikingly different. Diastase is a chemical substance of obscure composition, it is true, but inert and destitute of any vital properties, nor is it affected by the changes it induces. Yeast, on the other hand, which is the active agent in alcoholic fermentation, is a definite organism; it enormously increases during the process, and it appears to me impossible to resist the conclusion that fermentation is a necessary concomitant of the peculiar conditions of its life. Let me give you a few facts which go to prove this. In the first place, you cannot ferment a perfectly pure solution of sugar. The fermentible fluid must contain saline and nitrogenous matters necessary for the nutrition of the yeast protoplasm. In pure sugar the yeast starves. Next, Schwann found that known protoplasmic poisons, by killing the yeast-cells, would prohibit fermentation. He found the same result to hold good of putrefaction, and this is the basis of the whole theory of antiseptics. Nor can the action of yeast be attributed to any ferment which the yeast secretes. It is true that pure cane-sugar cannot be fermented, and that yeast effects the inversion of this, as it is called, into glucose and lævulose. It does this by a ferment which can be extracted from it, and which is often present in plants. But you can extract nothing from yeast which will do its peculiar work apart from itself. Helmholtz made the crucial experiment of suspending a bladder full of boiled grape-juice in a vat of fermenting must: it underwent no change; and even a film of blotting-paper has been found a sufficient obstacle to its action. We are driven, then, necessarily to the conclusion that in the action of "ferments," or zymases, we have to do with a chemical—*i.e.*, a purely physical process; while in the case of yeast we encounter a purely physiological one.

How, then, is this action to be explained? Pasteur has laid stress on a fact which had some time been known, that the production of alcohol from sugar is a result of which yeast has not the monopoly. If ripening fruits, such as plums, are kept in an atmosphere free from oxygen, Bérard found that they, too, exhibit this remarkable transformation; their sugar is converted appreciably into alcohol. On the other hand, Pasteur has shown that if yeast is abundantly supplied with oxygen it feeds on the sugar of a fermentible fluid without producing alcohol. But under the ordinary circumstances of fermentation its access to oxygen is practically cut off; the yeast, then, is in exactly the same predicament as the fruit in Bérard's experiment. Sugar is broken up into carbon dioxide and alcohol in an amount far in excess of the needs of mere nutrition. In this dissociation it can be shown that an amount of energy is set free in the form of heat equal to about one-tenth of what would be produced by the total combustion of an equivalent amount of grape-sugar. If the protoplasm of the yeast could, with the aid of atmospheric oxygen, completely decompose a unit of grape-sugar, it would get ten times as much energy in the shape of heat as it could get by breaking it up into alcohol and carbon dioxide. It follows, then, that to do the same amount of growth in either case it must break up ten times as much sugar without a supply of oxygen as with it. And this throws light on what has always been one of the most remarkable facts about fermentation—the enormous amount of change which the yeast manages to effect in proportion to its own development.

There are still two points about yeast which deserve attention before we dismiss it. When a fermenting liquid comes to contain about 14 per cent. of alcohol the activity of the yeast ceases, quite independently of whether the sugar is used up or not. In other cases of fermentation the same inhibiting effect of the products of fermentation is met with. Thus lactic fermentation soon comes to an end unless calcium carbonate or some similar substance be added, which removes the lactic acid from the solution as fast as it is formed.

The other point is that in all fermentations, besides what may be termed the primary products of the process, other bodies are produced. In the case of alcoholic fermentation the primary bodies are alcohol and carbon dioxide, the secondary succinic acid and glycerine. Delpino has suggested that these last are residual products derived from that portion of the fermentible matter which is directly applied to the nutrition of the protoplasm.

Yeast, itself the organism which effects the remarkable changes on which I have dwelt, is somewhat of a problem. It is clear that it is a fungus, the germs of which must be ubiquitous in the atmosphere. It is difficult to believe that the simple facts which are all we know about it constitute its entire life history. It is probably a transitory stage of some more complicated organism.

I can only briefly refer to putrefaction. This is a far more complex process than that which I have traced in the case of alcoholic fermentation. In that nitrogen is absent, while it is an essential ingredient in albuminoids, which are the substances which undergo putrefactive changes. But the general principles are the same. Here, too, we owe to Schwann the demonstration of the fact that the effective agents in the process are living organisms. If we put into a flask a putrescible liquid such as broth, boil it for some time, and during the process of boiling plug the mouth with some cotton wool, we know that the broth will remain long unchanged, while if we remove the wool putrescence soon begins. Tyndall has shown that if we conduct the experiment on one of the high glaciers of the Alps the cotton wool may be dispensed with. We may infer, then, that the germs of the organisms which produce putrefaction are abundant in the lower levels of the atmosphere, and are absent from the higher. They are wafted about by currents of air; but they are not imponderable, and in still air they gradually subside. Dr. Lodge has shown that air is rapidly cleared of suspended dust by an electric discharge, and this, no doubt, affords a simple explanation of the popular belief that thunderous weather is favourable to putrefactive changes.

Cohn believes that putrefaction is due to an organism called *Bacterium termo*, which plays in it the same part that yeast does in fermentation. This is probably too simple a statement, but the general phenomena are nevertheless similar. There is the same breaking down of complex into simpler molecules; the same evolution of gas, especially carbon dioxide; the same rise of temperature. The more or less stable products of the process are infinitely more varied, and it is difficult, if not impossible, to say, in the present state of our knowledge, whether in most cases they are the direct outcome of the putrefactive process or residual products of the protoplasmic activity of the organisms which induce it. Perhaps, on the analogy of the higher plants, in which some of them also occur, we may attribute to the latter category certain bodies closely resembling vegetable alkaloids; these are called ptomains, and are extremely poisonous. Besides such bodies, Bacteria undoubtedly generate true ferments and peculiar colouring matters. But there is in most cases of putrefaction a profusion of other substances, which represent the various stages of the breaking up of the complex proteid molecule, and are often themselves the outcome of subsidiary fermentations.

These results are of great interest from a scientific point of view. But their importance at the present moment in the study of certain kinds of disease can hardly be exaggerated. I have already mentioned Henle as having first found the true clue to animal histology in the structure of plants. As early as 1840 the same observer indicated the argument for regarding contagious diseases as due to living organisms. I will state his argument in the words of De Bary, whose "Lectures on Bacteria," the last work which we owe to his gifted hand, I can confidently recommend to you as a luminous but critical discussion of a vast mass of difficult and conflicting literature.

It was, of course, clear that contagion must be due to the communication of infectious particles or contagia. These contagia, although at the time no one had seen them, Henle pointed out, "have the power, possessed, as far as we know, by living creatures only, of growing under favourable conditions, and of multiplying at the expense of some other substance than their own, and therefore of assimilating that substance." Henle enforced his view by comparison with the theory of fermentation which had then been promulgated by Schwann. But for many years his views found no favour. Botanists, however, as in so many other cases, struck on the right path, and from about the year 1850 steady progress, in which De Bary himself took a leading part, was made in showing that most of the diseases of plants are due to parasitic infection. The reason of this success was obvious: the structure of plants make them more accessible to research, and the invading parasites are larger than animal contagia. On the animal side all real progress dates from about 1860, when Pasteur, having established Schwann's theory of fermentation on an impregnable basis, took up Henle's theory of living contagia.

The only risk now is that we may get on too fast. To put the true theory of any one contagious disease on as firm a basis as that of alcoholic fermentation is no easy matter to accomplish. But I believe that this is, notwithstanding a flood of facile speculation and imperfect research, slowly being done.

There are two tracts in the body which are obviously accessible to such minute organisms as bacteria, and favourable for their development. These are the alimentary canal and the blood. In case of the former there is evidence that every one of us possesses quite a little flora of varied forms and species. They seem for the most part, in health, to be comparatively innocuous; indeed, it is believed that they are ancillary to and aid digestion. But it is easy to see that other kinds may be introduced, or those already present may be called into abnormal activity, and fermentative processes may be set up of a very inconvenient kind. These may result in mere digestive disorder or in the production of some of those poisonous derivatives of proteids of which I have spoken, the effect of which upon the organism of the part may be most disastrous.

The access of bacteria to the blood is a far more serious matter. They produce phenomena the obvious analogy of which to fermentative processes has led to the resulting diseases being called zymotic. Take, for example, the disease known as "relapsing fever." This is contagious. After a period of incubation violent fever sets in, which lasts for something less than a week, is then followed by a period of absence, to be again followed in succession by one or more similar attacks, which ultimately cease. Now you will observe that the analogy to a fermentative process is very close. The period of incubation is the necessary interval between the introduction of the germ and its vegetative multiplication in sufficient numbers to appreciably affect the total volume of the blood. The rise in temperature and the limited duration of the attack are equally, as we have seen, characteristic of fermentative processes, while the bodily exhaustion which always follows fever is the obvious result of the dissipation by the ferment organisms of nutritive matter destined for the repair of tissue waste. During the presence of this fever there is present in the blood an organism, *Spirochæte Obermeieri*, so named after its discoverer. This disappears when the fever subsides. It is found that if other individuals are inoculated with blood taken from patients during the fever attack the disease is communicated, but that this is not the case if the inoculation is made during the period of freedom. The evidence then seems clear that this disease is due to a definite organism. The interesting point, however, arises, why does the fever recur? and why eventually cease? The analogy of fermentation leads to the hypothesis that, as in the case of yeast, the products of its action inhibit after a time the further activity of the *Spirochæte*. The inhibiting substance is, no doubt, eventually removed partially from the blood by its normal processes of depuration, and the surviving individuals of *Spirochæte* can then continue their activity, as in lactic fermentation. With regard to the final cessation of the disease, there are facts which may lead one to suppose that in this, as in other cases, sufficient of the inhibiting substance ultimately remains in the organism to protect it against any further outbreak of activity on the part of the *Spirochæte*.

Here we have an example of a disease which, though having a well-marked zymotic character, is comparatively harmless. In anthrax, which is known to be due to *Bacillus subtilis*, we have one which is, on the contrary, extremely fatal. I need not enter into the details. It is sufficient to say that there is reason to believe that the *Bacillus* produces, as one of those by-products of protoplasmic destruction to which I have already alluded, a most virulent poison. But the remarkable thing is that this *Bacillus*, which can be cultivated externally to the body, if kept at a heightened temperature, can be attenuated in its virulence. It drops, in fact, the excretion of the poison. It is then found that if injected into the blood it does no mischief, and what is more extraordinary, if the *Bacillus* in its most lethal form is subsequently introduced it too has lost its power. The explanation of the immunity in this case is entirely different to that which was suggested by a consideration of the facts of relapsing fever. The researches of Metschnikoff have led to the hypothesis that in the present case the white-blood corpuscles destroy the *Bacillus*. When they first come into contact with these in their virulent form they are unable to touch them. But if they have been educated by first having presented to them the attenuated form they find no difficulty in grappling with the malignant. This is a very remarkable view. I should not have put it before you had there not been solid reasons for regarding the idea of the education of protoplasm with scientific respect. The plasmodia of the myxomycetes, which consist of naked protoplasm, are known to become habituated to food which they at first reject, and the researches of Beyerinck on the disease known as "gumming" in plants have apparently shown that healthy cells may be taught, as it were, to produce a ferment which otherwise they would not excrete.

If Metschnikoff's theory be true we have a rational explanation of vaccination and of preventive inoculation generally. It is probably, however, not the only explanation. And the theory of the inhibitive action upon itself of the products of the ferment-organism's own activity is still being made the basis of experiment. In fact, the most recent results point to the possibility of obtaining protection by injecting into the blood substances artificially obtained, entirely independent of the organisms whose development they inhibit.

It is impossible for me to touch on these important matters at any greater length, but I doubt if the theory of fermentation, as applied to the diseases of organisms, has as yet more than opened its first page. It seems to me possible that, besides the rational explanation of zymotic diseases, it may throw light on others where, owing to abnormal conditions, the organism, as in the case of Bérard's plants, is itself the agent in its own fermentative processes.

And now I must conclude. I have led you, I am afraid, a too lengthy and varied a journey in the field of botanical study. But to sum up my argument: I believe I have shown you that at the bottom of every great branch of biological inquiry it has never been possible to neglect the study of plants; nay, more, that the study of plant-life has generally given the key to the true course of investigation. Whether you take the problems of geographical distribution, the most obscure points in the theory of organic evolution, or the innermost secrets of vital phenomena, whether in health or disease, not to consider plants is still, in the words of Mr. Darwin, "a gigantic oversight, for these would simplify the problem."

ABSTRACT OF THE ADDRESS TO THE GEOGRAPHICAL SECTION OF THE BRITISH ASSOCIATION,

By Colonel Sir C. W. Wilson, R.E., K.C.B., K.C.M.G., D.C.L., LL.D., F.R.S., F.R.G.S., Director-General of the Ordnance Survey, President of the Section.

The great civilisations of high antiquity appear to have risen and expanded in four riverain districts; Chinese in the basins of the Hoang Ho and the Yang-tse-Kiang; Hindu in those of the Indus and the Ganges; Chaldæan and Assyro-Babylonian in those of the Tigris and Euphrates; and Egyptian in that of the Nile. India is separated from China, on the one hand, by rugged, lofty monntain ranges, and the high-lying plateau of Thibet; and from Mesopotamia, on the other, by the Suleiman Mountains and the Perso-Afghan plateau. Intercommunication between these early seats of man's activity must, therefore, have been of slow growth. From Mesopotamia, on the contrary, there is easy access to the Nile basin by way of Syria and Palestine, and there are indications of traffic between these districts at a very remote period. Enquiry into the causes which first led to intercommunication and into the means by which it was effected is needless. Desire of gain, lust of power, were as much a part of human nature in the earliest ages as they are now. The former induced the pioneers of commerce to feel their way across trackless deserts, and to brave the hidden dangers of the sea; and for nearly three hundred years it led gallant men to seek a way to the wealth of India through the ice-laden seas of the Arctic region. The latter brought the great empires of Assyria and Egypt into hostile conflict, and carried Alexander to the banks of the Oxus and the Indus; and it is largely answerable for the land-hunger of European states in our own generation.

Nations rise, fall, and disappear, but commerce extends in ever-widening circles, and knows no limits. Efforts are constantly being made to discover and open up new fields of commercial activity and to connect the great centres of commerce by quicker and shorter trade routes. The earliest traffic was conducted by land; men travelled together in caravans for mutual protection, and rested where food and water were to be obtained; at the most important of these halting places cities were founded. As trade extended it became necessary to carry goods through independent tribes or countries which often insisted on retaining the transit trade in their own hands, and this led to the rise of cities at points convenient for the transfer of loads and the exchange of the commodities of one country for those of another. Generally speaking this early overland trade was co-extensive with the geographical limit of the camel. Next in order to land traffic came that by water, first on rivers, then on the sea; and cities naturally sprang up at places on the coast where the merchandise brought down the rivers in boats could, conveniently and safely, be transferred to galleys or ships suitable for coasting. Increased knowledge of the globe, improvements in the art of shipbuilding, and the invention of the steam-engine have gradually led to the ocean traffic of the present day, conducted by large steamers which, regardless of wind and tide, follow the most direct course from one point to another. The trade routes of the world are subject to two great modifying influences, one physical, the other political. The inland trade of India, for instance, can only reach Central Asia and the West by way of Herat or Bamian; caravan roads across the deserts of Asia and Africa must follow lines of springs or wells; climatic conditions render all Polar routes impracticable; and the removal of a physical obstacle, by the construction of the Suez Canal, is now causing a remarkable redistribution of the channels of commerce. So, too, disturbance of traffic by war, or its designed destruction by conquerors; and great political changes, such as the establishment of the Persian Empire, the rise of Rome, the disruption of the Roman Empire, and the advent of the Arabs to power in Western Asia, divert trade from its accustomed routes and force it into new channels, to the ruin of some cities and states and the enrichment of others. The general tendency of trade so diverted is to seek, where possible, a maritime route, for water transport is not only less costly but less liable to interruption than land transport.

India, partly from its geographical position, partly from the character of its people, has always played a passive rôle in commerce, and allowed the initiative in commercial enterprise to rest with the West. The greatest advantages have always been derived from the possession of the trade between the East and the West, and, from a remote period, the nations of the world have contended for this rich prize. One state after another has obtained and lost the prize; England now holds it, but if she is to keep what she has obtained there must be a far closer study than there has hitherto been, of geography and terrestrial phenomena in their relation to commerce.

Since the discovery of the Cape route there has been one long struggle for the possession of the commerce of India; who should be the carriers and distributors of Indian commodities was for more than two and a half centuries a much contested point amongst the maritime nations of the West. At first there seems to have been a general acquiescence in the claim of the Spaniards and Portuguese to a monopoly of the southern sea-routes, and this led to those heroic efforts to find a north-east or north-west passage to India which have so greatly added to our geographical knowledge. Failure in this direction was followed by attempts to reach India by the Cape in the face of the hostile attitude of Spain and Portugal. The mighty events which in turn transferred wealth and commerce from Lisbon to Antwerp, Amsterdam, and the banks of the Thames are matter of history, and it is scarcely necessary to say that at the close of the Napoleonic wars, England remained undisputed mistress of the sea, and had become not only the carrier of all ocean-borne traffic, but the distributing centre of Indian goods to the whole world. A period of keen competition for a share in the commerce of India has again commenced amongst the states of Europe, and symptoms of a coming change in the carrying and distributing trade have been increasingly apparent since Africa was separated from Asia, nearly twenty years ago, by the genius of M. de Lesseps.

The opening of the Suez Canal, by diverting trade from the Cape route to the Mediterranean, has produced and is still producing changes in the intercourse between the East and the West which affect this country more nearly, perhaps, than any other European state. The changes have been in three directions.

First. An increasing proportion of the raw material and products of the East is carried direct to Mediterranean ports, by ships passing through the Canal, instead of coming, as it once did, to England for distribution. Thus Odessa, Trieste, Venice, and Marseilles are becoming centres of distribution for Southern and Central Europe, as Antwerp and Hamburg are for the North; and our merchants are thus losing the profits they derived from transhipping and forwarding Eastern goods to Europe. It is true that the carrying trade is still, to a very great extent, in English hands; but should this country be involved in a European war the carrying trade, unless we can efficiently protect it, will pass to others, and it will not readily return. Continental manufacturers have always been heavily handicapped by the position England has held since the commencement of the century, and the distributing trade would doubtless have passed from us in process of time. The opening of the Canal has accelerated the change to the detriment of English manufactures, and consequently of the national wealth; and it must tend to make England less and less each year the emporium of the world. We are experiencing the results of a natural law that a redistribution of the centres of trade must follow a rearrangement of the channels of commerce.

Second. The diversion of traffic from the Cape route has led to the construction of steamers for special trade to India and the East through the Canal. On this line coaling stations are frequent, and the seas, excepting in the Bay of Biscay, are more tranquil than on most long voyages. The result is that an inferior type of vessel, both as regards coal-stowage, speed, endurance, and seaworthiness has been built. These "canal-wallahs," as they are sometimes called, are quite unfitted for the voyage round the Cape, and should the Canal be blocked by war or accident, they would be practically useless in carrying on our Eastern trade. Since the Canal has been deepened they have improved, for it has been found cheaper to have more coal-stowage, but they are still far from being available for the long voyage round the Cape. Had the Canal not been made, a large number of fine steamers would gradually have been built for the Cape route, and though the sailing ships which formerly carried the India and China trade would have held their own longer, we should by this time have had more of the class of steamer that would be invaluable to us in war time, and our trade would not have been liable, as it is now, to paralysis by the closing of the Canal.

Third. Sir William Hunter has pointed out that, since the opening of the Canal, India has entered the market as a competitor with the British workman; and that the development of that part of the empire as a manufacturing and food-exporting country will involve changes in English production which must for a time be attended by suffering and loss. Indian trade has advanced by rapid strides, the exports of merchandise have risen from an average of 57 millions for the five years preceding 1874 to 88 millions in 1884, and there has been an immense expansion in the export of bulky commodities. Wheat, which occupied an insignificant place in the list of exports, is now a great staple of Indian commerce, and the export has risen since 1873 from $1\frac{3}{4}$ to 21 million hundredweight. It is almost impossible to estimate the ultimate dimensions of the wheat trade, and it is only the forerunner of other trades in which India is destined to compete keenly with the English and European producers.

The position in which England has been placed by the opening of the Canal is in some respects similar to that of Venice after the discovery of the Cape route; but there is a wide difference in the spirit with which the change in the commercial routes was accepted. Venice made no attempt to use the Cape route, and did all she could to prevent others from taking advantage of it; England, though by a natural instinct she opposed the construction of the Canal, was one of the first to take advantage of it when opened, and so far as the carrying trade is concerned she has hitherto successfully competed with other countries.

The increasing practice of the present day is for each maritime country to import and carry the Indian and other commodities it requires, and we must be prepared for a time when England will no longer be the emporium of Eastern commerce for Europe, or possess so large a proportion as she now does of the carrying trade. So great, however, is the genius of the English people for commercial enterprise, and so imbued are they with the spirit of adventure, that we may reasonably hope loss of trade in one direction will be compensated by the discovery of new fields of commercial activity. The tendency at present is to shorten sea-routes by maritime canals; to construct canals for bringing ocean-going ships to inland centres of industry; and to utilise water carriage, wherever it may be practicable, in preference to carriage by land. For a correct determination of the lines which these shortened trade routes and great maritime canals should follow, a sound knowledge of geography and of the physical condition of the earth is necessary; and instruction in this direction should form an important feature in any educational course of commercial geography. The great problem of the future is the inland carrying trade, and one of the immediate commercial questions of the day is—who is to supply the interiors of the great continents of Asia and Africa, and other large areas not open to direct sea traffic?

The question of supplying European goods to one portion of Central Asia has been partially solved by the remarkable voyage of Mr. Wiggins last year, and by the formation of the company of the "Phœnix Merchant Adventurers." Mr. Wiggins started from Newcastle-on-Tyne for Yeniseisk, the first large town on the Yenesei, some 2,000 miles from the mouth of that river and within a few hundred versts of the Chinese frontier. On the 9th October, 1887, he cast anchor and landed his cargo in the heart of Siberia. The exploit is one of which any man might well be proud, but in Mr. Wiggins's case there is the additional merit that success was the result of conviction arrived at by a strict method of induction, that the Gulf Stream passed through the Straits into the Kara Sea and that its action, combined with that of the immense volume of water brought down by the Obi and Yenisei, would free the sea from ice and render it navigable for a portion of each year. The attempts of England to open up commercial relations with the interior of Africa have too often been marked by want, if not open contempt, of geographical knowledge, and by a great deficiency of foresight; but the competition with Germany is forcing this country to pay increased attention to African commerce, and the formation of such companies as the British East African Company, the African Lakes Company and the Royal Niger Company is a happy omen for the future.

I am afraid that I have frequently travelled beyond the sphere of geography. My object has been to draw attention to the supreme importance to this country of the science of commercial geography. That science is not confined to a knowledge of the localities in which those products of the earth which have a commercial value are to be found, and of the markets in which they can be sold with the greatest profit. Its higher aims are to divine, by a combination of historical retrospect and scientific foresight, the channels through which commerce will flow in the future, and the points at which new centres of trade must arise in obedience to known laws. A precise knowledge of the form, size, and geological structure of the globe; of its physical features; of the topographical distribution of its mineral and vegetable products, and of the varied forms of animal life, including man, that it sustains; of the influence of geographical environment on man and the lower animals; and of the climatic conditions of the various regions of the earth, is absolutely essential to a successful solution of the many problems before us. If England is to maintain her commanding position in the world of commerce she must approach these problems in the spirit of Prince Henry the Navigator, and by high scientific training fit her sons to play their part like men in the coming struggle for commercial supremacy. The struggle will be keen, and victory will rest with those who have most fully realised the truth of the maxim that "knowledge is power."

I may add that if there is one point clearer than another in the history of commerce it is this: that when a state cannot effectually protect its carrying trade in time of war, that trade passes from it and does not return. If England is ever found wanting in the power to defend her carrying trade, her fate will only too surely, and I might almost say justly, be that of Venice, Spain, Portugal and Holland.

In Africa the existence nearly everywhere of a wide coast plain with a deadly climate, and the difficulties attending land transport in a country where the usual beasts of burden, such as the camel, the ox, the horse, and the mule, cannot be utilised, will probably for many years retard the development of the land trade. On the other hand, the Congo with its wide-reaching arms, the Niger, the Nile, the Zambesi, the Shiré, and the great lakes Nyassa, Tanganyika, and the Victoria and Albert Nyanzas offer great facility for water transport, and afford easy access to the interior without traversing the pestilential plains. Already steamers ply on most of the great waterways—each year sees some improvement in this respect; and a road is in course of construction from Lake Nyassa to Tanganyika which will tend, if Arab raiders can be checked, to divert inland traffic from Zanzibar to Quilimane, and will become an important link in what must be one of the great trade routes in the future. It is possible, I believe, with our present knowledge of Africa, and by a careful study of its geographical features, to foresee the lines along which trade routes will develop themselves and the points at which centres of trade will arise; but I have already detained you too long, and will only venture to indicate Sawákin, Mombasa, Quilimane, or some point near the mouth of the Zambesi, and Delagoa Bay, as places on the east coast of Africa which, from their geographical position, must eventually become of great importance as outlets for the trade of the interior.

The future of Africa presents many difficult problems, some of which will no doubt be brought to your notice during the discussion which, I trust, will follow the reading of the African papers; and there is one especially—the best means of putting an end to slave-hunting and the slave-trade—which is now happily attracting considerable attention. It is surely not too much to hope that the nations which have been so eager to annex African soil will remember the trite saying that "property has its duties as well as its rights," and that one of the most pressingly important of the duties imposed upon them by their action is to control the fiends in human form who, of set purpose, have laid waste some of the fairest regions of the earth, and imposed a reign of terror throughout Equatorial Africa.

ABSTRACT OF THE ADDRESS TO THE MECHANICAL SCIENCE SECTION OF THE BRITISH ASSOCIATION.

By William Henry Preece, F.R.S., M.Inst.C.E., etc.,
President of the Section.

"Canst thou send lightnings, that they may go, and say unto thee, Here we are?" were pregnant words addressed to Job unknown centuries ago. They express the first recorded idea in history of the potentiality of electricity to minister to the wants of mankind. From Job to Franklin is a long swing in the pendulum of time. It was not until that American philosopher brought down atmospheric electricity by his kite-string in 1747, and showed that we could lead it where we willed, that we were able to answer the question addressed to the ancient patriarch. Nearly another century elapsed before this mysterious power of nature was fairly conquered. It has been during this generation, and during the life of the British Association, that electricity has been usefully employed; and it is because I have taken a subordinate position in inaugurating nearly all of its practical applications, that I venture to make the developments of them the text of my address to this section.

People are singularly callous in matters affecting their own personal safety; they will not believe in mysteries, and they ridicule or condemn that which they do not understand. The Church itself set its face against Franklin's "impious" theories, and he was laughed to scorn by Europe's scientific sons; and even now, though commissions composed of the ablest men of the land have sat and reported on Franklin's work in England, France, and nearly every civilised nation, the public generally remains not only ignorant of the use of lightning conductors, but absolutely indifferent to their erection, and, if erected, certainly careless of their proper maintenance. I found in a church not very far from here the conductor leaded into a tombstone, and in a neighbouring cathedral the conductor only a few inches in the ground, so that I could draw it out with my hand. Although I called the attention of the proper authorities to the absolute danger of the state of affairs, they remained in the same condition for years.

Wren's beautiful steeple in Fleet-street, St. Bride's, was well-nigh destroyed by lightning in 1764. A lightning rod was fixed, but so imperfectly that it was again struck. In July last (1887) it was damaged because the conductor had been neglected, and had lost its efficiency.

As long as points remain points, as long as conductors remain conductors, as long as the rods make proper connection with the earth, lightning protectors will protect; but if points are allowed to be fused, or to corrode away; as long as bad joints or faulty connections are allowed to remain; as long as bad earths, or no earths exist, so long will protectors cease to protect; and they will become absolute sources of danger. Lightning conductors, if properly erected, duly maintained, and periodically inspected, are an absolute source of safety; but if erected by the village blacksmith, maintained by the economical churchwarden, and never inspected at all, a loud report will some day be heard, and the beautiful steeple will convert the churchyard into a new geological formation.

We have not yet acquired that mental confidence in the accuracy of the laws that guide our procedure in protecting buildings from the effects of atmospheric electrical discharges which characterises most of the practical applications of electricity. Some of our cherished principles have only very recently received a rough shaking from the lips of Professor Oliver Lodge, F.R.S., who, however, has supported his brilliant experiments by rather fanciful speculation, and whose revolutionary conclusions are scarcely the logical deduction from his novel premisses. The whole subject is going to be thoroughly discussed at this meeting.

We are now obtaining much valuable information about the nature of lightning from photography. We learn that it does not, as a rule, take that zigzag course conventionally used to represent a flash on canvas. Its course is much more erratic and sinuous, its construction more complicated, and pictures have been obtained of *dark* flashes whose *raison d'être* has not yet been satisfactorily accounted for. The network of telegraph wires all over the country is peculiarly subject to the effects of atmospheric electricity, but we have completely mastered the vagaries of lightning discharges in our apparatus and cables. Accidents are now very few and far between.

The art of transmitting intelligence to a distance beyond the reach of the ear and the eye, by the instantaneous effects of electricity, had been the dream of the philosopher for nearly a century, when in 1837 it was rendered a practical success by the commercial and far-sighted energy of Cooke, and the scientific knowledge and inventive genius of Wheatstone. The metallic arc of Galvani (1790) and the developments of Volta (1796) had been so far improved that currents could be generated of any strength, the law of Ohm (1828) had shown how they could be transmitted to any distances, the deflection of the magnetic needle by Oersted in 1819, and the formation of an electro-magnet by Ampère and Sturgeon, and the attraction of its armature had indicated how those currents could be rendered visible as well as audible.

Cooke and Wheatstone, in 1837, utilised the deflection of the needle to the right and the left to form an alphabet. Morse used the attraction of the armature of an electro-magnet to raise a metal style to impress or emboss moving paper with visible dots and dashes. Steinheil imprinted dots in ink on the different sides of a line on paper, and also struck two bells of different sound to affect the ear. Bréguet reproduced in miniature the actual movements of the semaphore then so much in use in France; while others rendered practical the favourite idea of moving an indicator around a dial, on which the alphabet and the numerals were printed, and causing it to dwell against the symbol to be read—the A, B, C instrument of Wheatstone in England, and of Siemens in Germany. Wheatstone conceived the notion of printing the actual letters of the alphabet in bold Roman type on paper—a plan which was made a perfect success by Hughes in 1854.

At the present moment the needle system of Cooke and Wheatstone, as well as the A, B, C dial telegraph, are very largely used in England on our railways and in our smaller post-offices. The Morse recorder and the Hughes type-printer are universally used on the continent; while in America the dot and dash alphabet of Morse is impressed on the consciousness through the ear by the sound of the moving armature striking against the stops that limit its motion. In our larger and busier offices the Morse sounder and the bell system, as perfected by Bright, are very largely used, while the press of this country is supplied with news which is recorded on paper by ink dots and dashes at a speed that is almost fabulous.

Sir William Thomson's mirror—the most delicate form of the needle system—where the vibratory motions of an imponderable ray of light convey words to the reader, and his recorder, where the wavy motion of a line of ink spirted on paper by the frictionless repulsion of electricity performs the same function, are exclusively employed on our long submarine cables.

Bakewell in 1848 showed how it was possible to reproduce facsimiles of handwriting and of drawing at a distance, and in 1879 E. A. Cowper reproduced one's own handwriting, the moving pen at one station so controlling the currents flowing on the line wire that they caused a similar pen to make similar motions at the other distant station. Neither of these plans, the former beautifully developed by Caselli and d'Arlincourt, and the latter improved by Robertson and Elisha Gray, have yet reached the practical stage.

The perfection of telegraphy has been attained by that chief marvel of this electrical age—the speaking telephone of Graham Bell. The reproduction of the human voice at a distance, restricted only by geographical limits, seems to have reached the confines of human ingenuity; and though wild enthusiasts have dreamt of reproducing objects abroad visible to the naked eye at home, no one at the present moment can say that such a thing is possible, while in face of the wonders that have been done no one dare say that it is impossible.

At the meeting of the Association in Plymouth in 1877, I was able for the first time in this country to show the telephone at work. Since then its use has advanced with giant strides. There are probably a million instruments at work now throughout the civilised world. Its development has been regularly chronicled at our meetings. As far as the receiving part of the apparatus is concerned, it remains precisely the same as that which I brought over from America in 1877; but the transmitter, ever since the discovery of the microphone by Hughes in 1878, has been entirely remodelled. Edison's carbon transmitter was a great step in advance; but the modern transmitters of Moseley, Berliner, D'Arsonval, De Jongh, leave little to be desired. The disturbances due to induction have been entirely eliminated, and the laws regulating the distance to which speech is possible are so well known that the specification of the circuit required to connect the Land's End with John O'Groat's by telephone is a simple question of calculation. A circuit has been erected between Paris and Marseilles, 600 miles apart, with two copper wires of 6½ gauge, weighing 540 lbs. per mile, and conversation is easily maintained between those important cities at the cost of three francs for three minutes. One scarcely knows which fact is the more astounding—the distance at which the human voice can be reproduced, or the ridiculously simple apparatus that performs the reproduction. But more marvellous than either is the extreme sensitiveness of the instrument itself, for the energy contained in one heat unit (gramme-water-degree) would, according to Pellat, maintain a continuous sound for 10,000 years.

The influence which electric currents exert on neighbouring wires extends to enormous distances, and communication between trains, and ships in motion, between armies inside and outside besieged cities, between islands and the mainland, has become possible without the aid of wires at all, by the induction which is exerted through space itself. On the Lehigh Valley Railway, in the United States, such a system of telegraphing without wires is in actual daily use.

Electric lighting has become popular, not alone from the beauty of the light itself, but from its great hygienic qualities in maintaining the purity and coolness of the air we breathe. The electric light need not be more brilliant than gas, but it must be more healthy. It need not be cooler than a wax candle, but it must be brighter, steadier, and more pleasant to the eye. In fact, it can be rendered the most perfect artificial illuminant at our disposal, for it can illumine a room without being seen directly by the eye; it can be made absolutely steady and uniform without irritating the retina; it does not poison the air by carbonic acid and carbonic oxide, or dirty the decorations by depositing unconsumed carbon; it does not destroy books or articles of vertu and art by forming water which absorbs sulphur acids; and it does not unnecessarily heat the room.

The production of light by any means implies the consumption of energy, and this can be measured in *watts*, or the rate at which this energy is consumed. A watt is $\frac{1}{746}$ part of a *horse-power*. It is a very convenient and sensible unit of power, and will in time replace the meaningless horse-power.

				watts
One candle light maintained by		tallow	absorbs	124
,,	,,	wax	,,	94
,,	,,	sperm	,,	86
,,	,,	mineral oil	,,	80
,,	,,	vegetable oil	,,	57
,,	,,	coal gas	,,	68
,,	,,	cannel gas	,,	48
,,	,,	electricity (glow)	,,	3
,,	,,	electricity (arc)	,,	55

The relative heat generation of these illuminants may be estimated from these figures.

Though the electric light was discovered by Davy in 1810, it was not until 1844 that it was introduced into our scientific laboratories by Foucault; it was not until 1878 that Jablochkoff and Brush showed how to light up our streets effectually and practically; it was not until 1881 that Edison and Swan showed how our homes could be illuminated softly and perfectly.

The greatest development of the electric light has taken place on board ship. Our Admiralty have been foremost in this work. All our warships are gradually receiving their equipment. Our ocean-going passenger ships are also now so illumined, and perhaps it is here that the comfort, security, and true blessedness of the electric light is experienced.

Railway trains are also being rapidly fitted up. The express trains to Brighton have for a long time been so lighted, and now several northern railways, notably the Midland, are following suit. Our rocky coasts and prominent landfalls are also having their lighthouses fitted with brilliant arc lamps, the last being St. Katherine's Point on the Isle of Wight, where 60,000 candles throw their bright beams over the English Channel, causing many an anxious mariner to proceed on his way rejoicing.

Fontaine showed in Vienna, in 1873, that a dynamo was reversible—that is, if rotated by the energy of a moving machine, it would produce electric currents; or, if rotated by electric currents, it would move machinery. An electric current is one form of energy. If we have at one place the energy of falling water, we can, by means of a turbine and a dynamo, convert a certain portion of the energy of this falling water into an electric current. We transmit this current through proper conductors to any other place we like, and we can again, by means of a motor, convert the energy of the current into mechanical energy to do work by moving machinery, drawing tramcars, or in any other way. We can in this way transmit and utilise 50 per cent. of the energy of the falling water wherever we like. The waste forces of nature are thus within our reach. The waterfalls of Wales may be utilised in London; the torrents of the Highlands may work the tramways of Edinburgh; the wasted horse-power of Niagara may light up New York. The falls of Bushmills actually do work the tramway from Portrush to the Giant's Causeway, and those of Bessbrook the line from Newry to Bessbrook.

The practicability of the transmission of energy by currents is assured, and the economy of doing this is a mere matter of calculation. It is a question of the relative cost of the transmission of fuel in bulk, or of the transmission of energy by wire. Coal can be delivered in London for 12s. per ton. The mere cost of the upkeep of a wire between Wales and London to deliver the same amount of energy would exceed this sum tenfold. For long distances the transmission of energy is at present out of the question. There can be no doubt, however, that for many purposes within limited areas the transmission of energy by electricity would be very economical and effective. Pumps are worked in the mines of the Forest of Dean, cranes are moved in the works of Easton and Anderson at Erith, lifts are raised in banks in London; water is pumped up from wells to cisterns in the house of Sir Francis Truscott, near East Grinstead; ventilation is effected and temperature lowered in collieries; goods, minerals, and fuel can be transmitted by telpherage.

The transmission of power by electricity is thus within the range of practice. It can be distributed during the day by the same mains which supply currents for light by night. Small industries, such as printing, watch-making, tailoring, boot-making, can be cheaply supplied with power. It is thus brought into direct competition with the distribution of power by steam as in America, or by air-pressure as in Paris, or by high-pressure water as in London; and the relative advantages and economies of each system are simple questions of calculation. When that evil day arrives that our supply of natural fuel ceases, then we may look to electricity to bring to our aid the waste energies of nature—the heat of the sun, the tidal wave of the ocean, the flowing river, the roaring falls, and the raging storm.

The property, which the electric current possesses, of doing work upon the chemical constitution of bodies so as to break up certain liquid compounds into their constituent parts, and marshal these disunited molecules in regular order according to a definite law upon the surfaces of metals in contact with the liquid where the current enters and exists, has led to immense industries in electro-metallurgy and electro-plating. The extent of this industry may be gathered from the fact that there are 172 electro-platers in Sheffield and 99 in Birmingham. The term electro-metallurgy was originally applied to the electro-deposition of a thin layer of one metal on another; but this is now known as electro-plating.

In 1839 Jacobi in St. Petersburg and Spencer in Liverpool laid the foundations of all we know of these interesting arts. Copper was deposited by them so as to obtain exact reproductions of coins, medals, and engraved plates. The first patents in this country and in France were taken out by Messrs. Elkington, of Birmingham, who still occupy the foremost position in the country.

The fine metals, gold and silver, are deposited in thin layers on coarser metals, such as German silver, in immense quantities. Christofle of Paris deposits annually six tons of silver upon articles of use and of art, and if the surfaces so electro-plated were spread out continuously they would cover 140 acres.

The whole of the copper plates used in Southampton for the production of our splendid Ordnance survey maps are deposited by copper on matrices taken from the original engraved plates, which are thus never injured or worn, are always ready for addition or correction, while the copies may be multiplied at pleasure and renewed at will.

Nickel-plating, by which the readily oxidisable metals like iron are coated with a thin layer of the more durable material nickel, is becoming a great industry; the trappings of harness, the exposed parts of machinery, the fittings of cycles and carriages and innumerable articles of daily use are being rendered not only more durable but more beautiful.

The electro-deposition of iron, as devised by Jacobi and Klein, in the hands of Prof. Roberts-Austen, F.R.S., is giving very interesting results. The dies for the coins which were struck at our Mint on the occasion of the Jubilee of the Queen, were modelled in plaster, reproduced in intaglio by the electro-deposition of copper, and on these copper moulds hard excellent iron in layers of nearly 1-10th of an inch was deposited.

The extraction of metals from their ores by deposition has received wide application in the case of copper. In 1871 Elkington proposed to precipitate copper electrolytically from the fused sulphide of copper and iron known to the copper smelter as "regulus." Thin copper plates were arranged to receive the deposited copper while the foreign metals, including gold and silver, fell to the bottom of the solution, the process being specially applicable, it was supposed, to regulus containing small quantities of the precious metals.

The electrical purification of copper from impure "blister copper" or "blade copper" has also made great progress, and special dynamos are now made which will, with an expenditure of 100 horse-power, precipitate 18 tons of copper per week. The impure metal is made to form the anode in a bath of sulphate of copper, the metal being deposited in the pure form on a thin copper cathode.

Both at Swansea and Widnes immense quantities of copper, in spite of the restrictive operations of the copper syndicate, are being produced by electro-deposition. Copper steam pipes for boilers are now being built up of great firmness, fine texture, and considerable strength by Mr. Elmore at Cockermouth, by electro-deposition on a rotating mandril in a tank of sulphate of copper. By this process one ton of copper requires only a little more than one ton of coal to raise the requisite steam to complete the operation.

It has been shown that the electrolytic separation of silver from gold by similar methods is perfectly practicable. The value of the material to be dealt with may be gathered from the fact, communicated to the "Gold and Silver Commission" now sitting, that nearly 90,000,000 ounces of silver are annually produced, and the greater portion of this amount contains sufficient gold to render refining remunerative. Although the old acid process of "parting" gold and silver remains practically undisturbed, there seems no reason to doubt that in the future electricity will render us good service in this direction as it has already in the purification of copper.

There is not much actual progress to report in the extraction of gold from its ores by electrical agency. The conversion of gold into chloride of gold by the direct, or indirect, action of chlorine is employed on a very large scale in [Grass Valley] California and elsewhere. This fact has led to well-directed efforts to obtain by electrolytic action, chlorine which should attack finely divided gold suspended (with the crushed ore) in the solution from which the chlorine was generated, the gold, so converted into soluble chloride, then being deposited on a cathode. The process would seem to be hopeful, but is not as yet a serious rival to the ordinary chlorination method.

In the amalgamation of gold ores much is expected from the possibility of keeping clean, by the aid of hydrogen set free by the electric current, the surfaces of amalgamated plates.

It is well known that the late Sir W. Siemens considered that the electric arc might render good service in the fusion of metals with high melting points, and he actually succeeded in melting 96 ounces of platinum in ten minutes with his electrical furnace. The experiments were interrupted by his untimely death, but in the hands of Messrs. Cowles the electric arc produced by 5,000 ampères and 500 horse-power is being employed on a very large scale for the isolation of aluminium (from corundum), which is immediately alloyed (*in situ*) with copper or iron, in the presence of which it is separated.

The heating power of large currents has been used by Elihu Thomson in the United States, and by Bernardos in Russia, to weld metals, and it is said to weld steel without affecting its hardness. It has even been proposed to weld together in one continuous metallic mass the rails of our railways so as to dispense entirely with joints.

The production of chlorine for bleaching and of iodine for pharmaceutical purposes, the economical production of oxygen, are also processes now dependent on the electrolytic effect of the electric current.

It is almost impossible to enumerate the various general purposes to which electricity is applied to minisier to our wants, and to add to our comforts. Every one appreciates the silent efficiency of the trembling electric bell, while all will sooner or later derive comfort from the perennially self-winding electric clock. Correct mean time is distributed throughout the length and breadth of the land by currents derived from Greenwich Observatory. Warehouses and shops are fitted with automatic contact pieces, which, on any undue increase of temperature due to fire, create an alarm in the nearest fire station; and at the corner of most streets a post is found with a face of glass, which on being broken enables the passer-by or the watchful and active policeman to call a fire-engine to the exact spot of danger. Our sewers are likely to find in its active chemical agency a power to neutralise offensive gases, and to purify poisonous and dangerous fluids. The germs of disease are attacked and destroyed in their very lairs. The physician and the surgeon trust to it to alleviate pain, to cure disease, to effect organic changes beyond the reach of drugs. The photographer finds in the brilliant rays of the arc lamp a miniature sun which enables him to pursue his lucrative business at night, or during the dark and dismal hours of a black November fog of London.

We learn from the instructive and interesting advertising columns of our newspapers that "electricity is life," and we may perhaps read in the more historical portion of the same paper that by a recent decision of the New York Parliament, "electricity is death." It is proposed to replace hanging by the more painless and sudden application of a powerful electrical charge; but those who have assisted at this hasty legislation would have done well to have assured themselves of the practical efficacy of the proposed process. I have seen the difficulty of killing even a rabbit with the most powerful induction coil ever made, and I know those who escaped and recovered from the stroke of a lightning discharge.

The fact that the energy of a current of electricity, either when it flashes across an air space or when it is forced through high resistance, assumes the form of heat of very high temperature led early to its employment for firing charges of gunpowder; and for many civil, military, and naval purposes it has become an invaluable and essential agent. Wrecks like that of the Royal George at Spithead were blown up and destroyed; the faces of cliffs and quarries are thrown down; the galleries of mines and tunnels are excavated; obstructions to navigation like the famous Hell Gate, near New York, have been removed; time guns to distribute correct time are fired by currents from Greenwich at 1 p.m. In the operations of war, both for attack and defence, submarine mining has become the most important branch of the profession of a soldier and a sailor. Big guns, whether singly or in broadside, are fired, and torpedoes, when an enemy's ship unwittingly is placed over them, are exploded by currents of electricity.

An immense amount of research has been devoted to design the best form of fuse, and the best form of generator of electricity to use to explode them. Gun tubes for firing consist of a short piece of very fine wire embedded in some easily fusible compound, while the best form of fuse is that known as the Abel fuse, which is composed of a small, compact mass of copper phosphide, copper sulphide, and potassium chlorate. The practice in the use of generators is very various. Some, like the Austrians, lean to the high tension effects of static electricity; others prefer magneto machines; others use the dynamo; while we in England cling with much fondness to the trustworthy battery. Since the electric light has also become such a valuable adjunct to war purposes, it is probable that secondary batteries will become of immense service. The strong inductive effects of atmospheric electricity are a source of great danger. Many accidental explosions of fuses have occurred. An experimental cable with a fuse at one end was laid below low-water mark along the banks of the Thames at Woolwich. The fuse was exploded during a heavy thunderstorm. The knowledge of the causes of a danger is a sure means for the production of its removal, or of its reduction to a minimum. Low tension fuses and metallic circuits reduce the evils of lightning, but have not removed them. Should war unhappily break out again in Europe, submarine mining will play a very serious part, and, paradoxical as it may appear—as has been suggested by the French ambassador, M. Waddington—its very destructiveness may ultimately prove it to be a powerful element of peace.

(To be continued.)

MR. PREECE'S ADDRESS.—To further the "advancement of science" we should have welcomed a little more light and leading than is to be found in the address of the President of the Mechanical Section. Mr. Preece is an electrician, and electricity was his theme, and we cannot but feel that he was not quite equal to the occasion. It is true he gave an interesting historical *résumé* of many of the applications of electricity, and that he pleased many of his hearers by the popular nature of his discourse, but the thoughtful and the scientific could not but have been disappointed. It is one thing to popularise scientific information in the sense of making it understood by those who have not been trained technically; it is another thing to give a rather common-place record of results more or less known, without any touches of the master mind.

It must not, however, be supposed that no grains of wheat were to be found amongst the chaff. Mr. Preece did good service in again calling attention to the ignorance and indifference of the public about the proper treatment of lightning conductors. If they are properly erected, duly maintained, and periodically inspected, they are an absolute source of safety; "but," says Mr. Preece, "if they are erected by the village blacksmith, maintained by the economical churchwarden, and never inspected at all, a loud report will some day be heard, and the beautiful steeple will convert the churchyard into a new geological formation." Speaking of the development of telegraphy, Mr. Preece mentioned that since the Government took over the telegraphs the number of messages has increased from six to fifty-two million per annum. On one important occasion as many as 1,500,000 words were sent from the Central Telegraph Office in London in one night. On the subject of electric lighting at the Central Savings Bank in London, Mr. Preece made a rather novel calculation. He said that after two years' experience the average absences from illness had been reduced by about two days a year for each person on the staff, and that this was equivalent to a gain to the service of the time of about eight clerks in that department. Taking this into account, he then estimated that the electric lighting costs £266 less than lighting by gas.

As regards the telephone, it appears that in and about New York there are 15,000 subscribers, but in London there are only 4,851, even Stockholm having more subscribers than our own capital. As a Government official, Mr. Preece was, however, careful not to suggest that the probable reason of this slow development was the well-known restrictive action of the Government.

After speaking of the transmission of power by electricity being within the range of practice, Mr. Preece added these words of comfort, "When the evil day arrives that our supply of natural fuel ceases, then we may look to electricity to bring to our aid the waste energies of nature—the heat of the sun, the tidal wave of the ocean, the flowing river, the roaring falls, and the raging storm." We trust, however, that as a nation we shall not allow ourselves to be prodigal of fuel, because of the power we may derive from the sun we so seldom feel, or from the raging storms which come at such uncertain intervals.

Mr. Preece referred to the progress made in the application of electricity to electro-metallurgy and electroplating, and speaking of the electrolytic separation of silver from gold, he mentioned that nearly ninety million ounces of silver are produced annually, and that the greater portion of it contains sufficient gold to render refining remunerative. He also referred to the very powerful electric furnaces now used for aluminium, and the alloys formed with it. The welding of metals, including steel, can now be effected by electricity, and Mr. Preece said it was even proposed to weld together in one continuous length the rails of our railways, so as to dispense entirely with joints! Later on he took occasion to speak rather slightingly of physicists as mere theorists, but if the superior "practical" electrician ignores the contraction and expansion of several miles of continuous iron rails, no wonder there is a want of agreement between them.

PROFESSOR AYRTON'S LECTURE.—The Friday evening discourse of Professor Ayrton on the Electrical Transmission of Power was a great success. Professor Ayrton has not only a thorough knowledge of his subject, but has also the valuable gift of explaining it in a clear and forcible manner. Moreover, he performed a well-arranged series of experiments which were very successful. In the course of his remarks he stated that it was well known that large steam engines could be worked more economically than small ones, and from this he argued that if it were possible to transmit *economically* the power from a few large engines to a great number of small workshops there would be a great saving of power, as well as a great saving of time.

He pointed out that there are four methods of transmitting power to a distance: by a moving rope, by air compressed or rarified, by water forced through a pipe, and by electricity. Hitherto the distribution of power by water pressure has been most in favour in this country, but Professor Ayrton is of opinion that the electric transmission of power, even now, bids fair to surpass all other methods, for the following reasons: It is economical in fuel; it gives more perfect control over each individual machine; tools can be brought to the work, instead of the work being taken to the tools; there is greater cleanliness; and finally the power which during the day-time might be mainly used for driving machinery, could, in the easiest possible way, be used during the night for giving light. By turning a handle one way the electric current could be made to work an electric motor, and by turning it the other way the current which would come and return by the same wires as before, could be used for electric lighting. Professor Ayrton remarked that it might be said that the transmission of power by coal-gas fulfilled this condition, but so also did the transmission by a loaded coal waggon. In both these cases it was the fuel itself that was transported, not the power.

The chief attraction of the evening was the welding of iron and steel bars one inch square in section by by a high tension current transmitted through a small wire. Aluminium was also welded quickly by the same means. It has yet to be proved whether or not this sudden heating of the metals can be effected without subjecting them to excessive strains, but the mere fact of being able to weld so quickly and so easily was of itself very striking. In conclusion Professor Ayrton showed a working model of the "Telpher Line," invented by the late Professor Fleeming Jenkin, Professor Perry, and himself.

Discovery of an Ancient City.—In the north-east of the province of Chihuahua there have been found, according to the *Revue Française de l'Etrangère*, the remains of an ancient city excavated and sculptured in the rocks like Petra in the land of Edom. No traditions concerning this city survive, but the ruins show that its prehistoric inhabitants must have been civilised. There are hundreds of rooms hewn in the solid rock on the side of the mountain, and the stone extracted has served for buildings. There are many heights of rooms and stairs cut in the rock leading from house to house. In many places the rock is elegantly sculptured and polished.

Legal Standards of Time.—M. Bouquet de la Grye, in a communication to the Academy of Sciences, mentions a project for the adoption of a uniform time throughout France, Algeria, and Tunisia. The standard adopted will drobably be Paris time.

Earthquake in Greece.—Two violent shocks of earthquake occurred on September 10th at Vostitza, in the Northern Peloponnesus. Great destruction was caused to property.

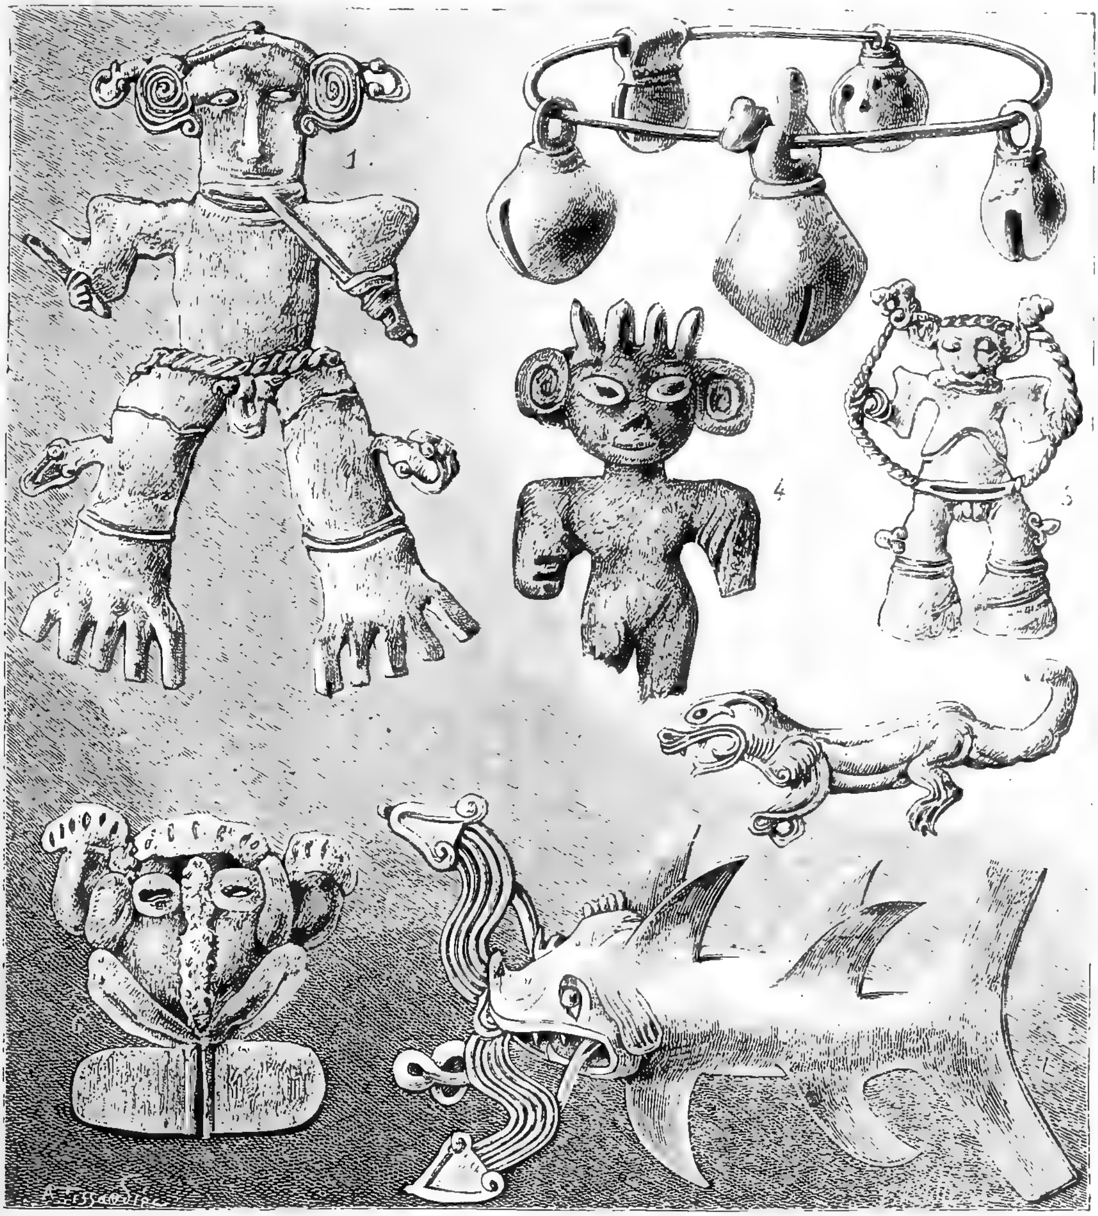
The Buffon Centenary.—On the 17th of this month the centennial anniversary of the death of Buffon will be solemnised at Montbard.

THE HUACAS OF CHIRIQUI.

The ancient tombs in Central America, which are known in the Spanish-American of the country by the name of "huacas," abound in interesting relics of long past generations.

The whole coast of the Isthmus of Darien, especially on the shore washed by the Pacific, is thickly studded with these "huacas," but those at Chiriqui, on the Atlantic coast, are for the most part in a better state of preservation than those elsewhere. Until within the last few years, Chiriqui was almost an unknown land, having apparently even evaded the notice of the Spanish conquerors, although they penetrated into many parts of Darien and Panama, but the proposed cutting of a connecting canal between the Atlantic and Pacific Oceans, necessitating careful engineering surveys of the isthmus, has brought the district into comparatively prominent notice. The first important discoveries of old-world relics took place in 1858, when two workmen, in the course of their digging, unearthed a small gold figure, and incited by this unlooked-for treasure to further investigations, continued their excavations with an ardour which soon met with a very ample reward. The report of their success rapidly spread abroad, and within twelve months of the date of the first discovery the ground for miles around was furrowed with the excavations of eager treasure-seekers, most of whom reaped a wonderful harvest of idols, ornaments, etc., in gold and copper. Unfortunately, however, the interest since taken in the primitive races of America was then only in its infancy, and the greater part of these ornaments, which might perhaps have thrown important lights upon the ethnology of Central America, was melted down for the sake of the metal of which they were composed. Only comparatively few specimens were preserved intact from these first excavations, but happily their discoverers left in some cases copious notes as to the tombs where they were found, and it is partly to this earlier testimony, corroborated by the experiences of later days, that we owe much of our knowledge on the subject. As in parts of Peru, the tombs in Chiriqui are sometimes square, sometimes oval; they are arranged without regard to any particular direction, extending to a depth of some eighteen feet beneath the surface of the soil, and are lined with rough stones covered with a kind of paving stone, which must have been brought, in most instances, from a considerable distance. The ground was covered with pebbles, upon which the corpse was laid, wrapped in a simple shroud, the elaborate garments and bandages of the Peruvian mummies being absent. These corpses are commonly called "mummies," but the term is, as a matter of fact, a misnomer, these bodies owing their preservation to the lightness of the soil and air, and not to any artificial process, as in the case of the true mummy of the Egyptians and of the Guanchos (the aborigines of the Canary Isles), where the body underwent an elaborate process of embalming with resinous gums, salts, or wax.

In the "huacas" of Chiriqui the skeletons of the dead, save occasional fragments, have, in many cases, disappeared, the atmosphere there being apparently deficient in those marvellous properties of the atmosphere of Western Peru, which have preserved the bodies in the coast tombs in a condition almost as perfect as that ensured for the Egyptian mummies by the old embalming. The relatively destructive effects of the air have, however, had but little influence upon the stone, pottery, and metal objects found in the Chiriqui tombs, deposited there, as was the case throughout the whole of America, by the mourning relatives, who invariably buried with their dead the implements, ornaments, toys, etc., which they had used during life. As in most of the North American mounds, articles made of rough terra-cotta are more numerous than are the arms and tools of stone and wood, and are only exceeded in quantity by the ornaments made of gold, silver, copper, and tin, and sometimes even of a skilful mixture of the two latter, forming a good durable bronze. In the Museum at Washington there are more than four thousand pottery articles of divers shapes, all collected from the tombs at Chiriqui, some simple vessels for holding foods, cooking utensils, or drinking vessels, others fashioned of baked clay in the strange devices of the ornamental art of those primitive days, sometimes rude representations of animals or reptiles, as, for example, the frog (No. 6) in the accompanying engraving, which we borrow from our courteous contemporary *La Nature*. The metal images, idols, etc., have given rise to some discussion as to whether they were made by means of casting or by simple hammering; the generally accepted opinion at the present day inclining to the theory that the artist had recourse to a method still employed in some countries of the East, namely, that he modelled his subject in some fusible substance, wax



Ornaments found in the Huacas of Chiriqui.

or resin, for example, then covered it with a thick coat of potter's clay, and exposed it to fierce heat. The inner model melted away, and left the hardened clay as a mould into which could be poured the molten metal. It is possible that sometimes a mixture of gold and mercury was used; this being more pliable, could be modelled to the required shape, exposed to heat, and finished by the aid of coarse tools; the little figures numbered 1, 3, and 4 in our illustration, were probably made in this manner, as were also many of the Peruvian ornaments. The artists of Chiriqui do not appear to have understood the art of engraving or of embossing, judging at least from the fact that no specimens of such work have hitherto been found in their huacas, but they were very clever in joining the separate parts of their designs together, the joins being often almost invisible, and were also very deft in their manipulation of fine gold wire, frequently attaching extra ornamentation to their figures by means of twisted wires. Fig. 3 shows a good example of this kind of work. Occasionally objects, instead of being made of pure gold, are made of copper, gilded, while others are plated with a layer of gold, as sometimes occurs in the North American mounds, where, however, the gold is often supplanted by iron, which in those early days was accounted rather more precious than the less rare gold. How these various metals were all worked together, and how the more elaborate ornamentation was achieved, remains to this day an unsolved problem, for it seems inexplicable that a people whose ideas of imitative arts were, as the representations of human figures, animals, etc., clearly prove, primitive to a degree, should yet have been so far advanced in metallurgic craft.

One is sometimes tempted to imagine that these models of the human form divine must have been intended as grotesque caricatures, and not as *bona-fide* copies from the original, though it must be confessed that birds and animals also obtain but scant justice at these artists' hands. Eminently unsatisfactory though these achievements appear to us in the light of nineteenth century art criticism, yet the Chiriqui artists seem to have taken great delight in these reproductions from life, sharing in this respect a predilection manifested throughout the whole of Central America. After the human form, the owl, eagle, parrot, and frog seem to have been the most popular models, but animals and fish of divers species were also pressed into the service. The puma (No. 5 of the illustration) we accept as such, purely by faith, on the strength of *La Nature's* asseveration that it is a puma; we ourselves might have been puzzled to decide which family of the animal world could fairly claim so curious a specimen. The fish (No. 7) is evidently symbolic of some old tradition, and is a decided improvement in point of both design and execution upon some of the artistic efforts of the same date. The Chiriqui artificers did not confine themselves solely to these images and models of animate objects as their only branch of decorative art; they were also expert in the manufacture of amulets, beads for necklaces, pins, bells, whistles, etc., made in pure gold or in an alloy of gold and copper, and even produced flat medallions of gold, etc., with added ornamentation, pierced with holes at the top, evidently intended to be worn round the neck as medals of honour. One of these medallions in the Museum, Washington, measures about 28 inches in diameter. Occasionally the bells were made of bronze, gilded, elongated in shape, with apertures at the bottom for the sound to escape, and containing little metal balls to serve as clappers. They were frequently suspended on a gold wire (as in Fig. 2).

The Marquis de Madaillac, in his interesting paper on the subject in *La Nature*, to which we are indebted for much of the above information, draws attention to a significant fact—the great disparity between the amount of metal produced by the country and that used by the inhabitants in the manufacture of the countless ornaments, etc., found in such numbers in all parts of the isthmus. There are no traces of ancient mines in this particular district, and, so far as we know, no veins of metalliferous deposit, and although there is a certain amount of gold in the form of dust and small nuggets found in the rivers, it seems very improbable that this supply could ever have been sufficient to meet the demand in those old days of metallurgic industry. The raw material must therefore have been imported from other countries, and the inhabitants of Chiriqui must have had, at a very early date, intercourse with other and distant nations. It is interesting to observe, however, that this intercourse had no perceptible effect upon the artistic productions of the Chiriquians, their art being distinctly of native origin, and bearing no traces of foreign influence, either Peruvian or Mexican.

BIRDS' TONGUES.

WE are rather accustomed, most of us, to look upon the tongue as primarily and finally an organ of taste and of speech. Such are the functions which it fulfils in ourselves; and, although speech is a faculty not granted to mammals, we know that their sense of taste, if not always very keen, is certainly not wanting. And so, in them, we are apt to consider the tongue as an instrument of that special sense, seldom realising that it may have other duties to perform, and those very possibly of a far more important character. And this, in point of fact, we find to be the case in such mammals as the lion, the giraffe, and the ant-eater. In the first of these the tongue becomes a rasp, suitable for scraping the flesh of a victim from the bones; in the second it is an instrument of prehension, adapted for plucking the foliage of trees; and in the third it is principally a weapon, lubricated with a kind of natural bird-lime, which causes ants and other small insects to adhere to it as it is swept to and fro among them. Yet there can be no doubt that, in the generality of mammals, it *is* an organ of taste, and very little else, although in some it has its uses as an auxiliary in mastication.

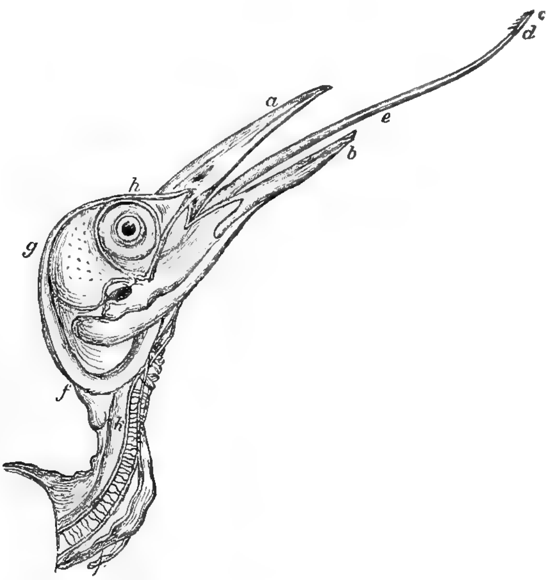
In the birds, however, the sense of taste seems almost wholly wanting; and, even were it present, it is difficult to see in what manner it could be of service. For many birds—most birds, in fact—swallow their food without any sort of preparation in the mouth. They are entirely without teeth—now-a-days—and therefore mastication is impossible. And so we find that predacious birds, insect-eating birds, fruit-eating birds, and seed-eating birds alike almost invariably swallow their food in such a manner that its flavour could not by any possibility be appreciated by the nerves of taste, even were such nerves not only present, but present in a highly developed degree.

The tongue, therefore, when present in any but a rudimentary form, is adapted to fill far other offices than that of mere sensual gratification. It is, indeed, generally covered with a sheath of horn —an evident sign that the sense of taste must be wanting—and it becomes, usually, either an instrument for the capture of living prey, or else one for the extraction of liquid nourishment from honey-bearing flowers. Or, as in the parrots, it may serve as a kind of thumb, and, being opposable to the upper mandible, assist greatly in holding and turning nuts, seeds, or morsels of fruit. And, following the invariable rule of Nature, it is in all such cases considerably modified, always in such a manner as best to adapt it to the duties which it is called upon to perform.

In the woodpeckers it is especially curious. These, as no doubt most of us know, are birds whose task it is to extract wood-boring insects from their burrows, and in so doing to chip away the unsound wood in which they have made their home; thus performing a kind of rough surgery which may not impossibly save a slightly-diseased tree from death, just as a human operator, by cutting away diseased flesh, prolongs or preserves the life of his patient. Therefore do we find, in these birds, that not only does the beak constitute a sort of natural chisel, but that the tongue is specially modified in order that it may perform the actual task of capture; for that is a work for which the bill itself is obviously unsuited. The one instrument cuts away the wood and exposes the insects to view; the other must capture them. And therefore modification takes place in a very remarkable degree.

In the first place, the hyoid bones, which support the base of the tongue, and which also serve as an attachment for the important muscles of the throat, are greatly lengthened, and, passing over the back of the head, are fastened into the skull just above the right nostril; and they are accompanied by a narrow strip of muscle, by means of which they are moved. Thus great elasticity at the base of the tongue is provided. That organ itself is extremely long and slender—almost filamentary, in fact—and is terminated by a long horny appendage, sharply pointed at the extremity, and covered with small barbs, the points of which are directed down the throat. Finally, the saliva, as in the ant-eater among mammals, and in the chameleon among reptiles, is of a highly glutinous consistency. Thus, when the tongue is inserted into the burrow of a wood-boring insect—first enlarged by the beak—the tenant, if a small one, adheres to the extremity by reason of the glutinous saliva; if a larger, the reversed barbs drag it from its retreat. It was formerly asserted that these barbs transfixed the victim, but this is now denied. It may well be, however, that in the case of a powerful insect the sharply-pointed horny tip itself does so, thus killing, or at any rate greatly weakening it, and enabling it to be withdrawn with comparative ease.

In the night-jars, the martins, the swallows, and the swifts, we find the saliva again playing a very important part in the capture of prey, although the tongue is not developed. In the titmice, however, we have an approach to the woodpecker structure, for the tongue, which is shaped at the extremity something like a "J" pen, is terminated by four reversed spines—two upon either side; and the saliva is again of a highly glutinous character. Thus these little birds are enabled to extract small insects from the crevices and crannies in the bark of trees, and especially from those in the lower surface of the branches, wherein they are perfectly safe from the attacks of birds in general.



HEAD OF A WOODPECKER, SHOWING—
a, upper mandible; *b*, lower ditto; *c*, *d*, *e*, tongue; *f*, *g*, *h*, hyoid bones.

In the humming-birds, those gems of the feathered race, we once more find the woodpecker structure very closely followed. The hyoid bones are again carried over the top of the skull and terminated upon the forehead, and the tongue is again long and thread-like (although double nearly to its base), so that it can penetrate to the base even of the long, bell-shaped flowers which are so plentiful in some of the South American forests, and extract the liquid treasures as well as the small insects which are to be found therein; for the humming-birds are fond of a mixed diet, and eat both honey and insects. In the honey-eaters themselves, or *Meliphagidæ*, the tongue is terminated by a tuft of slender fibres, which evidently answer the purpose of a brush.

Many birds possess a varying number of small spines near the base of the tongue, always set in such a manner that the points are directed down the throat. Probably these aid in some degree in the operation of swallowing, and are analogous to the double row of teeth which we find upon the palates of the non-venomous serpents, and which bear so very important a share in the task of deglutition. In the duck, however, and also in some of its near relatives, these spines are considerably extended in their range, the last inch or so of the tongue itself being fringed with delicate bristles, while on either side of the organ are five sharp spines of some little size, the intervening spaces being again occupied by a row of slender bristles. Finally, upon the upper surface of the tongue are two small bony projections, which seem to correspond with four spines situated opposite to them upon the upper jaw. This rather complicated structure appears, in concert with the corrugated margins of the beak itself, to assist in the filtration of the mud, etc., from which these birds extract so large a proportion of their food.

In the parrots, as already stated, the tongue, which now assumes the form of a thick, fleshy organ, fulfils the duties of a thumb, the upper mandible, to which it can be opposed, in like manner serving as a finger. Probably most of us are acquainted with the facility with which a parrot turns and twists a nut, a large seed, or any similar article of diet; and it is to the character of the tongue, also, that these birds owe their singular powers of articulation. On the other hand, there are many birds, and among them some of the largest, in which that member is scarcely developed at all. In the ostrich, for example, it is little more than an inch in length, and there is some difference of opinion among ornithologists as to whether, in this particular instance, it is actually the tongue itself or only the epiglottis. And there are a great number of birds in which it is more rudimentary still, and which, for all practical purposes, are without tongues at all.

ON THE GIGANTIC DIMENSIONS OF CERTAIN FOSSIL MAMMALIA.

M. ALBERT GAUDRY, in a memoir read before the Paris Academy of Sciences, states that he has just received from M. Strauch, the Director of the Museum of the St. Petersburg Academy of Sciences, some photographs of the celebrated mammoth of that collection.

The mammoth (*Elephas primigenius*) of the St. Petersburg Museum is that whose entire body was found, in 1799, upon the shore of the Icy Ocean, near the mouth of the Lena. As seven years had intervened between its discovery and its arrival at St. Petersburg, a part of its flesh had been devoured by dogs and other ferocious beasts, and the greater portion of the remainder had been detached from the bones, as it rendered the conveyance too difficult. The photograph shows that the skin and the flesh have only been preserved on the head and around the feet.

According to Tilesius, the skeleton is 11 ft. 2½ in. in height from the top of the head to the sole of the feet. It is not so large as the skeleton of *Elephas meridionalis* from the pliocene of Durfort, which is in the new gallery of the Paris Museum. The Durfort skeleton is 12½ ft. in height at the withers, and 13 ft. 10 in. to the top of the head. In length it is 21 ft. 8 in. from the ends of the tusks to the posterior margin of the pelvis, and 17 ft. 5 in. from the front of the head (not including the tusks) to the hinder margin of the pelvis. These dimensions are very superior to those of our skeleton of the mastodon from Sanram, and surpass even those of the gigantic American mastodons. The Durfort skeleton is the largest entire mammalian skeleton known at present.

We have separate bones which must have belonged to still mightier beasts. Thus M. Haussmann, when Prefect of the Seine, presented to the Museum a humerus of *Elephas antiquus*, found quite near Paris, in the quaternary of Montreuil-sous-Bois; this bone measures 50 in., whilst that of the *Elephas meridionalis* of Durfort measures only 48 in. M. Gandry brought from Pikermi a tibia of a *Dinotherium*, which is to that of the Durfort elephant as 94 to 80, and the metacarpal bones present quite as great a difference.

If the proportions between the tibia, the humerus, the metacarpals, and the total height of the skeletons have been the same in *Elephas antiquus* and in *Dinotherium giganteum* as in the *Elephas meridionalis* of Durfort, we must suppose that *Elephas antiquus* reached the height of 14½ ft. to the top of the head, whilst the Dinotherium was no less than 16¼ ft. in height. Thus three tall men standing on each other's shoulders would scarcely reach the top of the head of the *Dinotherium giganteum* of Pikermi.

It is natural to find the maximum of stature in the Dinotherium, for this majestic creature reigned along with two species of mastodons, an *ancylotherium*, a giraffe, and a *helladotherium*, at the epoch of the upper miocene—the culminating point of the animal world. The *Elephas meridionalis* and the *Elephas antiquus* lived along with hippopotami in the hot stages of the pliocene and the quaternary, when there must have been a rich vegetation. If anything may astonish us, it is that the mammoth of the glacial lands of Siberia, dwelling in regions too cold to have a forest vegetation, should attain the great stature of the St. Petersburg skeleton.

The mightiest mammalia may thus be classed in order of magnitude :—

1st. *Dinotherium giganteum*, from the Upper Miocene of Attica.

2nd. *Elephas antiquus*, of the Quaternary (hot phase) of the neighbourhood of Paris.

3rd. *Elephas medionalis*, of the Upper Pliocene of Durfort (Gard).

4th. *Mastodon Americanus*, of the Quaternary of the *United States*.

5th. *Elephas primigenius*, of the Quaternary of Siberia, and the present elephants.

It is not probable that man has seen the Dinotherium, but it is certain that he has been face to face with *Elephas antiquus* and the mammoth. To combat them he had only flint weapons, and yet he conquered them. This enables us to believe that our forefathers of the quaternary were not lacking in intelligence and courage, although it is also possible that some o these gigantic creatures were conquered not by man but by climatic changes.

LENGTH OF HUMAN ENDURANCE UNDER WATER.—According to the recent investigations of M. Lacassagne, the longest time that a diver can remain under water is four minutes.

General Notes.

NATURAL GAS.—The Chinese obtain and utilise natural gas, especially near the town of Tsulin-Tsing, in Su-Tchuan. The gas, when reached, which is at depths of 500 to 600 yards, is conveyed away in pipes of bamboo, and is to a great extent used for boiling down the lime from the neighbouring salt-mines. Below the salt lie deposits of petroleum.

THE GREENLAND EXPEDITION.—The *Jason*, which conveyed Dr. Mansen and his fellow-explorers from Iceland to the east coast of Greenland, has recently returned to Norway. It landed the daring adventurers on July 17th in 65° 2′ N. lat. upon the ice, at about ten miles from the coast. There was every reason to suppose that they would reach the land in safety, the ice being apparently solid and continuous.

THE SATELLITES OF MARS.—M. E. Dubois (*Comptes Rendus*) suggests that Phobos and Deimos may have been two members of the large group of small planets circulating in the region between Mars and Jupiter, which having passed excessively near to Mars have recently become his satellites. This conjecture would account for the fact that they had never been observed prior to the month of August, 1877.

THE VAPOUR TENSIONS OF ALCOHOLIC SOLUTIONS.—M. F. M. Raoult (Academy of Sciences) had some time ago concluded that one molecule of a solid, non-saline substance on dissolving in 100 molecules of any volatile liquid whatever, diminishes the vapour-tension of the liquid by a constant fraction of its value close upon 0·0104. He now finds that this law extends to metallic salts as well as to organic bodies.

CAUSES OF BALDNESS.—The alleged causes of baldness are undue nervous strain, excessive heat from head-covers, constriction of the blood-vessels of the head by tight hats. In opposition to the two latter theories, Mr. G. O. Rogers (*Popular Science Monthly*) cites the fact that the Parsees of Bombay never have their heads uncovered, and when out of doors wear a very stiff, tall hat, fitting tightly to the head. Yet among them baldness is said to be unknown.

THE SUBSIDENCES OF THE EARTH'S SURFACE.—This subject, with especial reference to France, has recently been carefully studied by M. C. M. Goulier. He concludes that the movements of the ground, the existence of which along the coasts has long been established, especially along the north of France and Holland, take place also in the interior of continents, and that with an intensity and a complexity little suspected.

ARCHÆOLOGICAL DISCOVERIES.—Reports have lately appeared in Austrian and German papers of discoveries of Roman antiquities made within the last few weeks. At Doboj, in Bosnia, the remains of a fortress, erected probably to hold the Dacians in check, were traced by Dr. Tuhelka, who is the *custos* of ancient monuments in Bosnia. They lay on the summit of a cliff, which is at the junction of the Bosnia and Usura, and were covered with a shallow layer of mould. The ruins formed a series of terraces, at the highest point of which was a sort of citadel. An inscription was found, which showed that at some time the first Belgic cohort was in garrison at the spot. The utterly shattered condition of the remains of masonry, which are simply rubbish, indicates that they have been the scene of some great catastrophe. It has been suggested that an earthquake may have been the destructive agent, for a quantity of broken skeletons have been found buried in the greatest confusion all over the place in crumbled masonry and mortar. The place is an admirable situation for defence, being practically impregnable on two sides; and it dominates the surrounding country. Various articles, such as would be likely to be found in a Roman military colony, have been collected from the ruins. At Deutsch Altenburg, supposed to be the site of the ancient Carnumtum, not far from Pressburg, the outline of a circus has been traced, and much of the interior has been laid bare. The place has been for centuries tilled, all the remains being covered over with a rich loam, in some places only a few inches deep. This has, no doubt, chiefly contributed to the very perfect preservation of the ground plan. The *Oderzeitung* reports the finding in the Lossow district, near Frankfort on the Oder, of about 30 clay vessels of various sizes and patterns, some urns, some pots, deep saucers, flasks, etc. They were filled with the ashes of burnt corpses mixed with sand. The colour was a brownish yellow; some were broken, and the fractures showed that coal ashes had been mixed with the clay of which they were made. Some bronze needles were found with them, finished at the top in a semicircular shape. The vessels seem to have been formed on a lathe, and are tolerably smooth, regular in shape, and only slightly baked. The largest were about 30 centimetres in diameter at the widest part, and 26 centimetres high. The ornaments were either triangles or semicircles scratched on the surface with points impressed on the surface. Possibly the site where they were found was a refuge and a place of sacrifice in old German times.

CORAL.—The *Journal de la Chambre de Commerce de Constantinople*, writing of coral, says that it is found in every sea from the equator to the polar regions, but it develops best in the tropical parts of the Pacific, where the temperature of the water never falls below 20 degs. C. The coral of commerce, which is that used for jewellery, is known as *corallum rubrum*, or red coral, and is found in abundance in the Mediterranean, principally off the coast of Italy, in the neighbourhood of Sicily and Messina, off Sardinia, Corsica, and the Balearic Islands, Provence, Catalonia, Morocco, Algiers, and Tunis. It is dark-red on the Barbary coast, yellow on that of Sardinia, and rose on the Italian and Tunisian coasts. The most beautiful rose coral is found especially on the rocks off Galita and Fratelli islands, off the north coast of Tunis. White coral is also met with off Barbary; it is only a variety of the red. Black coral is found in the same place, but this is believed to be merely broken branches under the influence of chemical action. Most of the coral boats are Italian. Fishing is carried on in water of varying depths; but the deeper it is the greater the probability of obtaining valuable coral. Hence it is usual not to fish within a distance of three leagues from the coast. That obtained from a depth of 50 metres is not comparable to that got from 600 metres by means of the dredge. In shallow water there is very little chance of finding the beautiful rose coral, which is said to be worth fifty times its weight in gold. The Italian fishermen take their coral to Leghorn usually, where it is either worked up or sold in its rough state. There are extensive establishments in Leghorn for working coral, the greater part of it being sent to India by way of Marseilles. The export to Europe is inconsiderable, except to Russia and Germany, where some articles in coral are much sought after. The principal markets are Torre-del-Greco, Messina, Naples, and Genoa, in Italy, Bona and La Calle, in Algeria, and Marseilles; but this latter has been shorn of much of its importance by the closing of the factories. But Europe takes an insignificant part of the coral produced; the most important markets are in Central Africa, the East Indies, Japan, and South America. The *débris* of coral after working and setting, beaten to powder and scented, makes a tooth powder which is sold at a considerable price by perfumers. The best rose coral has been sold in Naples at £18 10s. per ounce; but in the rough state, good and bad mixed, it may be obtained from 18s. to 40s. a pound, while choice coral is worth about £12 a pound. But the price naturally varies with the quantity obtained and with the fluctuations of taste.

The Public Health.—The Registrar-General reports that the deaths registered last week in twenty-eight great towns of England and Wales corresponded to an annual rate of 17·5 per 1,000 of their aggregate population. In London 2,508 births and 1,342 deaths were registered. Allowing for increase of population, the births were 135, and the deaths 143 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 18·0, 16·2, and 17·5 in the three preceding weeks, declined again last week to 16·4. During the first nine weeks of the current quarter the death-rate averaged 16·2 per 1,000, and was 4·4 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,342 deaths included 39 from measles, 15 from scarlet fever, 23 from diphtheria, 24 from whooping-cough, 10 from enteric fever, 1 from an undefined form of continued fever, 144 from diarrhœa and dysentery, 2 from cholera and choleraic diarrhœa, and not one from small-pox or typhus; thus 258 deaths were referred to these diseases, being 58 below the corrected average weekly number. No death from small-pox was registered, the corrected average being 7; only 2 small-pox patients were under treatment in the Metropolitan Asylum Hospitals, and 1 in the Highgate Small-pox Hospital, on Saturday last. The 15 deaths from scarlet fever showed a decline of 6 from the number in the previous week, and were 23 below the corrected average; 3 belonged to St. Luke, 3 to Bethnal Green, and 2 to Lambeth sanitary areas. At the end of the week the Metropolitan Asylum and London Fever Hospitals contained 793 scarlet fever patients, against 774 and 783 in the two preceding weeks; 93 cases were admitted during the week, against 66 and 83 in the two previous weeks. The deaths referred to enteric fever, which had been but 2 and 7 in the two preceding weeks, further rose last week to 10, but were 6 below the corrected average; 2 belonged to Islington sanitary area. The Metropolitan Asylum Hospitals contained 73 cases of enteric fever, but none of typhus, on Saturday last; 7 cases of enteric fever were admitted during the week, against 7 and 10 in the two previous weeks. The deaths referred to diseases of the respiratory organs, which had been 167 and 172 in the two preceding weeks, declined last week to 130, and were 45 below the corrected average. Different forms of violence caused 53 deaths; 48 were the result of negligence or accident, among which were 29 from fractures and contusions, 2 from burns and scalds, 8 from drowning, and four of infants under one year of age from suffocation. In Greater London 3,241 births and 1,644 deaths were registered, corresponding to annual rates of 30·6 and 15·5 per 1,000 of the estimated population.

The Effects Produced by Earthquakes upon the Lower Animals.—In the last issue of the "Transactions of the Seismological Society of Japan," Professor Milne, the well-known student of volcanic phenomena, discusses the effects of earthquakes on animals. The records of most great earthquakes refer to the consternation of dogs, horses, cattle, and other domestic animals. Fish also are frequently affected. In the London earthquake of 1749 roach and other fish in a canal showed evident signs of confusion and fright, and sometimes after an earthquake fish rise to the surface dead and dying. During the Tokio earthquake of 1880 cats inside a house ran about trying to escape, foxes barked, and horses tried to kick down the boards confining them to their stables. There can, therefore, be no doubt that animals know something unusual and terrifying is taking place. More interesting than these are the observations showing that animals are agitated just before an earthquake. Ponies have been known to prance about their stalls, pheasants to scream, and frogs to cease croaking suddenly a little time before a shock, as if aware of its coming. The Japanese say that moles show their agitation by burrowing. Geese, pigs, and dogs appear more sensitive in this respect than other animals. After the great Calabrian earthquake it is said that the neighing of a horse, the braying of an ass, or the cackle of a goose, was sufficient to cause the inhabitants to fly from their houses in expectation of a shock. Many birds are said to show their uneasiness before an earthquake by hiding their heads under their wings and behaving in an unusual manner. At the time of the Calabrian shock little fish like sand-eels (*cirricelli*), which are usually buried in the sand, came to the top and were caught in multitudes. In South America certain quadrupeds, such as dogs, cats, and jerboas, are believed by the people to give warning of coming danger by their restlessness; sometimes immense flocks of sea-birds fly inland before an earthquake, as if alarmed by the commencement of some sub-oceanic disturbance. Before the shock of 1835 in Chili all the dogs are said to have escaped from the city of Talcahuano. The explanation offered by Professor Milne of this apparent prescience is that some animals are sensitive to the small tremors which precede nearly all earthquakes. He has himself felt them some seconds before the actual earthquake came. The alarm of intelligent animals would then be the result of their own experience, which has taught them that small tremors are premonitory of movements more alarming. Signs of alarm days before an earthquake are probably accidental; but sometimes in volcanic districts gases have emanated from the ground prior to earthquakes, and have poisoned animals. In one case large numbers of fish were killed in this way in the Tiber, and at Follonica on the morning of April 6, 1874, "the streets and roads were covered with dead rats and mice. In fact, it seemed as if it had rained rats. The only explanation of the phenomena was that these animals had been destroyed by emanations of carbon dioxide."

Natural History.

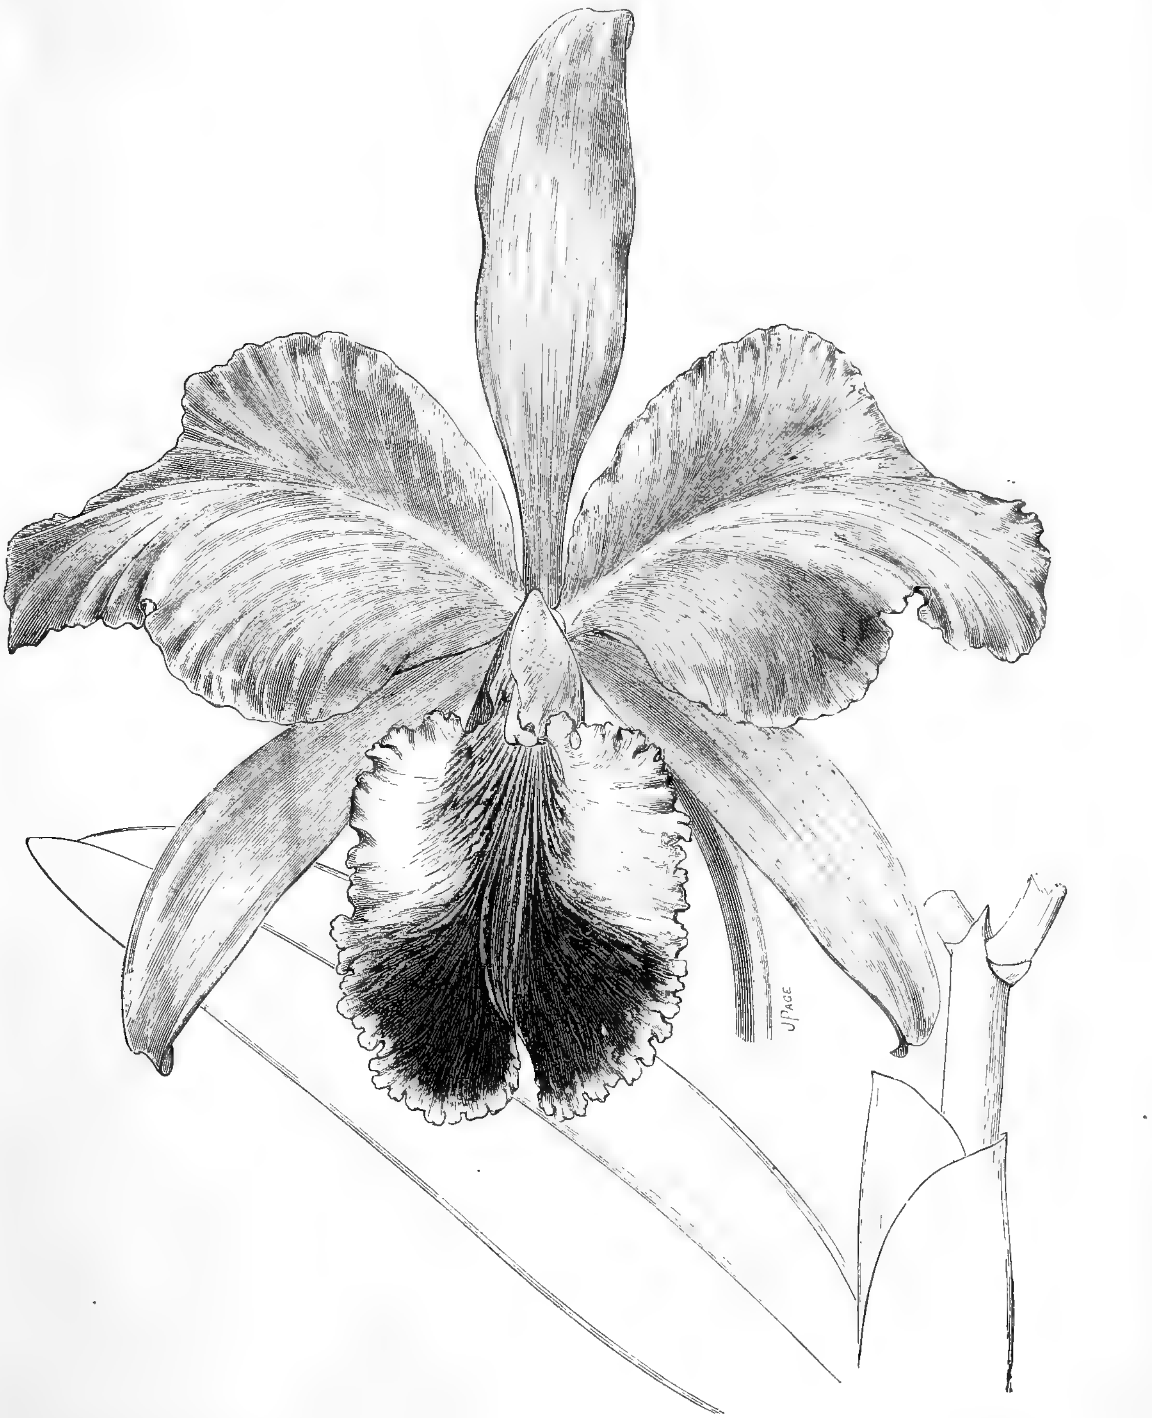
ORCHIDS, WHAT ARE THEY?—III.

(Concluded from p. 60.)

THE genus *Cattleya*, also South American, rivals *Odontoglossum* in beauty, and is equally apt to form artificial, if not natural hybrids. Its favourite centres are three: in Mexico and Guatemala, in that part of South America which stretches across from New Granada to British Guayana, and in Southern Brazil.

The essential characters of Cattleya are: *sepals* free, nearly equal, spreading; *petals* broader than sepals; *lips* attached to the base of column; *column* long, robust, rarely winged, often incurved; *pollinia*, four in two pairs.

Cattleya labiata vera has flowers from five to six inches in diameter, sepals and petals, bright satiny rose, faintly touched with mauve; the anterior lobe of the lip is a rich



CATTLEYA LABIATA VERA (AFTER VEITCH).

magenta colour, bordered with rosy lilac; beneath is a pale yellow blotch, streaked and veined with rosy purple.

The genus *Laelia*, rivalling *Cattleya* in beauty, can be clearly distinguished from it only by the number of the pollinia, which in Cattleya form a single series of four, but in Laelia they form two series of four, eight in all.

From the "cool" orchids of the western hemisphere we pass to their kindred and rivals, the "hot" species of the eastern continent, and especially of India, in the widest sense of the term. Among these three genera are prominent, Dendrobium, Bulbophyllum, and Cirrhopetalum.

Of these the Dendrobia form a kind of parallel to the Epidendra of the west. Each genus comprises hundreds of species or varieties—if these two terms have any clearly distinct meaning. Each displays gorgeous colouration, delicacy, and refined beauty. Some have rod-like stems more than ten feet in height covered with hundreds of flowers. Thus in *Dendrobium fimbriatum* as many as 1,216 flowers have been counted on a single plant.

The Dendrobia extend over a very large portion of the earth's surface, from the Western Himalaya to Australia, Tasmania, New Zealand, and even the islands of the Pacific. Their head-quarters, however, seem to be the Eastern Himalaya and the country stretching from the valley of the Brahmaputra along the eastern side of the Bay of Bengal. In the district of Moulmein alone 43 species sufficiently showy to come under the notice of collectors and horticulturists are recorded. The Philippine Islands produce several fine species, as also does Java. Borneo and New Guinea, considering their extent and their climate, have not sent us hitherto many Dendrobia, or indeed orchids of any type. It is probable that further observation will tell a different tale.

The eastern side of Australia, from Cape York southwards to Cape Howe, yields not a few Dendrobia. As a rule, they require a higher temperature than the South American species. Thus in the lower Himalayan zone the temperature ranges from 80 degs.—90 degs. F. in the summer to perhaps as low as 65 degs. F. in December and January. The atmospheric moisture is abundant; in the Khasia Hills a rainfall of 600 ins. has been registered in one year, and 250 ins. in the month of August alone. It is noticed, however, that in these very moist, hot districts the Dendrobia grow on trees at the height of from 10 to 50 ft., so that they are above the low dense jungle growth, and have the full benefit of the air. A species found in the Andaman Islands flourishes in situations where it is exposed to the spray of the sea. In the hot plains of Moulmein the native Dendrobia are almost baked during the dry season, when they rest, just as the plants of cold climates do in the winter.

Mr. Veitch, to whose courtesy we are indebted for the illustration which we lay before our readers, points out, in his excellent "Manual of Orchidaceous Plants" (SCIENTIFIC NEWS, vol. ii., p. 14), that we can supply orchids, or indeed any tropical plant, with the exact temperature and quantity of moisture which it receives in its native country. But we cannot give it the same amount of light, and that light will fall upon the plants at different angles owing to the lower altitude of the sun. It is certainly possible that this difference may account for the difficulty of cultivating some species under glass. Will the electric light ever make up the deficiency?

The botanical characteristics of the genus Dendrobium are:—*sepals* nearly of equal length, the dorsal one free, the two lateral attached to the foot of the column and forming with it, in some species, a short gibbous skin, in others a longer or shorter spur; *petals* generally of the same length as the sepals, sometimes longer, often broader, rarely narrower; *lip* more or less contracted at base into a claw, lying on or attached to the foot of the column; *column* produced below point of attachment to the ovary into a kind of foot, the portion above ovary being very short; *pollinia*, four in number, of a waxy texture, oval or oblong, compressed and lying parallel within the anther case; *capsule* ovoid, or oval oblong, rarely elongate.

The colouration of the flowers varies greatly: *Dendrobium arachites* is of a uniform vermilion-red, the lip veined with purple. *D. Bensoniæ* is milk-white with an orange disc on the lip, at the base of which are two maroon spots. *D. Boxalli* is white, bordered, and tipped with pale mauve purple; lip yellow, bordered with white, and with a purple blotch on the anterior margin.

The genera *Bulbophyllum* and *Cirrhopetalum* follow closely upon Dendrobium, which they much resemble. Bulbophyllum, however, has a still wider range than Dendrobium. Its head-quarters are in India and the Malay Islands, but it spreads not merely into Australia and New Zealand, but into Africa—especially Sierra Leone—and Central and South America. Seven Brazilian species are known, a very curious fact. Many of the Bulbophyllums have long, rambling rhizomes, and attain gigantic dimensions. *Bulbophyllum Beccari*, one of the most curious, a native of Borneo, entwines the trees like a serpent. Its flowers, spotted yellow and red, are very small, but they form remarkably large, dense clusters. They emit, however, so abominable a scent that the plant is practically excluded from cultivation. What being is this stench to repel, or to attract? The functions of sweetly-smelling flowers have been studied not unsuccessfully, but those of the "stink-worts," if we may so call them, still remain an unsolved problem.

Another interesting question here suggests itself: Why is Africa so poor in orchids, and why are both its fauna and its flora comparatively so monotonous?

A SWALLOW'S NEST IN AN ELM.—In a letter to the *Times*, Mr. J. A. Smith, of Akenham, states that—"A pair of swallows have chosen a novel nesting-place in this parish, having attached their nest to a small elm bough overhanging my fish pond. Yarrell records a similar instance, except that the nest was built upon the forked branch of a sycamore. In the case I now record the nest beautifully harmonises in appearance with the bark of the bough, and the mud used in its construction is well mixed with grass so as to withstand the storms of wind and rain. The nest is well lined with feathers, and to-day the young birds are looking around as if anxious to leave the structure which they have outgrown. What should induce the swallows to leave my dining-room chimney for this novel situation? Possibly they disliked the smoke from a fire rendered necessary this year on a chilly evening in July, or they may have reasoned that the bough was in a convenient situation, the surface of the pond yielding the best supply of insect food in a cold, showery season."

THE FOSSIL TORTOISE OF PERPIGNAN.—In a paper read before the Paris Academy of Sciences, M. P. Fischer shows that this tortoise is a gigantic form of an existing African group *Testudo pardalis*. Its alleged affinities with the modern gigantic tortoises of the Seychelles and the Gallapagos, and with the *Chersites* of Southern Europe have not been established. It may be considered as a relic of a more ancient fauna of an African type.

A New Hypnotic Agent.—According to M. J. Luys, the fascinating effect produced upon larks by a revolving mirror is capable of developing analogous phenomena in the human species, especially in neuropathic subjects of both sexes.

THE INTERNATIONAL GEOLOGICAL CONGRESS.

THE fourth triennial session of this Congress will be held, by permission of the Senate of the University of London, in the University buildings in Burlington Gardens. The first general assembly of the Congress will take place in the theatre of the University at 7.30 o'clock on Monday evening, September 17th, when the inaugural address will be delivered in French by Professor Prestwich, as President, French being the official language of the Congress. At 9 p.m. Professor and Mrs. Prestwich will hold a reception.

On Tuesday morning the Congress will meet at 10 o'clock, when questions bearing upon geological nomenclature and classification will be discussed. A full report on these subjects will be presented by the American Committee. This report, which has been printed in advance, forms a volume of 220 pages, edited by Professor Persifor Frazer. Although written in English, a French abstract has been prepared by Professor Dewalque, the Secretary of the General Committee on Unification of Nomenclature; and copies of this abstract will be distributed at the meeting. The English Committee, under the presidency of Professor T. McK. Hughes, will also present its revised report, which is now being printed, and forms a substantial work.

On Wednesday morning the sitting will be devoted to the discussion of a subject which has of late years excited much attention in geological circles—the nature and origin of the crystalline schists. Special authorities on this subject have been invited to contribute short memoirs which have been printed in advance. As copies of these papers will be distributed to the members, the communications may be taken as read and the time of the meeting occupied only in their discussion. The volumes of papers entitled "Etudes sur les Schistes Crystallins," contains the following communications:—"Les Schistes Cristallins," by Dr. Sterry Hunt; "Zur Klassification der krystallinischen Schiefer," by Professor A. Heim, of Zürich; "Sur la Constitution et la Structure des Massifs de Schistes Cristallins des Alpes Occidentales," by Professor C. Lory, of Grenoble; "Bemerkungen zu einigen neueren Arbeiten über krystallinisch-schiefrigen Gesteine," by Professor J. Lehmann, of Kiel; "Sur l'Origine des Terrains Cristallins Primitifs," by M. Michel-Lévy, of Paris; "The Archæan Geology of the Region North-West of Lake Superior," by Mr. A. C. Lawson, of the Geological Survey of Canada; "On the Crystalline Schists of the United States and their Relations," by various members of the United States Geological Survey; and a paper by Herr K. A. Lossen, of the Geological Survey of Prussia. The group of papers contributed by the United States Survey contains first an "Introduction," by Major J. W. Powell, the Director, followed by a paper on "The Crystalline Schists of the Lake Superior District," by the late Mr. R. D. Irving, and Messrs. T. Chamberlin, and C. R. Van Hise; this is succeeded by a sketch of "The Crystalline Schists of the Coast Ranges of California," by Mr. G. F. Becker, and a brief description of "The Crystalline Rocks of Northern California and Southern Oregon," by Captain C. E. Dutton.

On Wednesday evening the Congress will be received by Dr. A. Geikie, as Director-General of the Geological Survey, at the Museum of Practical Geology in Jermyn Street. With the view of illustrating the subjects that will have been discussed at the morning sitting, it is proposed that during the evening a series of microscopic sections showing the structure of the crystalline schists shall be exhibited on the screen, by means of the lime-light, in the theatre of the Museum.

At 10 o'clock on Thursday morning the Congress will re-assemble in the University theatre, and proceed to the discussion of questions bearing upon the International Map of Europe. A report will be presented by the Map Committee, and specimen sheets illustrating the character of the work. In the afternoon the members will make excursions in various directions. One party will visit Windsor and Eton, where they will be entertained by the masters of Eton College; another party will visit Kew, and be received by Mr. Thiselton Dyer, as Director of the Royal Gardens; other members will go down the river to Erith and Crayford for the purpose of examining the brick-earths and gravels of the Thames valley; while others will probably visit Watford and St. Albans.

On Friday morning the discussion on nomenclature and classification, and on the coloration of maps, will be resumed. In the evening there will be a reception at the rooms of the Geological Society at Burlington House, by Dr. W. T. Blanford, as President of the Society. The concluding business of the Congress, mostly of a formal character, will be taken at Saturday morning's sitting.

Several geological excursions have been organised for the week following the London session. One of these, which promises to be extremely popular, is to the Isle of Wight, under the direction of Messrs. W. Whitaker, J. Starkie Gardner, A. Strahan, and H. Keeping. By invitation of Sir Charles Wilson, this party will also visit the offices of the Ordnance Survey at Southampton. Another interesting excursion is to North Wales under Dr. H. Hicks, assisted by Professor J. H. Blake for Anglesey, and by Mr. G. H. Morton for the carboniferous limestone of Llangollen. A third excursion is planned to East Yorkshire, under the direction of Mr. J. W. Woodall and Mr. C. Fox-Strangways, assisted by Mr. W. H. Hudleston, for some of the oolitic series, Mr. G. H. Lamplugh for the Flamborough chalk, and Mr. Hugh Bell, for the mines and iron-works of Middlesborough. West Yorkshire will also be visited by a party under the guidance of Mr. J. Marr and Mr. R. H. Tiddeman. Finally, an excursion to East Anglia has been organised under Mr. F. W. Harmer (Mayor of Norwich) and Mr. Clement Reid, assisted for the older Pliocence beds of Suffolk, by Dr. J. E. Taylor, of the Ipswich Museum. A guide-book containing geological descriptions of the localities about to be visited, written in French, and illustrated by coloured geological maps has been prepared, and will be presented to the members of the Congress. To this guide-book Mr. Topley has contributed a sketch of the geology of the various railway routes by which foreigners will reach London.

The Official Report of the Berlin Congress has just been issued.

The British Association.

SECTIONAL MEETINGS.

FULL REPORT OF THE DISCUSSIONS.

[FROM OUR OWN REPORTERS.]

MATHEMATICAL AND PHYSICAL SECTION.

(*Continued from p.* 255.)

LIGHT AND ELECTRICITY DEPARTMENT.

SATURDAY, SEPT. 8TH.

Professor G. F. FITZGERALD, F.R.S., presiding.

The first paper was on *The Harmonic Series of Lines in the Spectra of the Elements*, by Professor Dr. CARL RUNGE, who said that Messrs. Liveing and Dewar, in their researches on the ultra violet spectra of elements, had drawn attention to the appearance of what they called the harmonic series of lines. Similar to the formula found by Dr. Balmer, of Zurich, in 1885, for the wave lengths of thirteen lines of hydrogen spectrum, there existed, as Professor Kayser and he (the speaker) had found, formulas for the groups of lines of other elements, which Professors Liveing and Dewar, as he had before observed, had named the "harmonic series of lines." This series of lines had been compared to the series of overtones emitted by a vibrating elastic body. He took the liberty of laying before the section a photographic map of the visible and ultra-violet part of the spectrum of iron. It was meant to serve as an instrument for determining the wave lengths of the lines of other elements, and was going to be copied in phototype and published by the Academy of Berlin, together with the wave lengths of the lines measured by Professor Kayser and himself. The scale on the map was rather inexact, but it sufficed to identify a line so as to be able to look up the wave lengths in the tables. He thought that even the weakest lines had been determined with an exactness of 0·1 Angström's unit, and that the probable error of the sharp ones was less than 0·03 Angström's units.

Dr. J. JANSSEN, a foreign member of the Royal Society, addressed the section in French at considerable length on the *Application de l'Analyse Spectrale à la Mécanique Moléculaire. Spectres de l'Oxygène.* He said he had made observations on the absorption spectrum of oxygen. He found there was a series of lines in the spectrum, the two most prominent of them coinciding with Fraunhofer's A and B. There were also a series of bands, the three most prominent being about 628, 575, 477. He said he had shown that the lines depended on the quantity of oxygen through which the light had passed.

Sir WM. THOMSON, F.R.S., congratulated Dr. Janssen upon his extremely lucid statement. He thought that the French of the Professor would be better understood by members of the Association than would be the English of most of the inhabitants of this island, or, he might add, the English of the neighbouring continent of North America. So important did he consider Professor Janssen's paper, that he proposed that it should be printed at the expense of the Association, and circulated amongst the members.

Dr. GLADSTONE seconded the motion, which was agreed to.

A paper on *The Absorption Spectrum of Oxygen*, written by Professors LIVEING, F.R.S., and DEWAR, F.R.S., was read by Mr. R. T. GLAZEBROOK, M.A., F.R.S., one of the secretaries of the section.

Papers on *A Vortex Analogue of Static Electricity*, and on *A Diffusion Photometer*, were read by Professor W. M. HICKS, F.R.S., and Mr. J. JOLY respectively, and votes of thanks were passed to those gentlemen.

The *Report of the Committee on Electrolysis* was then read. This we may give in some future issue.

DEPARTMENT OF MATHEMATICS AND GENERAL PHYSICS.

Professor EVERETT, M.A., D.C.L., F.R.S., etc., presiding.

Papers by Professor R. W. Genese, on *Centres of Finite Twist and Stretch*, and on *Recurring Decimals and Fermat's Theorem*, were read, for which the author received the thanks of the meeting.

The PRESIDENT then read a paper on *The Relation between Orbits, Catenaries, and Curved Rays.* Professor A. M. WORTHINGTON, in dealing with *The Tensional Stress and Strain within a Liquid*, described the three methods that have been employed by previous observers to subject a liquid to tension. These are :—

(1) *The barometer tube method*, by which Professor Osborne Reynolds had succeeded in subjecting mercury to a tension of five or six atmospheres due to its own weight.

(2) *The centrifugal method*, devised by the same observer, and by means of which he had subjected water to a pull of about five atmospheres (72·5 lbs. per square inch); while the author had succeeded in reaching with alcohol a tension of 7·9 atmospheres, or 116 lbs. per square inch, and with strong sulphuric acid a tension of 11·8 atmospheres, or 173·4 lbs. per square inch.

(3) *The method of cooling*, discovered by Berthelot, and described by him, "Ann. de Chimie" xxx. (1852): Sur la dilatation forcée des liquides.

The author then described the form of apparatus, arrived at after many trials, by which the tension of the liquid and the extension produced by it could be simultaneously measured.

The experimental proof that tensional stress within a mass of liquid is necessarily accompanied by a corresponding strain, was, in the author's opinion, an important point in the theory of surface tension, since it showed that the diminution of density or extension of the surface liquid, which could be shown to be a necessity of the equilibrium at the surface, was sufficient to account for the surface being a seat of energy. It became, in fact, unnecessary to ascribe to the energy any other form than that in which it existed in stretched matter.

Professor HELE SHAW, M.Inst.C.E., then gave an address on a *New Sphere Planimeter.*

MONDAY, SEPTEMBER 10TH.

Mr. WM. ESSON, M.A., F.R.S., presiding.

Mr. R. T. GLAZEBROOK, M.A., one of the Secretaries, laid before the section the fourth report of the Committee, consisting of Professor Balfour Stewart (Secretary), Professor W. Grylls Adams, Mr. W. Lant Carpenter, Mr. C. H. Carpmael, Mr. W. H. Christie (Astronomer Royal), Professor G. Chrystal, Captain Creak, Professor G. H. Darwin, Mr. William Ellis, Sir J. H. Lefroy, Professor S. J. Perry, Professor Schuster, Professor Sir W. Thomson, and Mr. G. M. Whipple, appointed for the purpose of considering *the Best Means of Comparing and Reducing Magnetic Observations.*

He said since their last report the Committee have to record the death of their Secretary, Professor Balfour Stewart, whose loss will be deeply felt in the scientific world, especially by those who are engaged in researches in terrestrial magnetism and in the work of magnetic observatories. A meeting of the Committee was held on February 2nd, 1888, at which Professor W. Grylls Adams was requested to act as Secretary to the Committee and to forward to the directors of magnetic observatories copies of the third report of the Committee, calling special attention to the paragraphs relating to the determination of scale co-efficients.

At the second meeting of the Committee, on July 11th, 1888, Mr. W. L. Carpenter handed to the Committee a paper which had been prepared by Professor Balfour Stewart, on a comparison between the wind values and declination disturbances at the Kew Observatory. The Committee have thought it right to recommend that this paper and the table accompanying it be printed as an appendix to the report.

The Committee learn that all the scientific material found among Dr. Stewart's papers is in the possession of Professor A. Schuster. Professor Schuster has continued his reduction of the diurnal variation of terrestrial magnetism, and has nearly completed a paper on the subject, which he proposes to present to the Royal Society.

A paper has also been communicated to the Committee by Major Dawson, on magnetic observations taken at Fort Rae in 1882-83.

The Hon. RALPH ABERCROMBY read a paper on *Modern Views about Hurricanes, as Compared with the Older Theories.* He said the old idea of a hurricane was that of a circular-shaped eddy, round which the wind blew in circles; the whole system was not supposed to be connected with any surrounding trade-wind or monsoon, and the idea that a hurricane changes its shape, as well as its depth and intensity, during its progress, was never thought of.

Modern research showed that a hurricane was really an oval eddy, and that the vortex, or centre of the wind rotation, was not in the geometrical centre of the oval, but usually nearer one edge or other of the depression. The former was a very simple, the latter a very difficult conception; nevertheless, such were the facts, as the author has proved by an examination of hurricanes on sixty different days.

The wind blew as a spiral of variable incurvature round the vortex, not round the centre of the oval. The general sense of the rotation was counter-clockwise in the Northern, clockwise in the Southern Hemisphere; but the amount of incurvature varied in different parts of the oval, for a number of reasons. As a rule, in all hurricanes the incurvature was less in front than in rear of the vortex.

A hurricane was also always changing its shape, so that the oval lay sometimes in one way, and sometimes quite in a different direction; while sometimes the vortex was displaced towards one side of the oval one day, and towards quite another side on the next.

The path of the hurricane was not in a regular line, for the vortex sways about, and sometimes even described a loop.

For all these reasons, no rule was possible for determining absolutely the bearing of the vortex by observations on board a single ship, whereas it used to be stated positively that facing the wind the vortex bore 8 points—at right angles—to the right in the Northern, and to the left in the Southern Hemisphere.

It can only be said now that, when fairly within the storm-field and facing the wind, the vortex will be to the right and a little to the rear—that was, from 8 to 12 points to the right of the wind—in the Northern Hemisphere, and to the left and a little to the rear—that was, from 8 to 12 points to the left of the wind—in the Southern Hemisphere. If the wind blew exactly in a circle round a circular hurricane the vortex would always bear 8 points to the right or left according to the hemisphere, and the rule to take 8 to 12 points is simply allowing for the effects of variable incurvature.

The above rule does very well for a first approximation to the bearing of the vortex, but greater precision can be attained in certain circumstances. If the condition indicated that a ship was nearly in front of the vortex the bearing of the vortex will probably not be much more than 8 points to the right or left, according to the hemisphere, because, as before mentioned, the incurvature was very small in front of a hurricane. Great care must be taken not to apply this rule to an increasing trade with a falling barometer, as will be explained hereafter.

In the rear of a hurricane, on the contrary, the vortex might bear 12 or even more points to the right or left of the wind, because the wind was very much incurved in that part of a hurricane. A ship should therefore always then lie-to till the barometer began to rise and the weather to improve, otherwise she would probably run right into the vortex. She might easily scud 10 knots, while the hurricane might not be advancing more than 5 miles an hour, so that it was very easy to catch up the vortex. The discovery of this great incurvature is one of the most important modern developments of the subject.

It used to be thought that if the wind increased in force, without changing in direction, with a falling barometer, a ship must necessarily be in the line of progression of the vortex, and that she should run at once. This was owing to the idea that a hurricane was an isolated disturbance.

Now we know that if it be only the usual trade-wind, which increases without changing in direction, and with a falling barometer, a ship should lie-to till the mercury has fallen at least 6·10ths of an inch before she runs as a last resource. Modern research had proved that a hurricane is usually embedded in some prevailing trade or monsoon, and that there was therefore a belt of intensified trade-wind outside the true storm-field. This belt was always on the side of the hurricane farthest from the equator. A ship in this belt experienced an increasing trade without change of direction, and with a falling barometer, though she might be far away from the line of progression of the vortex. She would equally experience an increasing and unchanging wind, with a falling barometer, if she were in the line of progression; but as there was no means of knowing whether she was in the line of progression or only in the belt of intensified trade, the empirical rule says, "Lie-to till the mercury has fallen 6-tenths of an inch before beginning to run."

The old rules for finding which semicircle of a hurricane a ship may be in, and the old rules for heaving-to in either hemisphere, are all proved to be both true and valuable by modern research. These rules remain as follows: Facing the wind in both hemispheres, if the wind changes by the right the ship is in the right-hand semicircle, and she should heave-to on the starboard tack; if the wind changes by the left she is in the left semicircle, and should heave-to on the port tack. If circumstances compel her to run she should keep the wind well on the starboard quarter in the North Hemisphere, and well on the port quarter in the South Hemisphere.

It is much to be regretted that the examination-papers of the Board of Trade for master and mates are painfully behind the modern standards of knowledge, and that in these matters the Germans and other nations are now ahead of England. The whole knowledge which is required in our merchant service is contained in six questions, and a candidate is expected to say that the centre bears 8 points, or perhaps a little more, from the direction of the wind, while no notice is taken either of the small incurvature in front or of the great incurvature in rear, or of the belt of intensified trade, where the usual indications of being exactly in front of the vortex fail.

No one should blame the master of a ship for not following the established rules, without the closest investigation, for, as Piddington says, "absolute rules are all nonsense," and much depends on the capabilities of a ship and on the ever-varying conditions of a heavy cross sea.

Professor DOUGLAS ARCHIBALD felt that many vessels had been lost through following strictly antiquated rules. Seamen were rather conservative, and liked to stick to their old rules, but he was of opinion that the sooner the results of modern observation were adopted the better it would be all round. He was sorry that M. Faye and those who thought with him were not present to hear Mr. Abercromby's paper, because he thought they would have found it rather hard to say, in the face of that paper, that there was no such thing as an elliptical hurricane.

Dr. W. H. RUSSELL desired to ask a question as to the rotatory action of winds. He saw a number of new faces on the platform, and he wished to inquire, therefore, if any one could explain why it was that winds were so frequently rotatory in their motion.

Mr. W. N. SHAW, M.A., one of the Secretaries of the section, explained what he considered was the cause of hurricanes having a circular motion. His argument tended to show that rotatory winds were caused by rushes of hot air from one quarter meeting rushes of cold wind from an opposite direction, which caused the rotatory motion the last speaker had inquired about.

Dr. H. R. MILL then read the report of the Committee on *The Surface Temperature of Water*, and followed it up by a paper on *The Temperature of some Scottish Rivers*.

Professor C. G. KNOTT discoursed on *The Recent Magnetic Survey of Japan*. He observed that, generally speaking, the magnetic features of Japan present great irregularities—a fact which the highly volcanic condition of the country would lead us to expect. The south-western portion of the main island, with the adjacent islands fringing the inland sea, presents fairly uniform magnetic features. The regions where the greatest disturbances exist are (1) the great central mountain region to the north and north-west of Fujiyama, and (2) the region included between the 38th and 40th parallels of latitude.

The general characteristics of the iso-magnetic lines corresponding to the observations made are as follows: The lines of equal dip, of equal horizontal force, and of equal total force are approximately straight, while the lines of equal declination are distinctly parabolic or hyperbolic, approximating very closely to the general form of the main island.

The full details of the survey are given in the second volume of the "Journal of the College of Science, Imperial University, Japan," where also will be found the charts, of which the large charts now shown were rough copies.

Mr. J. JOLY lectured on *Reading Electrically Meteorological Instruments Distant from the Observer*.

Mr. W. N. SHAW, in the absence of Professor G. H. DARWIN, F.R.S., put before the section the paper of the latter on *The Mechanical Condition of a Swarm of Meteorites*, and *on theories of cosmogony*, and then read his own communication on *Some Charts of Kew Corrections for Mercury Thermometers*.

The Committee upon *Standard Lights* submitted their final report upon this subject. In the course of a lengthy document the Committee stated that they had experimented upon ordinary candles, upon sperm candles (six to the pound), with pentane standard lights, and also with the pentane lamp, and with the amyl-acetate lamp. As the result of the experiments the Committee considered that the standard candle, as defined by Act of Parliament, was not worthy of the present state of science, and they gave their opinion in favour of an alteration of the law with regard to standard lights and the adoption of the pentane standard. They further recommended that it should be urged upon the Board of Trade that legislative action should be taken, with a view to speedily bringing about the change suggested in the report.

Mr. WM. SHAW read a paper on *An Apparatus for Determining the Temperature by the Variation of Electrical Resistance*.

TUESDAY, SEPTEMBER 11TH.

Professor FITZGERALD presiding.

There was a very large attendance, Section "G" joining with Section "A" to carry on a discussion on

LIGHTNING-CONDUCTORS.

Mr. W. H. PREECE, F.R.S., opened the debate. He said that it was a most remarkable thing that if we wanted to know much about atmospheric electricity we had to go back to the days and works of Benjamin Franklin, a hundred and forty years ago. Up to 1878 there were absolutely no rules for the guidance of people who desired to erect lightning-conductors for the protection of their houses. In that year a great conference was held on the subject, and the result of its deliberations was published in a book, and included a set of rules for the construction of conductors. He had under his personal observation no less than 500,000 lightning-conductors. Some time ago a lectureship was founded in memory of Dr. Mann, who had experimented on the protection of buildings from lightning in South Africa. Professor Oliver Lodge was selected as the lecturer, but instead of cracking up the work of the Conference, he took the other line, and if his statements were true, lightning-conductors would be of no use, and no buildings would be safe in a thunderstorm. Professor Oliver Lodge had committed himself to fallacies which it was now his (the speaker's) duty to bring before the meeting. The professor assumed that a lightning-rod formed part of the flash. Well, as a matter of fact, it did not. Nobody had ever seen a flash of lightning strike a conductor. The function of the conductor was to prevent the possibility of the building on which it was erected being struck by the flash of electricity. If a building was struck there was some defect in the construction of the conductor. Lightning did not go careering wildly about, but passed along a path prepared for it. There was another fallacy which prevailed, and that was that a flash of lightning was instantaneous. No proof, so far, had been produced of that. They saw a flash of light which indicated part of the discharge, but how long that discharge lasted they did not know. There were invisible flashes of lightning, which was proved by the fact that persons had been killed under trees when there was no visible flash. He had, however, come to the conclusion, by the effect on telegraph wires, when there were currents of sensible duration, that the flash was not instantaneous. He argued that if Professor Lodge were correct no lightning-conductor could protect, and no discharge could possibly be led to the earth. The assertion of the oscillatory character of the lightning flash was based more on mathematical reasoning than it was upon absolute observation. There were those amongst mathematicians who made mathematics their slaves, and when they got into the slough of despond they found it difficult to get out again. Engineers had no great respect for mere mathematical development, unless it was proved by absolute experiment. Mathematical developments should be received with extreme caution, and the theory, beautiful as it was, must, as he had before remarked, be received with great circumspection. There were several facts against the proposition. As to the theory of self-induction there was also much doubt. There was no doubt that Professor Lodge had started a new and fresh hare which electricians must hunt up and kill. Professor Lodge was on the brink of a great discovery, although he (the speaker) did not accept his theory of self-induction. Whatever the result of the present conference was, he would certainly have the advantage of bringing to the front what they were all anxious to see—namely, the true theory of electricity shadowed forth by Professor FitzGerald in his address, which would mark the present meeting of the Association as an important epoch upon that subject.

Professor OLIVER LODGE, F.R.S., said he had had nothing like the experience of Mr. Preece. So far from having half a million lightning-conductors under his supervision, he had not got a solitary one. He had frequently asked his friends to put up conductors on their houses, but the answer he invariably received was that conductors were too expensive, and "it was cheaper to insure." It was perfectly true, as Professor Preece had said, that few public buildings were effectively protected from lightning, the reason being that the conductors used were not efficient. If conductors were used on all lofty buildings, their price would probably be as many shillings as they now cost pounds to put up, and the result would be a great saving to life and property. Mr. Preece had said that a properly constructed conductor had never failed to do its work, but he (the speaker) could not quite agree with that statement, for he thought that lightning-conductors had frequently failed to act when they were called upon to do so. The Hôtel de Ville at Brussels was supposed to be protected from lightning by innumerable conductors, but nevertheless on the 1st of June last year it was struck by the electric fluid and set on fire. The lightning-rod had two functions—one was to act as a point to attract the flash, and the other was to carry off the fluid. It was not desirable that conductors should immediately take the fluid to the earth, for it was often better to allow the great energy of the flash to slowly exhaust itself. He thought the address they had listened to was a very interesting one, and he considered that the thanks of the section ought to be accorded to Mr. Preece for his lecture.

The Hon. R. ABERCROMBY, who followed, produced a number of photographs of lightning flashes. He felt sure good would result from the discussion.

Lord RAYLEIGH observed that whatever might be the failings of mathematicians, he felt that scientists must go to them eventually.

Sir WILLIAM THOMSON, F.R.S., could not help thinking it would be well for the Professor to continue his experiments in regard to the superiority of iron over copper rods. As to protecting buildings, he must confess that it was rather disturbing to find that lightning-rods had so little protecting power. Before, however, iron was generally recommended for lightning-rods, further experiments must be carried out with regard to the conducting power of that metal.

Professors FORBES and ROWLAND (of John's Hopkins College, U.S.A.) and M. de F. FONVIELLE (of Paris) continued the discussion, which, after a few observations from Mr. SYDNEY WALKER, Mr. BROWN, and Mr. WOOD, followed.

Dr. J. JANSSEN, a foreign member of the Royal Society, read a paper on *Analyse Chrcnometrique des Phénomenes Electriques Lumineux*, and Mr. R. T. GLAZEBROOK, F.R.S., discussed *the Standard of Electrical Re istance.*

CHEMICAL SECTION.

(*Continued from p.* 257.)

SATURDAY, SEPTEMBER 8TH.

Professor TILDEN, F.R.S., presiding.

The first business was to receive the report drawn up by Professor Dunstan of the committee appointed for the purpose of inquiring into and reporting on *The Present Methods of Teaching Chemistry.* This was a very long and important report, which we shall probably give *in extenso* in a future issue.

The PRESIDENT said he should like to offer a single criticism on the foregoing report. If, as appeared to be admitted by everybody, chemistry was such a valuable element in school education, surely those advantages should be shared by girls. It was a very extraordinary circumstance, but he did not notice a single reply from a girls' school embodied in the report. It was a regrettable fact that chemistry did not at present seem to have found its way into girls' schools, and he could not help but regard it as a serious misfortune in the interests of the higher education of women. The report, in brief, confirmed the view expressed in his address, that until they had teachers better qualified to impart instruction, these difficulties would not be overcome practically.

The Rev. A. IRVING, in a paper on *Chemistry as a School Subject*, said that chemistry could not properly be taught apart from physics; there was a physical side to every phenomenon. Lecture work should precede laboratory work, and continue *pari passu* with it. Analysis rationally, not mechanically taught, was an excellent mental training. The two should be closely correlated; exercises should be given in the laboratory, preparatory to or suggested by the subjects treated in the lectures, and facts learnt in the laboratory should be turned to account in the lectures. The teacher must not be trammelled by text-books; these must be his instruments, not his masters. Quantitative treatment of subjects in the lectures should be introduced as far as possible from the first, and as pupils advanced they should be trained individually in the use of the balance. Numerical exercises based on (not as a substitute for) lecture demonstration helped to give fixity and precision to ideas. Pupils should be trained to think out, in their note-books, the connection between experimental demonstration and theory, and not have notes dictated to them to be committed to memory. Their knowledge should also be tested by frequent short exmination papers.

Mr. ANGEL (Manchester), in opening the discussion, strongly criticised the system of teaching boys chemistry by mere lectures and note-taking. Such a method, he declared, involved utterly incompatible processes being set up in the juvenile mind. It engendered no scientific thought, and left no clear impression of any phenomena on the mind. The result was entire failure. In nine cases out of ten such a method of teaching made clear scientific thought an impossibility. With regard to examinations, he held that the present progress of science was more due to our system of examination than anything else.

Mr. GATEHOUSE (Bath) thought the report of the Committee in some of its phases confounded the making of the intelligent man with the making of the chemist.

Miss LYDIA BECKER thought the Committee would do well to entirely eliminate from their report the word boy, and substitute for it pupil, student, or child. There were very many difficulties in the way of girls sharing in the benefits to be derived from the study of chemistry and physical science; and there could be no doubt that it was owing to such causes as these that the higher education of women had not made more rapid progress. As regarded the mode of teaching, she thought the habit of questioning pupils was one that should not be practised without more thought. Too often teachers persisted in putting tormenting questions to their pupils. Teachers should impart their knowledge in such a simple, intelligent, direct, and straightforward manner so as to at once produce an impression on the youthful mind. The questions should come from the pupil, and not from the teacher.

Mr. WEST (Bournemouth) thought it was not much good trying to give definite scientific teaching to boys before they were of the public school age.

Mr. LASCELLES, Chemical Master at Harrow, considered the lecture system interspersed with catechism the best. He did not, however, recommend the abstract teaching of chemistry to boys; he believed in imparting to them general facts.

Mr. HUGH MADAN (Exeter), Mr. HARVEY HICHEN (Radley), Mr. VELEY (Oxford), also took part in the discussion.

The PRESIDENT, in adjourning the sitting, expressed a hope that by another year the Committee would be in possession of some definite recommendations to be submitted to the head masters of the great public schools throughout the country.

MONDAY, SEPTEMBER 10TH.

Professor TILDEN, F.R.S., presiding.

Professor H. E. ARMSTRONG, F.R.S., opened a discussion on *Valency*. He said: This was undoubtedly one of the most important and at the same time most difficult problems chemists have to solve. It was clear of course to every chemist that the determination of valency in any particular element involved the constitution of that element. And of course the determination of the constitution involved the idea of valency. The problem presented the greatest difficulties, and all people who were not blind followers of any particular system must admit that in regard to it chemists have yet a great deal to learn. The meaning of the term chemical action must be largely extended, and chemists would have ultimately to regard the physical action involved in the changes as essentially chemical in their nature. Chemical action must be defined as a change in the molecular condition. No doubt chemists had got too much in the habit of treating the nature of chemical affinity from too narrow a point of view. A very considerable widening of our conception in this regard must be insisted upon. There were two forms of valency to be looked at—fixed valency and variable. And he would point out that the only definite conception of valency was practically that which involved the acceptation of the doctrine of fixed valency. But before they could come to any definite conclusion on the subject there must be a greater interchange of opinion between chemists and physicists. It was practically hopeless for the chemists to endeavour to solve the problem by themselves. And one of the greatest difficulties that surrounded the question was the difficulty in putting the chemists' investigations in such a form as to be perfectly intelligible to those outside the circle. Dr. Williamson had advocated the view that in a large number of double salts we were to assume that there was a redistribution of the constituent elements, so that the constituent elements all become associated with one central element. The doctrine of fixed valency assumed that the elements in a great many cases are of a different order, and that in a compound there is no sacrifice of the original substances, but that they are still present. The assumption is that there are the constituent radicals of the compound, and that they are held together in a special way by the mere juxtaposition of the molecules. The great question to decide upon was in relation to the existence of these two classes of compounds. It involved the distinction between atomic and molecular compounds, and that led up to the question, In what manner are the constituent radicals of the molecular compounds held together? One view he particularly desired to advance was one which involved what might be termed the property of supervalency in certain elements. Valency might be described as the atom-fixing power of an element—the power of associating distinct elements in a single atom. Unless they admitted this, the problem must be given up; from this point of view a chlorine was a super-valent element, and they must admit that the chlorine atom was capable of entering into association with more than one other atom. He did not think, however, that mere discussion would help them much, and until they agreed upon some definite line of going to work, the problem would be as far from solution as ever.

The PRESIDENT, in the course of a few remarks, said: Of course, neither Professor Armstrong nor any one else could expect that every chemist would agree with him in all the views he took, but he should like to say how fully he agreed with him with regard to the statement that it was impossible to give any exact definition of chemical action, or indeed of a chemical compound. The discussion of the question of valency peculiarly involved the theory of what is chemical action or chemical combination. One important omission in Dr. Armstrong's argument was the fact that chemical combinations depended almost entirely on the temperature.

Professor A. W. WILLIAMSON, F.R.S., said: Chemists well knew that it was but comparatively recently that their attention had been drawn to the fact that there were atoms which differed from others in the complexity of the group they held together, the power of uniting together various atoms and combining them being possessed in a very different degree. Naturally chemists had made various attempts to explain these phenomena, but, unfortunately, in many cases it had only been a case of putting on intellectual blinkers to shade the horizon so as to limit the view to the particular portion in regard to which pet theories existed. A remarkable instance of variable valency was afforded by nitrogen, which was found in chemical compounds with three and sometimes with five monads. And the important fact must not be lost sight of that in proportion as the temperature was raised did they find the power of holding many atoms in combination diminish. There were two classes of compounds which had different valencies, and one class was quite as characteristic of compounds in the same degree as the other. Nothing but phrases could be used to establish a distinction between them. With regard to some other points which claimed very special attention, they could not fail to notice that the bodies in which many atoms were found grouped together chemically were of rare occurrence. The changes of temperature ought to be particularly noted, in that it diminished the power of the one central atom. But before they made progress with so complex and difficult a subject they must proceed on the clear statements of ascertained facts, and with as little supposition as possible.

Lord RAYLEIGH, Sec.R.S., said it was a very wide question that had been touched upon as to how far it was desirable to introduce new names for expressing physical or chemical results. He thought that both advantages and disadvantages would be experienced. No doubt it would please physicists if every element could be determined as having a fixed valency. He, however, failed to see how they could get over such phenomena as that afforded in ammonium chloride.

Dr. GLADSTONE, F.R.S., suggested that the refraction and dispersion of bodies was an object that would bear largely upon the consideration of some of the difficult questions that had been brought forward. It ought to be a most powerful argument in explaining some of the peculiarities of combination. Physical phenomena and chemical facts sometimes agreed, and he thought they would have to note this relationship more definitely before they came to complete agreement on so complex and difficult a subject.

Professor STERRY HUNT said he had maintained for years that all changes, such as condensation, etc., and those remarked upon by Dr. Gladstone, were essentially changes in their nature, and that in the case of chemical combination it was nothing more than a disposition which all matter had to unite and condense—the tendency to intrinsic condensation.

Dr. MORLEY and other members having spoken on the subject, Professor ARMSTRONG briefly replied.

The other papers read were as under:—

Evidence of the Quantivalence of Oxygen, derived from the Study of the Azo-Naphthol Compounds. By Professor R. MELDOLA, F.R.S.

Theory of Solution. Professor STERRY HUNT.

The Composition of Copper-tin Alloys. Mr. A. P. LAURIE, F.C.S.

Analysis of Ancient Mortar from the Roman Wall of London. Mr. S. SPILLER, F.C.S.

Action of Acids on Copper. Mr. V. H. VELEY, F.C.S.

Recovery of Ammonia and Chlorine in the Ammonia-soda Process. Mr. FRED. BALE.

TUESDAY, SEPTEMBER 11.

Professor TILDEN, F.R.S., presiding.

After the report of the Committee on *Isometric Naphthalene Derivatives* had been received from Professor ARMSTRONG, Dr. J. H. GLADSTONE read some *Notes on the Molecular Weight of Caoutchouc and other Colloids*, and Professor EMERSON REYNOLDS described *the Properties of some New Silicon and Thiocarbamide Compounds and the method he had followed in obtaining the same.*

In a paper on *The Action of Light on Water-colours* Dr. RICHARDSON discussed the effect of light on colours, and drew attention to the very important part played by moisture in assisting their decomposition. Colours he divided into two groups: those that bleach by oxidation under the combined influence of light, air, and moisture; and those on which light exerts a reducing action which is independent of the air, and in some cases takes place in the absence of moisture. The author condemned as unsafe those pigments which fade in dry air, and showed that the greater number of paints are stable in sunlight, provided moisture is absent.

Professor T. W. LANGLEY read a paper on *Proposed International Standards of Iron and Steel,* in which he showed the necessity for identical standards being adopted in every country, so that the different productions might be assured of an absolutely uniform material.

GEOLOGICAL SECTION.

(*Continued from p.* 262.)

SATURDAY, SEPTEMBER 8TH.

Professor BOYD DAWKINS, M.A., F.R.S., presiding.

Professor O. C. MARSH, of Newhaven, U.S.A., gave a long address *On the Dinosauria of Europe and America,* explaining them by means of diagrams, and entering into a comparison of the principal forms.

The PRESIDENT said Professor Marsh had laboured in America under more advantageous circumstances than they did in Europe. Here there were only isolated fragments of these difficult creatures, but in the great Continent from which Professor Marsh came they had nearly perfect skeletons; and he certainly welcomed the communication they had had, not merely on account of the addition it made to their knowledge, but also for the prospect which it afforded that they might have some of the long names attached to some of the fragments on this side of the water knocked on the head.

Mr. H. F. OSBORN, Professor of Comparative Anatomy at Princeton, explained a number of diagrams intended to illustrate the *Evolution of the Mammalian Molar Teeth to and from the Tritubercular Type.* He showed that the placental mammalia of the present day have passed through a stage in which the superior and inferior molars presented in the upper and lower jaws three component cusps, and from the molars of this type have been derived the various types of molars among the living mammalia. This tritubercular type, discovered by Professor Cope in the lower Eocene Rocks of North America is shown to have been derived from the molars of the mammals of the Jurassic period, and the latter bear evidence of their descent from the single reptilian cone. The formation of these complicated teeth from the simple teeth may be attributed to the mechanical effect of the interference of the upper and lower molars in the vertical and horizontal motions of the jaws.

Professor H. G. SEELEY objected to the classification of the group alluded to, but beyond this there was no discussion.

Professor GAUDRY (Paris) gave a short note *On the Gigantic Size of certain Fossil Mammalia.* He instanced the skeleton of *Elephas meridionalis* of the Paris Museum, which is nearly five yards high, and said he had himself obtained from Greece a still larger animal —the Deinotherium. (*See p.* 278.)

The PRESIDENT said they were exceedingly obliged to Professor Gaudry for bringing these interesting facts before them. It was well to know that at all events the ancestors of some of the larger mammalia were the larger the further they went back. The Deinotherium stood at the head of the list, and then there was a gradual decrease in the size down to the present.

Professor G. A. LEBOUR, M.A., read a *Note on the Relation of the Percentage of Carbonic Acid in the Atmosphere to the Life and Growth of Plants,* written by the Rev. A. IRVING, D.Sc., B.A., F.C.S., in which the author referred to the discussion raised recently on this question in the pages of the *Geological Magazine.* In order to test the hypothesis adopted by Professor Prestwich, three series of observations had been made during the past summer on plants exposed, under similar physical conditions, to atmospheres of different compositions. The evidence obtained all pointed in one direction, and went to show that, with an increase of the percentage of carbonic acid up to about that of the free oxygen present, the vigour of plant life and growth is also increased, so long as the plants are freely supplied at their roots with water, as we have good reason to suppose was the case with the vascular cryptogams from which the carbonised materials of the coal-measures are for the most part derived. The author further considered the theory as throwing some light upon a certain stage of development of life upon the earth in later palæozoic time; the great development of plant growth in the carboniferous age, having served as the means of storage of carbon in the earth's lithosphere, and thus purified the atmosphere so as to render it fit for the development of air-breathing forms of life in the Mesozoic Age.

Dr. STERRY HUNT considered that the amount of carbonic acid now condensed in vegetation was not entirely due to the purification of impure atmosphere, but that it derived it from an extra-terrestrial source. They must go back to the idea first enunciated by Newton —that there had been a constant interchange between our atmosphere and the atmosphere of other bodies in space.

Professor SEELEY pointed out that nowhere when carbonic acid was given off by the burning of lime did they find any very vigorous vegetable growth. In the neighbourhood of lime kilns they did not find that excessive amount of vegetation they would anticipate on the theory of luxuriant growth during the carboniferous period.

Professor LEBOUR, in the absence of Mr. JAMES SPENCER, read a paper written by the latter on *The Occurrence of a Boulder of Granitoid Gneiss or Gneissoid Granite in the Halifax Hard-bed Coal.*

Professor LEBOUR said it was nothing new to find boulders of gneiss in coal. He knew of many.

Mr. W. WHITAKER (now occupying the chair) agreed with this, and said boulders were so common in the Manchester coal-field, that the Manchester Geological Society had published a series of papers on the subject with illustrations—not only the gneiss, but a great variety of rocks occurred. The boulders also occurred in Germany, and indeed anywhere where they took the trouble to look for them.

Professor CLAYPOLE said there were also many in the United States.

The next paper read was on *The Caverns of Luray,* the author being the Chevalier R. E. REYNOLDS (Washington, U.S.A.).

These famous caverns are situated near the crest of a limestone hill of Silurian Limestone, near Luray Court House, in the valley of the South Shenandoah, Virginia, U.S.A. The valley is bounded on the east by the Blue Ridge Mountains, and on the west by the Massanulton range, the caverns lying equidistant from each. They were discovered in 1880, during which year the Smithsonian Institution sent out a scientific commission for the purpose of exploring and reporting on the same. The writer was a member of this commission.

The caverns—several distinct ones united by engineering operations—are similar to others found in limestone regions. They are mostly the result of erosion; one only—the Ramble, a plateau of 500 feet long by 300 wide—resulting from displacement of the adjacent strata.

Human remains have been found, but the character of their environment proves them to be of Indian origin. From the depth of the travertine which enclose them they appear to have been imprisoned for nearly a thousand years. The bones that are now visible consist of the right femur, the lower jaw, a rib, the segment of a clavicle, and a few teeth detached from the superior max. They appear to have belonged to a female of seventeen or eighteen years, the sex and age being determined by anatomical structure, ossification, and dentition.

The writer's memoir on this subject embraced a vast amount of information on the early or incipient growth of stalactites, some of which is believed to be wholly original. He is also engaged in studying the ratio of stalagmitic growth in the Atlantic coast caverns. The result now obtained shows that the vertical growth of stalagmite is one inch in forty years. The growth of stalactites is nearly twice as fast, or one inch in twenty years.

Mr. W. TOPLEY, F.R.S. (Recorder), presented a report on *The Rate of Erosion of the Sea Coasts of England and Wales.*

MONDAY, SEPTEMBER 10TH.

VOLCANIC DEPARTMENT.

Professor BOYD DAWKINS, F.R.S., presiding.

Dr. TEMPEST ANDERSON, B.Sc., exhibited a number of photographs (by the aid of Mr. Pumphrey and lime-light) of *the Volcanoes of the two Sicilies.* The exhibitor has recently visited the volcanoes of Naples, the Lipari Islands and Sicily, including Vesuvius, Stromboli, Vulcano, and Ætna, and taken photographs of their craters, and some of their lava streams, and other most important parts, in order to obtain a record of their present condition which may be available for comparison in case of future eruptions.

Dr. H. J. JOHNSTON-LAVIS contributed, in combination with this lecture, voluminous *Notes on the Formation and Geological History of Volcanoes.*

Accompanying it was a graphic account of the eruption of August last by Mr. A. E. NARLIEN, who was on the island at the time, an account, said the lecturer, which was well worthy from its analogy of being placed side by side with the renowned epistle of Pliny the younger to Tacitus.

Dr. H. J. JOHNSTON-LAVIS followed with a *Report on the Volcanic Phenomena of Vesuvius,* which we may publish in a future issue.

Dr. JOHNSTON-LAVIS then read a paper on the subject of *The Conservation of Heat in Volcanic Chimneys.* He said: One who daily follows the phenomena of an active volcano such as Stromboli, Vesuvius, and others of the same type, cannot but be struck with the fact that the enormous evolution of watery and other vapours does not suffice to reduce the temperature of the magma to the point of solidification.

By carefully following the details of the varying activity of the above-mentioned volcanos, which we will choose as our types, the matter becomes comprehensible. There is little doubt that all igneous magmas are originally in a vitreous condition, and that the passage from that state to a crystalline one must be accompanied by the evolution of an enormous amount of heat, just as occurs in the passage from the solid state of ice to the liquid water. Were the magma composed of a single chemical compound, we should expect that it would remain at a fixed temperature from the commencement of crystallisation to the complete solidification as the result of that process. This would not be the case in the lava in a volcanic chimney in which we should expect that the temperature would fall by steps, remaining fixed as long as any definite mineral species was crystallising, and would then drop to the crystallising temperature of the next species, again remaining for a certain time fixed. What these temperatures should be we do not know until the crystallising temperature of each rock-forming species is known. It must be remarked that the simple fusion point of any mineral is no indication of the temperature of the crystallising of a given mineral from a magma; for, in the former case we have to deal with a simple physical process, whereas in the latter it is often a chemical one. This is illustrated well in the case of orthoclase and augite, which both crystallise before leucite, which can only be explained by a chemical reaction taking place in the magma.

This process I take to be dependent upon a magma open to the atmosphere, by which the alkaline chlorides break up, the HCl being liberated and the free alkalies combining with the silica and alumina of the basic iron glass. Part of the iron separates as magnetite and part combines with the HCl and escapes in the vapour as chloride, always accompanied by some of the alkaline chlorides.

In fact, it seems an almost impossible task, the determining theoretically or even practically the temperature of solidification of a lava.

However, a clear comprehension of what has been said demonstrates how the supply of heat is kept up for a long time in the volcanic chimney, and the varying activity resulting therefrom. We have good reason to suppose that in our type of volcanoes there comes to the surface a uniform quantity of magma in a given time, although the extrusion may be more or less rhythmical, due to tidal and other agencies. Let us suppose that the magma has been so long simmering in the chimney that by volatilisation of steam, etc., it begins to become pasty. In that condition the escape of vapour from the lower part of the magma in the chimney cannot go on, and consequently the fall of temperature is arrested although crystallisation may go on for some time, so that the temperature of the lava rises. Meanwhile more water is being dissolved or taken up by the magma, and, in consequence of this and the rise of temperature, the tension of the magma increases until it overcomes the resistance of the pasty magma choking the upper part of the chimney. Then occurs a more or less strong paroxysmal eruption, in which, from the excess of water and the higher temperature there will result a tendency to the issue of the magma in a fragmentary condition, and this will approach more or less the scoriaceous or even pumiceous character. This is what is constantly occurring at Stromboli and even at Vesuvius, but in the latter it is much modified by the lateral oozing of lava, the effect of which I propose to treat of elsewhere.

In fine, we must conclude that the calorific capacity of the original vitreous magma must be very great, although its temperature may not be very high, and that its heat energy under favourable conditions may keep up the temperature for a long time. This would be the case in a volcanic chimney when solidification was taking place by crystallisation instead of cooling as a glass—a similar condition, in fact, to what we observe in the solidification of melted sulphur.

The same author then read a *Note on a Mass containing Metallic Iron found on Vesuvius.*

He also contributed a *Note on the Occurrence of Leucite at Etna.*

Professor E. W. Claypole, B.A., D.Sc. (Lond.), F.G.S., of Bochtel College, Akron, Ohio, U.S.A., contributed a *Note on Some Recent Investigations into the Condition of the Interior of the Earth.* The difficulty of this great problem in geology was referred to as a reason for the slow progress made towards its complete solution, and indirect nature of the evidence was also quoted as a source of uncertainty. The chief element upon which reliance can be placed is the now seldom disputed datum that the earth must in all these inquiries be regarded as a heated body in cold space subject to laws of radiation as yet imperfectly understood. Reference was then made to the recent investigations of Mr. C. Darwin, Mr. T. M. Read, the Rev. A. Fisher, and Professor G. Darwin, claiming to prove that the following deductions from this datum have been established.

(*a*) That below 400 miles the cooling and consequently the contraction are imperceptible.

(*b*) That the cooling and consequently the contraction reach their maximum at the depth of 72 miles.

(*c*) That at the depth of five miles the contraction from cooling exactly equals the diminution of space due to the descent of the shell ensuing from the total vertical contraction of all the layers.

This layer, at the depth of five miles, has therefore been termed "the layer of no strain," being liable neither to extension nor compression, because the space is exactly sufficient for its diminished bulk. The layer of no strain is placed by one of the authors above named at the depth of five miles, and in a neutral zone between the bent and crushed strata above, and the compressed and horizontally extended strata below it. It is consequently impossible that any disturbance can occur in the layer of no strain.

Yet in some parts of the earth, and notoriously in the Appalachian region of North America, strata have been forced up from a depth greatly exceeding this limit. Beds are now exposed, which at the time of their folding, lay fully eight miles below the surface, and must therefore have been far below this neutral zone, which was then (at the end of the palæozoic age) less than five miles deep. Similar facts might be adduced from other parts of the world, and it is therefore difficult to avoid the conclusion that the layer in question has been placed too near the surface, though of the actual existence of such a zone after a careful study of these investigations scarcely a doubt can be entertained. The Professor concluded by pointing out that this theory would limit the depth and origin of earthquakes to a five-mile depth.

The President said the subject was one of exceeding difficulty, and exceeding interest, and it was a subject, moreover, upon which hardly any two observers were likely to come to exactly the same conclusion. To the point put before them by Professor Claypole they must really devote some discussion. Geologists were plain folk; they required evidence put clearly and plainly to the front, and he thought there was really no evidence of any such divisions.

The Rev. E. Hill, M.A., F.G.S., who pointed out that mathematicians (the authors of the theory put forward by Professor Claypole) obtained their deductions from hypotheses, declined to discuss that question, but confined himself to the question of volcanic agency. There were, he said, several theories of volcanic action. There was the theory of the crushing process; there was that of the gradual percolation of water to the heated depths; there was that of the sudden intrusion of water into the heated core; and there was the later one, which had much to say for itself, of heated gas gradually forcing its way out from the central nucleus. Some facts seemed to point in favour of one hypothesis and some in favour of another. For instance, the description which Miss Bird gave of a volcano in one of the Sandwich Islands, as that of a constant boiling going on, seemed to be best explained by the theory of heated gas; or, again, the fearful eruption which, in New Zealand, destroyed those wonders of the world, the Pink and White Terraces, seemed much more clearly to be attributed to the sudden intrusion of the waters of the lake into the heated central mass. Other observations pointed to other causes, and he was inclined to think they often made the mistake when they saw one phenomenon of immediately considering it must be due to one cause, whereas he strongly suspected that in these matters several causes were at work.

Dr. Irving, after dealing with the presence of flame in volcanic eruptions, pointed out that the architecture of the earth's crust was such as to throw serious difficulties in the way of Professor Claypole's theory of a zone of "no strain," especially in view of the fact that in earlier periods such a zone must have been much nearer the surface.

Mr. Stanley criticised the mathematical calculation by which the theory had been arrived at.

Mr. Beaumont, Mr. W. White, and Mr. Fergusson followed.

The Rev. F. Howlett, F.R.A.S., said he was astonished to hear the statement made by the mathematicians that at the depth of 400 miles the central mass was incapable of further cooling. If that were so what became of the theories and functions of the laws of convection currents of temperature? He was utterly incapable of comprehending how such a state of things could possibly be arrived at.

The President followed with a vigorous onslaught on the "no strain zone" theory. They had already heard some objections which, to his mind, were insuperable objections—that by the last speaker particularly. It was asserted that the temperature of the earth beyond the 400 miles limit would remain the same for ever and ever! That was a hypothesis which they could not for one moment entertain, unless they had most ample and conclusive proof. Now for this five-mile line—the line of "no strain." Now if there ever had been, at a depth of between one and five miles, such a layer as that then it seemed to him that in those thicknesses of rock which they were able to examine and test by the most minute methods of observation—he meant the stratified rocks—they would find evidences of certain strata in which there were no traces whatever of strain. As a geologist, he was bound to believe there were no such strata. His experience of the ancient history of the earth practically amounted to this, that the very deepest, the very oldest of the stratified rocks were those which had suffered the greatest amount of crumbling, the greatest amount of physical change, the greatest amount of folding. In other words, those which were sunk deepest were those which were compressed most. He found no trace whatever of this layer under consideration. Now for another point. It seemed to him that the condition of the interior of the earth was not to be made out by any mathematical assumptions, but it seemed to him they were really in the position of forming some definite idea from the modern development of stellar chemistry, of the application of spectrum-analysis to make out the physical constitution of the sun and stars, the planets, the meteorites, and the moon. And when from this he knew that space was full of bodies in various conditions of heat; when he knew that the planets varied from one another in their degrees of heat; when he knew that the moon was absolutely cold and lifeless, but that its physical constitution showed that in ancient times it was intensely hot; when he turned to meteorites, and saw before him heavy metallic and stony masses, which, at the time they were revolving in space and before they became entangled in the earth's atmosphere, were cold, and yet, which they knew from their very physical constitution, were originally intensely hot; when he knew all this he was bound to believe that there was a general law by which there was a steady loss of heat, and by which the intensely heated bodies gradually grew colder and colder, until at last even such a mass as the sun himself would become as cold as the meteorites. In the face of all such evidence it was wholly impossible for them to believe that the cooling of the earth was to be stopped at the 400 miles limit. The President devoted some further remarks to this subject, couched in the same tenour, and concluded by pointing out how appropriate it was they should be discussing the question of volcanic phenomena in that room, for it was at the last Bath meeting, in 1864, that the President of that section was his old master—Professor Phillips—and Professor Phillips was the historian of Vesuvius.

Dr. JOHNSTON-LAVIS said that volcanologists could trouble themselves but little about the interior of the earth, their time being taken up with studying the phenomena themselves, the origin of the material thrown up, and its cooling at the surface. He nevertheless rejected all Professor Claypole's theories, both because they assumed the crust of the earth to be one uniform mass and of one uniform thickness. He protested, also, against the theory that earthquakes and volcanic activity were confined to a depth of five miles, which, on the showing of the "no strain" zone, they would be. His experience led him to believe that the distribution of earthquakes on the surface was in proportion to their depth. The great Charleston earthquake, he believed, to have a depth of at least twelve miles, while other earthquakes of limited area he believed to be similarly limited in depth. To suppose that vast earthquakes, spreading over hundreds and thousands of miles, were limited to five miles depth was impossible; and he did not know how mathematicians could make such an assertion. With regard to the origin of volcanic action, he attributed the large amount of literature on the subject to imperfect information, and he entered a strong protest against the perfunctory system that some have of pretending to investigate these phenomena, saying that, before a proper opinion could be formed, it was necessary to be on the watch night and day for years together. Volcanic activity, he believed, did bear a relation to the barometer and the thermometer. It had been statistically proved that there was a definite relation between volcanoes and the tide and the position of the moon. For five years he had carried out a daily record at Vesuvius, and he found distinct evidence that the activity of the volcano was in most remarkable relationship to barometric pressure. As for the theory of the gradual percolation of water to the heated mass, he regarded it, to say the least, as a very crude theory.

Professor CLAYPOLE agreed with most of the objections which had been taken. No evolutionist could for a moment doubt the truth of the law of cooling which the President had referred to; but nevertheless, the President's objection was like a pyramid standing on its apex—it had no foundation. The mathematicians never intended it to be understood that cooling entirely ceased at 400 miles limit—they would be the last to accept such a corollary. What the mathematicians meant was this—that in discussing one of these intensely difficult mathematical problems their formularies became so long and complicated that they were bound to leave out all elements not absolutely necessary; and by drawing the line at 400 miles they meant—not that cooling would entirely cease there, but—that beyond that line the radiation into space was so small as to be utterly unappreciable and valueless in regard to their calculations. In regard to the convection currents, he would reply that he must be a hardy geologist in the present day who would maintain that the earth is liquid enough for the convection currents to occur at a depth of 400 miles.

A paper was read *On the Causes of Volcanic Action*, for Mr. J. LOGAN LOBLEY, F.G.S. After citing recent opinion as to the absence of an adequate explanation of the causes of volcanic action, the author showed that the accumulation of knowledge of the controlling facts of volcanic phenomena and the amount of attention which had been given to the question placed the subject on firmer grounds, and made the finding of a satisfactory solution of the problem now more probable.

The difficulty of the question lay in the great number of facts and the apparent conflict of many of them.

It was, in the first place, necessary that the leading and controlling facts should be recognised and kept in view. With this object a compendium or concise statement of forty-two such facts was given, followed by a brief review of the various theories that had been advanced, from Lemery's in 1700, to Prestwich's in 1886, with in each case numerical references to the facts in the compendium which were, in the author's opinion, at variance with the respective hypotheses.

The author's own conclusions were then submitted, which are, briefly, as follows:—

A. That the primary cause of the formation of lava is the internal heat of the globe inducing chemical action in subterranean regions where the materials and conditions are both favourable.

That since the fusion-point of temperature of solids is raised by extreme pressure, conditions for chemical action may be changed from unfavourable to favourable by the removal or relief of vertical pressure by lateral or tangential pressure.

That certain substances are fusible at low or moderate temperatures, and that thus at very moderate depths chemical action may be locally commenced that will extend until sufficient heat is produced to effect rock-fusion.

B. That the cause of the ejection of lava from its source, and its rise in the volcanic tube is the increase of bulk consequent upon the change from the solid to the fluid state, aided by the formation of potentially gaseous compounds by chemical reactions among the original materials of the magma.

That the ascent of the lava in the volcanic tube may be effected by the weight of the atmosphere and by lunar attractive influence, and that therefore a volcanic vent is a thermometer, and, secondarily, a barometer and helkusometer* combined.

C. That the explosive effects of volcanic eruptions are altogether secondary, and are due to the access of sea and land water to fissures, by percolation through cool rocks, up which lava is ascending.

That this water, when converted into steam, opens, by its expansive power, rents that admit large flows of sea-water to the lava, occasioning the formation of vents and the greater explosive phenomena of eruptions.

The formation of the actual surface volcano and the determination of its position is therefore due to the sea, near which volcanoes are almost always situated.

Emissions of lava without explosive effects are from volcanic tubes to which large flows of water have not obtained admittance, and, on the other hand, purely explosive eruptions, without lava flows, are caused by water reaching lava which fails to rise to the surface of the earth.

The various forms of volcanoes the author considered could be explained by these views, which opposed—

1. An infra-crust common central source of lava.
2. The passage of lava through thirty miles of rocks, and consequently through any greater thickness.
3. The ejection of lava from its source by vertical pressure.
4. The ejection of lava from its source by super-heated steam or "potential steam" force.
5. The passage of water through highly-heated rocks, either by fissures or by capillary transmission.
6. The accumulation or the presence of water at volcanic foci.
7. A primogeneal "water substance."
8. The importance of land surface water.

The author has given much thought during many years to volcanology, and had made personal observations of volcanic activity; and whether his views were approved or not he would be glad if they elicited facts and opinions that would further a solution of the problem. He thought a discussion on the subject would not be inappropriate at the city of Bath, famous as it was for thermal waters deriving

* From ἕλκυσις—εως = attraction.

their heat from what might be termed, according to his views, a volcanic focus, but in this case one from which only benefit to mankind was received.

The Eighth Report of the Committee, consisting of Mr. R. Etheridge, Mr. Thomas Gray, and Prof. John Milne, Sec., *appointed for the Purpose of Investigating the Earthquake and Volcanic Phenomena of Japan*, was then read.

Mr. O. H. Howarth communicated a paper on *The Recent Volcanic Structure of the Azorean Archipelago.* The object of the author's notes upon the relation of the Azorean group to the other islands of the West Atlantic was to indicate a line of inquiry by which some approximation might be made to the intervals separating the great eruptive changes; and to determine any modifications in the type of flora during that important succession of volcanic products, which has been evolved since the Upper Miocene period assigned to the islands generally. A field for such inquiry seems to be offered by the present phase of action in the Furnas district, in the eastern centre of St. Michael's, where existing activity is associated with some of the oldest formations in the series. The author has traced in that valley a series of beds of vegetable origin dating back from the most recent changes, immediately connected with the present boiling-spring area, to a period antecedent to the formation of the Furnas Valley itself. The intermediate intervals of repose are now represented by peaty beds and subaqueous vegetable deposits, interstratified with the successive lava streams, tuffs, and pumice beds of various dates, within and prior to the historical period. From the more recent of these, buried trunks and branches have been obtained which represent the intervals of recent eruptions; while in one of the older tuffs, underlying nearly the whole series at that portion of the islands, a tree (probably an *Erica*) has been found, presumably *in situ*, and offering possibilities of a subjacent soil for examination, which would be contemporaneous with the earliest vegetation of the island.

Professor G. A. Lebour presented the *Report of the Committee appointed for the purpose of considering the Advisability and Possibility of Establishing in other parts of the Country observations upon the prevalence of Earth Tremors, similar to those now being made in Durham.* The report was brief and preliminary only. The Committee, it seemed, has hitherto been engaged in considering the question of the best instruments adapted for the work, and their investigations being still incomplete, they did not as yet make any special recommendation. While some carefully finished seismoscopes would be needed, it would be only in comparatively small numbers, while on the other hand a larger number of instruments would be required of less delicate character. Next year the Committee would be in a position to give a more definite report, when they would ask for a grant, the rough outline of the proposal being to have a number of small observing stations where time records of tremors would be registered, and a few very carefully selected stations, where the intensity as well as the time would be recorded.

Geological Department.

Mr. W. Whitaker, F.R.S., presiding. The following papers were read :—

The Watcombe Terra-Cotta Clay. By Mr. W. A. E. Ussher, F.G.S., of the Geological Survey of England.

Beds exposed in the Southampton New Dock Excavation. By Mr. T. W. Shore, F.G.S., F.C.S.

Fossil Arctic Plants from the Lacustrine Deposit at Hoxne, in Suffolk. By Messrs. Clement Reid, F.G.S., and H. N. Ridley, M.A., F.L.S.

Report of the Committee, consisting of Mr. J. W. Davis, Mr. W. Cash, Dr. H. Hicks, Mr. G. W. Lamplugh, Mr. Clement Reid, Dr. H. Woodward, *and* Mr. T. Boynton, *appointed for the purpose of investigating an Ancient Sea-Beach near Bridlington Quay.* Drawn up by G. W. Lamplugh, Secretary.

Professor H. G. Seeley, F.R.S., contributed a paper on *The Origin of Oolitic Texture in Limestone Rocks.* The author stated his belief that Oolitic textures have originated in many ways. It is found occasionally in Silurian, Devonian, and Carboniferous rocks; but it is most characteristic of the Inferior and Great Oolites, Coralline Oolite, and Portland Oolite. The structure is not limited to limestone, being found in carbonate of iron and oxide of iron. A similar structure has long been known in the Dolomitic rocks of Durham, but some of the concretions are of large size, and this condition is seen in the Sprudelstein at Carlsbad. Experiment has shown that carbonate of soda may be the basis of concretions of carbonate of lime if they are suspended under suitable conditions in solution of chloride of lime. Dr. Carpenter regarded Oolites as Foraminiferal limestones in which the foraminifera are invested with calcite. Dr. Sorley regarded the grains as pellets formed by current drifting, and the author attributed the small size of the grains to the small force of the currents. The author considered that the microscopic structure of nullipores was practically identical with Oolitic grains, so as to suggest that in some cases Oolites may be organic rocks.

Professor Gilbert described the Oolite now forming in the Great Salt Lake, and Mr. Wheeler, U.S.A., the Chairman, Mr. Woodward, Mr. Wethered, and Mr. Wedborne spoke on the subject.

Tuesday, September 11th.

The Rev. H. H. Binwood presiding.

The first paper read was on Professor F. Bassani's *Researches on the Fossil Fish of Chiavon, Vicentino.*

These fossiliferous marls were first discovered by Baron Zigno in 1852, who referred them to the Lower Miocene, since which time Heckel, Herr Suess, Sauvage, and others have studied their fauna and flora. The abundant materials investigated were derived from many public and private museums, and represented plants and animals, amongst which were a few crustaceans badly preserved, very few insects, many beautiful fish, two bones of birds, and some amphibia. An examination of the list shows that the Chiavon fauna include no Ganoids, and is constituted of Chondropterygeans and Teleosteans. The whole list is comprehended in fifty-eight species, distributed in thirty-two genera and fifteen families. Comparing the fish fauna of Chiavon with twenty-one other analogous deposits of Europe, the author has come to the conclusion that they are in age Aquitanian, or belong, like the strata of Sotzka, to the base of the Lower Miocene.

The report of the Committee, consisting of Mr. R. Etheridge, Dr. H. Woodward, and Professor T. Rupert Jones (Secretary), on the *Fossil Phyllopoda of the Palæozoic Rocks*, was read, as was also the report on the *Flora of the Carboniferous Rocks of Lancashire and West Yorkshire*, by Professor Williamson.

Professor H. G. Seeley, F.R.S., gave an elaborate description of an *Ichthyosaurus from Mombasa*, with observations on the vertebral characters of the genus.

Mr. A. Smith Woodward, F.G.S., F.Z.S., read an interesting paper, in which he drew *a Comparison of the Cretaceous Fish-fauna of Mount Lebanon with that of the English Chalk.* He also read a paper on *Bucklandium diluvii König, a Siluroid Fish from the London Clay of Sheppey.*

Professor W. Boyd Dawkins, in the course of a few incidental remarks, alluded to the curious inversion of parts noticeable in some fishes, and instanced the common sole, which by dint of continual squinting caused the eye to travel right round the orifice to the upper surface in a curiously inverse fashion.

Mr. W. Terrill (Swansea) and Dr. Johnston-Lavis asked for and obtained further information.

Dr. C. Ricketts, F.G.S., read a paper on *A Probable Cause of Contortions of Strata.* The amount of compression to which the crust of the earth would be subjected as the effect of subsidence, by the presence of faults and other causes, as well as by the secular cooling of its mass (Rev. O. Fisher, *Phil. Mag.*, Jan., 1888), is too inconsiderable to develop the great contortions and foldings certain strata have undergone.

When accompanied by cleavage, the distortion of contained fossils and the displacement of included rock fragments (the flat sides lying parallel to the cleavage planes) indicate that the change occurred whilst the clay deposits were in an unconsolidated or plastic condition.

It is suggested that these flexures may be dependent on irregular pressure, caused by the local distribution of larger and heavier particles on accumulations of unconsolidated muddy deposits, in a similar manner to what may be demonstrated by spreading layers of clay of various colours, dried and reduced to powder, in a trough; when, on the admission of water, the clay has become plastic, sand is heaped on some special part and extra weight applied, which in the experiment is necessary. The heavier substance subsides into the plastic mass, and at the same time the clay beds are squeezed outwards, causing the layers underneath to be formed into films, which are still continuous with those on the sides, though these are rendered considerably thicker than in their original state, and are curved into folds, even to reversal of the beds, representing on a small scale what are frequently met with in stratified rocks. The experiment so coincides with natural phenomena that it is reasonable to expect that it will prove to be a true and frequent cause of the cortortions of strata.

The paper was accompanied by models, the result of experiments, and Mr. A. S. Reid and Mr. W. W. Watts spoke on the subject. The latter said the experiments made by Dr. Ricketts required to be modified before they actually represented the facts as they occurred. He pointed out that the sides of the vessels in which the experiments were made involved conditions of pressure which did not occur in nature. The scale of the models, too, was untrue, as to represent the actual conditions the model of the Ganges Delta would have to be elongated to 250 feet. He agreed that Dr. Ricketts was discussing an undoubtedly real cause of contortion, but limited its application, and said that the contortion of a schist, Mr. Reid had produced, was on far too small a scale to have been effected on the theory propounded.

A paper, written by Mr. J. JOLY, M.A., B.E., was read, on *The Temperature at which Beryl is Decolourised.*

Experiments on some translucent green and yellow beryls from Glencullen, Co. Dublin, show that these beryls are almost entirely deprived of colour when exposed for one hour to a temperature of 357° C., *i.e.*, the temperature of boiling mercury at atmospheric pressure. The loss of colour takes place whether the beryls are out of contact with the air or not. It was found further that exposure to a temperature of 230° C., for the space of thirty hours caused a marked loss of colour. In all cases the crystals retain their translucency. They have shown no signs of regaining colour during a lapse of three years since the date of the experiments. The author suggests that this observation may bear on the history of the containing granite subsequent to the formation of beryl, if the colour of the latter be regarded as indicating a major limit to the changes of temperature experienced by the rocks.

A second paper prepared by Mr. JOLY was read, on the *Occurrence of Iolite in the Granite of the County Dublin.*

Mr. W. W. WATTS gave an address on *Igneous Succession in Shropshire,* illustrating his remarks by diagrams. The author described the succession of igneous rocks in the Shelve and Corndon district of Shropshire. The earliest rocks had a high percentage of silica, and this diminished on each successive phase of volcanic activity, of which four stages were noted, so that the lightest rocks were erupted first, and densest rocks later. The last part of the paper was taken up with a discussion on the mode of occurrence of these rocks, which had been intruded into spaces formed during the folding and faulting of the strata.

A brief report was presented from the Committee appointed to investigate *the Circulation of Underground Waters in the Permeable Formation of England and Wales, and the Quantity and Character of Water supplied to various Towns and Districts from these Formations.* The drought to which the Committee drew attention, in its last report, continued up to June of the present year, and had a very marked influence in diminishing the volume of water yielded by a large number of springs, and a very considerable diminution in the supply afforded by the remainder over the greater portion of the central area of England, an area in which underground stores give the larger proportion of the daily water supply of the population. Much useful information had been obtained as to the amount of diminution experienced, but it had been thought desirable to combine it with information now being collected, showing the effect of the recent heavy rains in recharging the underground stores. Such statistics as to the most exceptional season of the present century would have a permanent value in future calculations as to the actual yield likely to be obtained from a given area after successive years of minimum rainfall, and this information was deferred until next year. It was hoped local observers would give special attention to diminution and increase in the yield of the springs.

A list of works was presented, referring to *British Mineral and Thermal Waters*, the CHAIRMAN remarking it was very appropriate such a list should be presented in Bath.

The Rev. Dr. IRVING dealt with the *Origin of Graphite in the Archæan Rocks*, reviewing the alleged evidence of life on the earth in archæan times. He asked, is archæan graphite of organic origin? So convincing has the presence of graphite appeared to some minds as evidence of the pre-existence of vegetation that in the report of the Smithsonian Institution (quoted by Dr. Sterry Hunt in his "Geological Essays"), the presence of graphite, even in aërolites, is said to "tell us in unmistakable language that the bodies came from a region where vegetable life has performed a part not unlike that which it still plays on our globe." It is well known that carbon does occur on meteorites; graphite—identical in properties with iron-graphite—was identified by Berthelot in the meteoric mass which fell at Crambourne, near Melbourne, in 1861; and during last year it was stated in *Nature* that carbon has been found between the caminal of the great mass of meteoric iron which fell near Cabin Creek, Johnson's County, Arkansas, in March, 1886. Mr. Lockyer's recent experiments on meteorites with the electric spark have given spectroscopic evidence of the presence of carbon in such bodies in some cases. Dr. Sterry Hunt, in his "Chemical and Geological Essays," remarks, "Graphite, which itself encloses apotite, is found included alike in quartz, pyroxene, and in calcite, in such a manner as to lead us to conclude that the crystallisation was contemporaneous with that of all these minerals." The alleged necessary phytogenic origin of graphite had, it appeared, no direct evidence to support it beyond the known fact that it occurred occasionally in later formations, as the result of extreme carbonisation of organic matter of vegetable origin. If, therefore, it could be shown that graphite could be produced in any other way in the archæan rocks it was evident that we must cease to urge its presence in these rocks, as evidence of contemporaneous organic life. Let them consider a few demonstrable facts as bearing upon the question. They knew that graphite occurred in segregated minute masses in "grey" or pig iron, and that it exuded from that metal in the process of cooling, to crystallise in the form of hexagonal plates. It was well known and easily demonstrated in the chemical laboratory that carbon could be obtained in the purest form by the reducing action of metals, of the alkalies, and even of magnesium, upon ordinary carbonic acid gas at high temperatures, or by chlorination of hydro-carbons at red heat. They knew that hydro-carbons could be formed, and were formed frequently in the laboratory by direct combination of carbon with elementary hydrogen, acetylene being formed by direct synthesis of hydrogen with carbon vapour at the temperature of the electric spark discharges. Marsh gas, too, had been produced by the reaction of carbon bisulphide upon hydrogen-sulphide, in contact with heated metals such as copper. More complicated hydro-carbons were produced when certain metals, such as iron united with carbon, and the metallo-carbides thus formed were acted upon by mineral acids. If now, it were to be admitted that the earth had developed out of a portion of the original nebulous mass from which the solar system is derived, it must have passed through such a condition of things that hydro-carbons must have been formed synthetically by such processes as had been mentioned, perhaps by others which laboratory research had not yet discovered. Given, then, the existence of hydro-carbons in the dense archæan gaseous envelope which enshrouded the glowing lithosphere of archæan rocks, it could easily be shown that carbon would be deposited from them. During the last two months the author had produced copious deposits of soft, amorphous carbon by the contact-action of heated fragments of previously calcined pumice upon currents of ordinary coal-gas. He had also observed that the carbon deposited at an incipient red heat had the steel-grey lustre of graphite, and that at higher temperatures, up to the incipient fusion of the hardest Bohemian glass, the carbon deposited had a more sooty character. From such evidence they were justified in inferring the deposit of graphite in the earliest crystalline rocks, by the dissociation of hydro-carbons through the contact-action of such rocks at high temperatures, as probable. As to animal life, he could only say that any one who, with a fair command of the German language and a moderate acquaintance with protozoan forms, could form a judgment of the merits of the eozoön controversy from an acquaintance with Möbin's splendid monograph, *Der Ban des Eozoon Canadense*, must admit that the evidence of the organic origin of that structure was very slender indeed. And in the face of the overwhelming physical evidence against the possibility of life on this globe, as we know it, having appeared in archæan times, the evidence of such mere mineral infillings representing organic forms must be made infinitely stronger than it has yet been made in order to establish a case.

A brief discussion ensued in general terms, and after the Rev. G. F. WHEDBORNE had read papers on *Some Fossils of the Limestones of South Devon* and on *Some Devonian Crustaceans*, the section formally brought its sitting to a close.

GEOLOGICAL DEPARTMENT.

W. WHITAKER, Esq., presiding.

Dr. T. STERRY HUNT, F.R.S., read a paper on *Mineralogical Evolution*, in the course of which he said, Mr. E. A. Ridsdale, who during the present year (1888) has done good service by publishing a suggestive essay, called "Notes on Inorganic Evolution," spoke of the production and conservation of more stable species as a gradual "selection of inert forms," and further, as "a survival of the most inert." But as inertness consisted in stability, and in fitness to resist alike the chemical and mechanical agencies which destroyed other species, it was evident that his phraseology is but another statement of the formula of "the survival of the fittest."

The great principle of the change of the mineral matters which existed in former conditions of our planet into other forms more stable, under the altered conditions of later ages, is but an extension to the mineral kingdom of the laws already recognised in astronomical and biological development. As was written in 1884, "That a great law presided over the development of the crystalline rocks was from the first the author's conviction, but until the confusion which a belief in the miracles of metamorphism, metasomatism, and vulcanism had introduced into geology had been dispelled the discovery of such a law was impossible." To this may be added that "the great successive groups of stratiform crystalline rocks mark necessary stages in the mineralogical evolution of the planet," and that the principles which have elsewhere been laid down will help us "to recognise the existence and the necessity of an orderly lithological development in time."

The CHAIRMAN and Professor J. F. BLAKE asked questions on the subject, and the points they referred to were further elucidated by Dr. HUNT.

The report was prepared at considerable length, but Professor Blake only read the conclusions he had arrived at, the bulk of the paper being taken up with detailed description of the rocks referred to, 252 in all. The series described, he said, were so various in their composition and structure that the results of their study could not be fully stated in a single proposition, but there were many conclusions of which they either afforded demonstration or rendered the probability considerably stronger. These were thirty-two in number, the chief of which were referred to and explained on the black-board.

Professor J. F. BLAKE presented a report upon the *Microscopic Structure of the Older Rocks of Anglesey.*

BIOLOGICAL SECTION.

(*Continued from p.* 265.)

MONDAY, SEPTEMBER 10TH.

Mr. W. T. THISELTON-DYER, F.R.S., presiding.

The Report of the Committee on the Marine Biological Station at Granton, in Scotland, was read by Mr. W. E. HOYLE.

The PRESIDENT, in commenting upon the report, said the sea afforded problems of extreme interest, and he trusted that the Association, having supported the work that was done at the various stations for some years past, would continue to give that aid, though it might not possibly be done in precisely the same manner as had hitherto been adopted. He could not believe that there would ever be wanting workers to take advantage of the appliances and conveniences which those stations afforded, and at subsequent meetings of the Association a very important feature of the proceedings would be accounts of investigations which had been made at those places.

Mr. HARMER, M.A., B.Sc., presented the report of the Committee on *the Development of the Oviduct in Teleostei.*

Mr. F. W. OLIVER, B.A., D.Sc, etc., gave an address on *Certain Adaptations for the Nutrition of Embryos.* He pointed out that in the new Chinese aquatic plant *Tapeiha* very remarkable accessory feeding organs were revealed at either end of the embryo-sac, which indubitably absorb food material which is handed on ultimately to the developing embryo. The organs which functioned in this way were respectively the *Synergidæ* and the terminal cell of the series of cap cells. This extraordinary state of things was co-ordinated with the atrophy in this plant of the raphe—the normal channel of food-material to the embryo. An absolute parallel occurred in the *Loasaceæ*, where the vascular bundle of the raphe was also wanting; and here a series of curious suckers were also found, these being special outgrowths of the embryo-sac. The author, in conclusion, gave a detailed review of feeders identical in function, though widely differing morphologically, in such plants as *Lathræa*, *Tropaeolum*, *Thesium*, and many orchids.

A brief discussion followed the delivery of the address, in which the PRESIDENT, Professor MARSHALL WARD, Mr. WALTER GARDINER, and Professor BOWER took part, the opinion generally expressed being that the investigations of Mr. Oliver were of great interest and importance.

Mr. C. A. BARBER read papers on *The Development of the Bulb of Laminaria bulbosa* and *Pachytheca, a Silurian Alga of Doubtful Affinities.*

The former paper was discussed by Dr. FRANCIS DARWIN, Mr. W. GARDINER, Professor BOWER, and Mr. J. R. VAIZEY.

Other papers were by Professor HARTOG, *A Preliminary Note on the Functions and Homologies of the Contractile Vacuole in Plants and Animals;* and by Mr. W. GARDINER, on *The Contrivances for the Seed Protection and Distribution in Blumenbachia Hyeronomi* (*Urban*).

Professor MARSHALL WARD, F.R.S. (for Mr. PERCY E. NEWBERRY) read an extremely interesting paper on *The Plant Remains Discovered by Mr. W. M. Flinders Petrie in the Cemetery of Hawara, Lower Egypt.* The author pointed out the importance of this discovery to botanical science. He briefly reviewed the species of plants determined by him among the ancient remains, and called attention to the fact that only a very small number were undoubtedly indigenous to Egypt. He had examined all the plant remains and found that they possessed the minute and, in some cases, apparently accidental peculiarities of their existing representatives. He did not wish to point out the bearing of these facts on any theoretical views entertained at the present day. He merely wished to place them before the members of the section as data which must be taken into account in constructing such theories, and as confirming the long-established axiom that by them, at least, as workers, species must be dealt with as fixed quantities. The author exhibited a series of the plant remains to illustrate his paper.

Dr. FRANCIS DARWIN and the PRESIDENT made some laudatory observations concerning the paper.

Mr. E. J. LOWE read an interesting paper, the joint production of Col. Jones and himself, on the subject of *Abnormal Ferns, Hybrids, and their Parents.* A number of specimens were produced and handed round among the members, some of them being ferns of great beauty.

ZOOLOGICAL DEPARTMENT.

Mr. P. S. SCLATER, M.A., Ph.D., etc., presiding.

Mr. S. BROWN read an interesting paper on *Locusts in Cyprus.* He gave a brief description of the habits of the common Cyprus locusts, and of the system which has been successfully employed for their destruction in Cyprus. These insects, he said, had from time immemorial been the scourge of the island, and as under the Turkish rule little was done to keep them down, their ravages formed probably the chief agency in reducing what was once a fertile and flourishing island to a condition of comparative desolation. Successful efforts were, however, made by the Turkish Government from 1862 to 1870 for the destruction of the locusts, and in the latter year the island was so far rid of them that for some time no injury was sustained by the crops. But the Government relaxed its exertions, and the locusts again bred and multiplied, until by the time of the British occupation of 1878 they had so increased as to cause anxiety for the future. Acting under local advice, the Government attempted to keep them down by collecting and destroying their eggs. This operation was continued for three years on a vast scale, involving a heavy outlay, but without success; for although this method was adopted on a scale almost without precedent, the locusts continued to increase with alarming rapidity, until, in 1882, they swarmed throughout the plains, and in spite of various attempts to destroy them, the damage sustained by crops was very great, and probably did not fall short of £80,000, or from 15 to 20 per cent. of the value of the crops on the infested area. In 1883 and 1884 operations against the locusts were limited exclusively to attacking them in the crawling stage by the apparatus known as the Cyprus system of screens. These were formed of canvas, and were stretched across the line of march, so that the onward progress of the locusts was arrested, and they were then diverted into pits, carefully trapped, from which there was no escape. By the operations of these for two years the power of the locusts was so effectually destroyed that no damage whatever has been sustained by the crops during the past five years; and although it was still necessary to watch the locusts and prevent their increase, this was now done at a comparatively small annual outlay, and their numbers had so steadily decreased year by year as to warrant the hope of their final extermination. In submitting the paper to the Association the author was influenced by the hope that some of its members might be able to throw light on problems which, although they had received from him considerable attention, he had been unable hitherto to solve in a definite and satisfactory manner.

The PRESIDENT having offered a few observations concerning the subject treated of in the paper—

The Rev. Canon TRISTRAM detailed his experiences in Cyprus and of the locust pest in that country. He expressed an opinion that it was almost hopeless to expect to exterminate the locusts of Cyprus.

Mr. E. B. POULTON, M.A., made several suggestions with the view to obtaining more complete observations in regard to the breeding of locusts.

Mr. W. E. HOYLE gave a description of *Dredging and Trawling Operations which he had been prosecuting in the Firth of Clyde,* which contained some six or seven deep water basins, separated by more or less shallow ridges. The object of investigation was to compare accurately the inhabitants of these various basins. The occurrence of numerous interesting forms of life was recorded several of which had hitherto been regarded as peculiar to Norwegian and Arctic regions.

Mr. W. E. HOYLE, in explaining *A New Deep-sea Tow Net,* said its object was to enable the sea geologist to determine with certainty the exact depth at which free swimming organisms wer obtained. The net was a conical bag two or more feet in diameter, and some six feet long, of a degree of fineness proportioned to the size of the animals it is intended to capture. The net is attached to a folding hoop, to which two rods are attached, so that on towing it by one of these it will open, while on towing it by the other it will shut. It is let down closed, and when it has reached the required depth a small weight, known as a messenger, is allowed to slide down the rope, and by touching a spring lever let go the first rod, so that the rope hangs by the second and opens. When the net has been working for a sufficient length of time another messenger reverses the process, and the net is brought up closed.

Mr. F. E. BEDDARD, M.A., F.Z.S. (Secretary to the section), characterised the invention of Mr. Hoyle as very important, an expression of opinion in which the President concurred.

Mr. J. J. LISTER, M A., described a number of points in *the Natural History of Coral Fungia*, illustrating his remarks by blackboard sketches.

TUESDAY, SEPTEMBER 11TH.

Mr. W. T. THISELTON-DYER presiding.

The PRESIDENT remarked that the section had met in conjunction with their colleagues from the Geological Section, to consider a question which at the present time was very much attracting the interest not merely of biologists, but also of geologists—the vexed question which had been raised with respect to the origin of *Coral Islands and Coral Reefs*. One of the earliest researches of the late Mr. Darwin was a memoir upon the origin of these islands, and in it he was disposed to attribute them in great measure to the subsidence of the land upon which they were ultimately formed. He would not anticipate the statement of the reader of the paper as to the points of difference between Mr. Darwin's views and those which were now held, but it was in consequence of the explorations of H.M.S. *Challenger* that a series of facts were brought before the scientific world which in some degree made it extremely probable that Mr. Darwin's views did not form the only explanation to which these curious phenomena were susceptible. A very distinguished individual had thought fit to bring before the scientific world the preposterous assertion that they were leagued together in a conspiracy of silence with the object of suppressing the progress of scientific truth. He (the President) could not pretend that that assertion had influenced him in discussing the question upon the present occasion. It so happened that they had the presence of two distinguished scientific men who had had opportunities of examining these questions for themselves. They would state their views, and those present would be able to judge for themselves in which direction they would be inclined to think the ultimate solution of the problem might be found. At any rate, he thought they might claim that their minds were absolutely open, and that they attributed no weight to the authority of tradition, however eminent. All they really wanted to know was the conclusion which commended itself to their minds with the greatest probability, and which was based upon the largest number of ascertained facts.

Mr. SYDNEY J. HICKSON, M.A, D.Sc., Deputy Linacre Professor at Oxford, then read his paper on *Theories of Coral Reefs and Atolls*, but before doing so he said he felt it to be the duty of the opener of such a discussion as that upon which they were about to enter first of all to explain the phenomena concerning which the discussion was to take place, and then to state as impartially as possible the different views held to explain the phenomena. The object of the discussion was, if possible, to arrive at the truth, and not to run any particular theory. Thus, he would endeavour to state as impartially as possible the different views which had been put forward to explain the presence of atolls and barrier reefs; and although he could not help indicating in his opening remarks the view which he was inclined to hold himself, he would endeavour to postpone his prejudice to that view to a subsequent part of the discussion. He hoped none of those who followed him would consider that his mind was so prejudiced that they would not be able to convince him that he was wrong in the view he took.

The PRESIDENT said all would agree in according to Mr. Hickson a hearty expression of thanks for his interesting paper. If he had any fault to find with it, he might say it had been of a too judicial and well-balanced character—that he had rather taken the sting out of anything like an animated controversy. They could not help admiring the fair way in which he had brought forward the arguments for and against in this controversy, and it would be a difficult matter to attack him.

Professor W. BOYD DAWKINS, M.A., F.R.S, Dr. J. EVANS, Mr. G. C. BOWNE, Professor SEELEY, Mr. S. F. HARMER, Dr. MILL, and Mr. POULTON continued the discussion.

There were also papers read by Professor HALLIBURTON, report of the Committee on *the Physiology of the Lymphatic System*; by Mr. F. E. BEDDARD, *Contributions to the Anatomy of the Tuberficidæ*; by Professor HALLIBURTON (for Dr. Collins), *The Effect of Various Substances upon the Rate of Secretion and Constitution of the Bile*; by the Rev. R. BARON, *On the Flora of Madagascar*; and Professor GILSON, *On the Odoriferous Apparatus of the Blaps mortisaga.*

Mr. E. J. LOWE, F.R.S., read a short paper on the *Effects of the Weather of* 1888 *on the Animal and Vegetable Kingdoms.* He first drew attention to the extraordinary mortality amongst birds, and the fearful increase in the number of slugs and insect pests during the present summer near Chepstow. At Shirenewton, at the present time, there was not a wren, redbreast, goldcrest, coal-tit, marsh-tit, long-tail-tit, nuthatch, creeper, night-jar, green wagtail, lesser spotted woodpecker, redcrest, redstart, blackcap, white-throat, or redpole, although usually they were all common. There were scarcely any examples of landrail, water-ousel, missel-thrush, thrush, dunnock, whinchat, garden-warbler, willow-warbler, greenfinch, house-sparrow, hawfinch, sisking linnet, or swallow, although these are also usually common in the district. Amongst birds of which there were an average number might be mentioned the crow, rook, jackdaw, magpie, jay, swift, sparrowhawk, skylark, moor hen, blackbird, and starling. Usually birds were so abundant here that without nets cherries, strawberries, raspberries, currants, and gooseberries were all devoured by them. This year there had been no necessity for nets, as the fruit had been untouched by birds, or rather there were no birds to eat it. The long, deep snow in February destroyed many birds, but this did not account for the absence of so many summer birds. Only four or five swallows could be seen at one time, and only a solitary landrail had been heard. During the past two or three weeks there had been an increase in the following species: blackbird, willow-warbler, sparrow, chaffinch, great-tit, blue-tit, spotted fly-catcher, swallow, and martin. It might be mentioned that in June a pair of sand-grouse were seen to settle close to the cricket-ground in Shirenewton Park, but they were not seen again. There was almost always an increase in the number of slugs and insect pests after a cold winter, and this year that increase has been enormous. All seedling plants, vegetables, leaves, and flowers had been destroyed wholesale, and great damage had been done to wheat, grass, and other agricultural crops, but what had been most noticeable was the destruction by caterpillars of all the leaves of the oak. Thousands of oaks had been without a leaf—bare, like winter—and now they were only just coming into leaf again; but unfortunately a second crop of caterpillars was noticed on Sunday last to be resuming their attack on the new leaves. The damage to the oaks had extended for miles around. There had been a great increase amongst destructive slugs of various kinds, and earwigs, woodlice, ants, butterflies, and beetles had been unusually abundant, but there had been an absence of wasps and very few moles. Snakes and adders had been very numerous. Early-sown peas were twenty-one weeks before they were fit for the table, and all fruit had been very late, many gooseberries being not yet ripe, and currants being still abundant. Pears were scarcely swelling, and of mushrooms there were none. Nuts were an enormous crop. The hay-crop had been the latest ever known, much remaining unharvested at the beginning of the month. Although toads and frogs had deposited vast quantities of eggs, as usual, in the sheet of water in Shirenewton Park not a single one had resulted, nor did the egg swell. The water-newt had also been absent. It was worthy of remark that many delicate plants were uninjured by the cold of last winter. The author explained that his reason for contributing the paper was in order that the facts might be recorded for future comparison.

Professor MARSHALL WARD having offered a few observations—

Mr. HENRY SOUTHALL proposed a vote of thanks to Mr. Lowe for having contributed such an interesting paper, and the resolution was carried amidst applause.

Mr. F. T. MOTT read extracts from the report of the Committee, consisting of Professor Valentine Ball, Mr. H. G. Fordham, Professor Haddon, Professor Hillhouse, Mr. John Hopkinson, Dr. Macfarlane, Professor Milnes Marshall, Mr. F. T. Mott (Secretary), Dr. Traquair, and Dr. H. Woodward, reappointed at Manchester for the purpose of preparing a further report upon *the Provincial Museums of the United Kingdom.* This we may print in full at a later date ..

Professor SCHOFER said he had often been questioned by outsiders as to the use of the British Association. A complete answer to the question was found in the admirable report which Mr. Mott had read, and he hoped the suggestions it contained would be adopted, and that some practical result had been achieved. He asked Mr. Mott whether anything had yet been done.

Mr. MOTT said that copies of the first report of the Committee had been forwarded to the curators of all provincial museums, and he intended to ask that copies of the present one should also be forwarded to them.

GEOGRAPHICAL SECTION.

(*Continued from p.* 266.)

MONDAY, SEPTEMBER 10TH.

Col. Sir C. W. WILSON, R.E., F.R.S., presiding.

The first paper read was one by Sir LAMBERT PLAYFAIR, entitled *Tunis since the French Protectorate*, of which the following is an abstract:—

A very short time ago the interior of the country was practically a *terra incognita;* now it is being rapidly opened out to European enterprise, and it promises soon to rival Algeria in what must always be the principal industry of North Africa, viticulture.

Commerce also has increased in a notable manner, but the beautiful and characteristic arts of the country appear to be in a state of decadence.

The second paper on the list, entitled *The Commercial Future of Central Africa*, was read by its author, Sir FRANCIS DE WINTON. In the course of his remarks he said it could hardly be doubted that the advance of civilisation in the district dealt with would only be a question of a few years.

Mr. FORD read a paper on *The Transvaal—the Safety of Stanley*, in which he advised any one who had any capital and an idea of emigrating to go to South Africa, the El Dorado of the future.

Amongst the speakers were Sir F. DE WINTON, who contended that with regard to Mr. H. M. Stanley, there was no cause for apprehension on his account. He was undoubtedly safe in the interior, and had probably met Emin Pasha some considerable time ago. With regard to the White Pasha, who was reported to have been seen in the region of the Congo, he said some people thought it might be General Gordon, but he thought however much they might hope it was he, there was but small chance of the lamented General turning up. Mr. Stanley had travelled these regions many times before, and he would undoubtedly turn up all right after a while. There was no more chance of his coming to grief than there was of his coming to grief in Bath, beyond the chances of mere accident.

Mr. RAVENSTEIN said he agreed with Sir Francis in all he had said, and he fully believed Mr. Stanley was safe and sound, and in due time he would turn up. The other gentlemen who spoke were Sir LYON PLAYFAIR, Sir R. FOWLER, and Mr. SILVER WHITE, of the Scotch Geographical Society, and Professor GEORGE.

Mr. H. H. JOHNSTONE gave a very graphic and realistic descriptive account of the *Cameroons.*

Dr. E. G. RAVENSTEIN next delivered an address on *Dr. Livingstone and Bangweolo, the First African Traveller's Last Journey*, in which he drew attention to the discrepancy between his map of the Bangweolo region and his account of the same in his Journal. Had Livingstone lived to finish his survey of the lake, it would have appeared very different.

TUESDAY, SEPTEMBER 11TH.

Sir C. W. WILSON, F.R.S., presiding.

The PRESIDENT read a paper by Col. J. H. BOLLAND, R.E., on *The Photographic and Photozincographic Processes Employed in the Ordnance Survey*, in which he explained at some length the various maps used in surveys of the country, mines, drainage, etc., and the way in which they were prepared. The photozincographic process was invented at the Ordnance Survey Office, Southampton.

General Sir H. E. L. THUILLIER said no brush ever touched the copies of the original maps produced and sent to head-quarters.

Dr. GUISBURG said, in Cairo there was a very old copy of the Bible which he tried to get when he was out there with Lord Wolseley, but he was unable to do so. He thought they might make a representation to the Government to borrow the Bible, when Sir Charles would take a copy of it, which would be very useful to students.

Other gentlemen entered into the discussion.

Mr. H. J. MACKINDER, M.A., delivered an address on *Geographical Terminology*, in which he pointed out that one of the great difficulties encountered in the learning of geography was the inaccuracy of the terms applied to physical features, and one of the worst of these was that used for the word "ocean." The present use of the word ocean, as in the case of the Southern Ocean, was perfectly fatal to beginners. By the way of teaching at present in vogue an impression was left in the mind that there were five plains in some way compatible. The mother of oceans was that great ring of water lying north of the Antarctic Circle.

Mr. SILVER WHITE discussed the paper.

A communication on *The River of Joseph, the Fayoum and Raian Basins*, by COPE WHITEHOUSE, M.A., was read. A few observations were made on the subject.

Captain CONYERS SURTEES read a descriptive paper on *A Mission to El Wedj*, giving in it a sketch of the manners and customs of the various Arab tribes inhabiting that region.

Mr. G. K. GILBERT, of the United States Survey Office, addressed the audience with regard to the manner of the *Preparation of Geological and Geographical Maps of the Survey and the Triangulation System of the Country.*

Dr. RAVENSTEIN said he was surprised to hear of the very small number of geographers the United States had contributed to exploring parties. Although Stanley had very strong claims across the Atlantic, he was undoubtedly an Englishman. He thought in a go-ahead country like America they would not be behind in such a great work.

Mr. GILBERT responded, remarking that their maps were not yet published, but he would show them some proofs to demonstrate that some work had been done.

Mr. W. BARRINGTON D'ALMEIDA read a paper on the *Panang* State of the Malayan Peninsula. The author said Panang was the district which lay between Tringana in the north, and Perak and Selangore in the west of the China Sea. This was practically *terra incognita*, and until 1875 no Englishman had been farther than the borders of the State. The question of railways was not Utopian. There were already several of them in full swing, and at Trass a Mr. Fraser was working a very large tin-mine. The heat of the State was very great, and the natives were much darker than they were on the other side of the peninsula. He never in all his travels met with such courtesy as he did in the Malay territory. All the spare time of the natives was devoted to top-spinning. The climate was good, and colonisation would be most beneficial.

Mr. MACKINDER read a paper on *The Characteristic Traits of the Aboriginal Inhabitants of Formo a*, by Mr. GEO. TAYLOR.

Signor CESARE TONDINI DE QUARENGHI read a paper on *The General Adoption of the Gregorian Calendar*, in relation with that of the universal hour, in which he pointed out that the Chinese had some time ago adopted the Gregorian Calendar, and there were no reasons why the Russians should not do the same. They were keeping outside the pale of civilisation by insisting upon being twelve days behind ourselves.

ECONOMIC SCIENCE AND STATISTICAL SECTION.

(*Continued from p.* 268.)

SATURDAY, SEPTEMBER 8TH.

MR. R. H. INGLIS PALGRAVE, F.R.S., F.S.S., occupied the chair.

The first paper read was on *The Revenue System of the United States*, by Dr. ALBERT SHAW, Ph.D.

Mr. R. H. INGLIS PALGRAVE, F.R.S., F.S.S., then read a paper on *The Distribution of the Licences proposed to be transferred in aid of Local Expenditure.*

This paper was followed by one on *The Standard, or Basis, of Taxation*, by Mr. CLAIR J. GRECE, LL.D.

Mr. G. HURST said these papers had brought before them one of the most important subjects they had to deal with, viz., the subject of Taxation. He considered that taxation ought to be strictly as Adam Smith laid it down, viz., that every one should contribute according to their means. All taxes should be levied in proportion to people's means, and indirect taxation would then fall upon the multitude. They could not reach the labouring man except by indirect taxation.

Mr. W. BOTLY, of London, thought they should do everything to encourage the outlay of expenditure by those who had the means to do it in anything that was useful and good to the country.

Dr. SHAW said they were now nearer the possibility of a Tariff Commission than they had been for some time past in America. He also pointed out that Protectionists and Free Traders were not so bitterly opposed to each other. Most of them, who were Economists, did not regard themselves as Free Traders or Protectionists; they were rather Economic Opportunists.

The CHAIRMAN explained, with regard to his own paper, that his object was to detail particular taxes, and not to go into the policy of the Local Government Bill.

A paper on *The Suitability of Small Towns for Factory Industries*, by Mr. RUSSELL R. TANNER, was then taken, after which the section adjourned.

MONDAY, SEPTEMBER 10TH.

Mr. R. H. INGLIS PALGRAVE, F.R.S., presiding.

Professor EDGEWORTH, F.R.S., read the report of the Committee appointed to investigate *The Best Method of Ascertaining and Measuring Variations in the Value of Monetary Standard*, and Mr. S. BOURNE followed with a paper on *The Use of Index Numbers.* The Committee in their report stated that the main practical uses for which the measurement of variations in a monetary standard have been desired are (1) the fixation of rents or other deferred payments extending over long periods of time, for which it has been desired to obtain a currency of a more stable sort than money was supposed to be; (2) to enable comparisons to be made between the value of money incomes in different places; and (3) to enable historians and other students making comparisons between past and present to give approximate meaning to the money expressions with which they deal, and say roughly what a given fine, or payment, or amount of national revenue or expenditure in a past age would mean in modern language.

The Rev. G. HURST said the establishment of an index number with regard to our commerce was a matter of very great importance, but it should be remembered that while they had an index number with regard to the exports, it was imperfect as far as foreign trade was concerned.

Mr. MACNIGHT said it appeared from what had been said that the trade of this country was on the increase instead of decrease, and he hoped Mr. Bourne would be requested to continue his researches.

Professor EDGEWORTH next read the report of the Committee appointed for the purpose of inquiring and reporting as to *The Statistical Data Available for Determining the Amount of the Precious Metals in use as Money in the Principal Countries, the Chief Forms in which the Money is Employed, and the amount annually used in the Arts.* Failing to complete their task, the Committee recommended their reappointment in order to institute further investigation.

In the absence of Mr. G. B. LONGSTAFF, the following paper on *Reasons for a Quinquennial Census* was read by Mr. PRICE.

An exact knowledge of the population is mainly useful as a basis for the calculation of birth-rates and death-rates. In England much money is expended on the calculation and publication of these in the various reports of the Registrar-General and the Medical Officers of Health. These reports are of great value in impressing the need of sanitary improvements on the people and the sanitary authorities, but they lose much of their value from the uncertainty as to the basis upon which such statistics must be built, viz., an exact knowledge of the population. Experience has proved that the official estimates and the census numbers often differ by 10 per cent. in either direction, and sometimes by 15 or even 22 per cent. The Registrar-General himself is ceasing to put any trust in the official estimates of populations, as shown by recent weekly and quarterly reports.

There is reason to believe that, mainly owing to unusually large emigration, the population of the whole United Kingdom was, in April, 1886, or five years after the census, between 400,000 and 500,000 *less* than the official estimate, an error of $1\frac{1}{4}$ per cent.; in smaller areas the errors are often, proportionately to the whole, very much greater.

These errors in the estimation of the population may involve an error of two or three per thousand in the death rate, so that elaborate calculations made with a view of correcting errors due to differences in age and sex, and constitution of the population, are thrown away.

Major P. G. CRAIGIE, F.S.S., London, said the subject was one of distinctly practical interest, and he hoped the Economic Section would take definite and immediate action in the matter. Anyone who followed the debates in the House of Commons on the Local Government Bill, or who had thought out the question of boundaries, could hardly have done so without coming to the conclusion that Dr. Longstaff had asked them to do something which they should lose no time in setting about.

Mr. BOURNE bore testimony to the value of having figures closer up to date in all cases of research, particularly in England, where they had not only to deal with the increase of population, but with migration from one portion of the country to the other.

Surgeon-Major INCE pointed out the importance of knowing exactly the precise number of men, women, and children inhabiting this portion of the earth, and strongly suggested that instead of recommending a quinquennial census, the British Association should press upon the Government that the duties of the Registrar should be so extended as to include this. It appeared to him that the name of every person in every district should be known; every police superintendent should know who came into his district and who left it.

Mr. SHAW spoke of the need that existed in the United States for a comprehensive and quinquennial census. Some sort of understanding should be arrived at, so that the leading nations of the world could gather in their statistics at the same time and by the same process.

Mr. T. H. ELLIOTT, Recorder of the section, advocated the continuity of administration.

The discussion was continued by Major-General BABBAGE (Cheltenham) and Professor EDGEWORTH, after which a motion was carried to the effect that the Government should be memorialised in favour of the establishment of a permanent census sub-department, taking the census of the United Kingdom every five years.

Mr. L. C. PROBYN read a paper on *The Effects on Indian Exports of the Fall in the Gold Price of Silver.*

Mr. W. T. HARRIS followed with a paper which examined into *The Reasons of the Price of Wheat Rising and Falling Contemporaneously with the Variation in the Value of Foreign Currencies.*

Professor EVERETT (Belfast) explained that the rise in the price of gold had found its expression by a sweeping fall all round in price. It was that great fall in price which had brought agriculture into the most disastrous condition in which it was now found. It had also inflicted serious injury upon the cotton manufacturers of this kingdom. It was in the interest of all classes that the difference between these two kinds of money should be removed, and that the common level of exchange should be restored.

Mr. E. J. WATHERSTON (London) observed that the Government of India lose for every penny reduction in the price of silver one million sterling. One remedy was bi-metallism, which was not, however, in the range of practical politics. A gold standard for India was improbable, but there was one remedy, which was to put silver in this country upon a completely free trade basis. It was in the highest degree impolitic to retain any obstacles to the consumption of the raw material for manufacturing purposes. The duty on silver plate should be abolished, and hall-marking made a voluntary institution.

Mr. EOTLEY and Professor EDGEWORTH having spoken,

Major-General BABBAGE expressed his belief that silver had decidedly depreciated owing to excessive production.

Mr. W. L. HEYES followed with a paper on *Statigrams*—in other words, a diagram to enable the public to more readily appreciate and grasp statistics, and to increase the value of greater uniformity in the graphic representation of statistics.

TUESDAY, SEPTEMBER 11TH.

Mr. INGLIS PALGRAVE presiding.

A paper on *Leasehold Enfranchisement* was read by Mr. J. G. RHODES, F.S.S., in the absence of Mr. CHAS. HARRISON, by whom the paper had been prepared. The author pointed out that practically the whole of the land on which the metropolis had been developed was formerly held by the Crown, by bodies ecclesiastic and corporate, or by a few great historical families.

Mr. ELLIOTT (Recorder of the section) pointed out that the acquisition of small property in town districts was at present to some extent forestalled. The system at present in use tended not only to perpetuate a monopoly of land-owning, but to create a monopoly of house-owning. Eventually they would have to face a great social problem, and its effect upon the working classes would be serious and damaging.

Mr. HANDEL COSSHAM, M.P. (Bristol), said the direction reform should take was very much open to discussion and argument. The Bill the details of which had just been read did not go as far as they would have to go. He was confident that the present system prevented the encouragement and development of thrift. They wished to encourage the acquisition of property by every legitimate means. The present law was one of the greatest barriers they had for the promotion of thrift and the development of healthy dwellings.

Mr. JOHN GEDDES (Southport) dwelt on the anomalies of the present leasehold system.

Mr. W. J. HARRIS, speaking as a London landowner, said this was an evil system, and he was perfectly willing to see it rectified in a fair and proper manner, with full compensation to those who held ground-rents.

Mr. ROWLANDS, M.P. (East Finsbury), contended that owing to the land in many places being in the hands of one or two landlords, they had a system of monopoly, and the ground landlord inflicted on a neighbourhood whatever terms he liked, and those who were bound, on account of their occupation, to reside in that area had nothing to do but accept the terms or go elsewhere.

Mr. SHAW (U.S.) said the experience of England in this matter would teach American legislators a great deal, and they could not be too prompt or too vigorous in legislating to check its growth.

Mr. RHODES, in reply, remarked that in the year 1930, which was the centenary of the Reform Bill, there would be a ground landlord who would own in London, unless some modification were instituted, no less an income, arising from a residential area, than £5,000,000. The monopoly should be revised.

The report of the Committee, consisting of Dr. J. H. Gladstone (Secretary), Professor Armstrong, Mr. Stephen Bourne, Miss Lydia Becker, Sir John Lubbock, Bart., Dr. H. W. Crosskey, Sir Richard Temple, Bart., Sir Henry E. Roscoe, Mr. James Heywood, and Professor N. Story Maskelyne, appointed for the purpose of continuing the inquiries relating to *the Teaching of Science in Elementary Schools*, was then read.

Mr. EDWARD J. WATHERSTON (London) next read a paper on *The Industrial Education of Women Abroad and at Home.*

Miss HELEN BLACKBURN read a paper upon *Irishwomen's Industries.*

Mrs. PALMER HALLETT said Miss Blackburn's paper touched upon the highest question of political economy. All the efforts referred to had been made by ladies of the landlord class.

Miss SHARMAN CRAWFORD, as one who had been intimate with the people in the South of Ireland for twenty years, said she had every reason to speak well of their industry and honesty. They could only compete with machinery by people working for starvation wages.

The discussion was continued by Mr. STOOR.

The following papers were then read :—

Economy in Education and in Writing. By Mr. EIZAK PITMAN, Bath.

Education: a Chapter of Economics. By Mr. T. W. DUNN, M.A.

Agricultural Education. By Professor JAMES LONG.

MECHANICAL SECTION.

(*Continued from p.* 271.)

SATURDAY, SEPTEMBER 8TH.

Dr. POLE, F.R.S., presiding.

Mr. J. GORDON (for Mr. Siemens) read a paper on *Rolling Seamless Tubes from Solid Bars or Ingots, by the Mannesmann Process*, of which the following is an abstract :—

The author referred to the circumstance that steel and toughened glass, though specially suitable, on account of their high qualities and strength, for use in the arts, had been somewhat neglected, owing to the difficulty of welding and cutting them. Attention was next drawn to the combination of strength with lightness which the tubular form admits of, and to the extensive use of tubes in construction which is likely to follow from a simple means of producing them. The different kinds of rolls hitherto employed, which are classed as the longitudinal, circular, and intermediate, were passed in review, and the process which forms the subject of the paper was then described. In the Mannesmann process a certain relation between longitudinal and rotary motion is maintained, so adjusted or each material to be worked, that a twist is imparted to the fibre resulting in great strength and toughness of the manufactured product. The following was the mode of manufacture : A bar is placed between conoidal rolls, where the diameter and therefore the velocity are least, and is gradually drawn forward into contact with those portions of the rolls which travel more and more rapidly. The rolls are so set that the space left between them for the passage of the bar decreases slightly, so as to cause a certain amount of material to be shifted. The action of the rolls preventing this material from being taken from the outside of the bar, it is consequently drawn from the interior, a hollow being first produced, and then a tube. A mandril may be employed to finish and smooth the interior and to enlarge the diameter of the tube. That the mandril is not required in the manufacture is proved by stopping the action of the rolls while the bar is passing through them, and breaking off the bar where the hollow is just commencing to form; the metal inside is found to be crystalline and bright, as before being cut there is a vacuum within the hollow, no air, of course, entering during the process of manufacture.

Several questions having been asked—

Sir FREDERICK BRAMWELL, F.R.S., spoke in favour of the adoption of the process, as possessing special advantages from a commercial point of view.

Colonel CUNNINGHAM, R.E., and Professor HELE SHAW, M.Inst.C.E., continued the discussion, and at its close Mr. GORDON replied, giving further explanations in answer to inquiries which had been made, menti oning, amongst other things, that the result of a frequent testing had been very satisfactory.

An interesting paper on the subject of *Gaseous Fuel* was read by Mr. J. EMERSON DOWSON, M.Inst.C.E., who explained that at the York Meeting of the Association in 1881 he described an apparatus for making cheap heating-gas by passing steam and air through incandescent fuel. Since then the apparatus has been considerably improved, and the gas made in it has been much used, not only for driving engines, but for heating in many industrial processes. The composition of the gas necessarily depends somewhat on the quality of the coal used and on the condition of the fire; the average composition is much the same whether the gas is made at the rate of 1,000 cubic feet per hour in a small generator or at the rate of 15,000 cubic feet per hour in a large one. In 1881 it was necessary for gas-engines to use five volumes of this generator gas for one of ordinary lighting-gas to develop the same power; since then some important modifications have been made in the Otto engines, and it is now necessary to use only four volumes. In 1881 only one engine of 3½ horse-power had been worked with the author's gas, but since then a large number of engines have been worked with it, one indicating over 80 horse-power. For more than four years Messrs. Crossley, the English makers of the Otto engines, have used this gas exclusively at their works for an average of 150 horse-power, and after a careful trial, extending over thirty-five weeks, they found that the fuel consumption was only 1·3 lb. per indicated horse-power per hour. At these large works there is no chimney except for the blacksmith's shop. Returns sent by eleven users of Otto engines working regularly in different places with the author's gas, and averaging 35 horse-power each, show an average fuel consumption of about 1·3 lb. per indicated horse-power per hour, which is less than half that required for the best steam-engines of equal power under ordinary working conditions. The results of other tests are given and seeing that all have been obtained under practical working conditions, the record is certainly satisfactory. Many letters have also been received testifying to the ease with which the gas plant can be managed. The author considers himself justified in saying that gas-power is now fairly launched in competition with steam-power, and he thinks, with the late Professor Fleeming Jenkin, that eventually the former will to a great extent supersede the latter. The results already obtained with this gas are good, but the author thinks it tolerably sure that even better results will be obtained when an engine is really designed to give the best effect with generator gas. It is well known that in the Otto engines each new charge of gas is diluted with a portion of the products of combustion from the previous charge, and this answers very well for ordinary lighting-gas. But as generator gas, such as the author's, has only about one-fourth the explosive power of the other gas, it is a disadvantage to dilute it with products of combustion, and he feels confident that sooner or later makers of engines will find it expedient to design all engines of large power specially for cheap generator gas. The best fuel to use for making the gas is anthracite, as it does not yield tar or other condensable products, and does not cake in the generator. Ordinary gas-coke can also be used with certain precautions.

Several instances are given of the use of this gas for heating of various kinds. At the Gloucester County Asylum it has been used daily for about five years. All the kitchen work for the staff and inmates is done with it, and there is no ordinary fire in the kitchen; about three hundred quartern loaves are baked with the gas every day, at a cost of about one shilling only for fuel. The gas is also used for two 12 horse-power (nom.) Otto engines, which pump water and drive a dynamo for electric lighting.

On the Continent several firms use this gas for singeing silk yarns and textile fabrics. It is also used by several linen manufacturers in the north of Ireland for stentering, which they formerly did with hot air. The cost of the gas somewhat depends on that of the fuel; but speaking generally, the equivalent of 1,000 cubic feet of ordinary lighting-gas costs from sixpence to one shilling.

Sir FREDERICK BRAMWELL said the subject dealt with in the paper was one in which he was much interested, for any invention which tended towards the method of driving engines by heat instead of by steam was most desirable. In his paper the author had alluded to some statements he (Sir Frederick Bramwell) had made in his address as President to the members of the Institution of Civil Engineers, and they were certainly very striking. He deplored the fact that in consequence of coal and slack being so cheap, people were indifferent to any proposal to substitute an improved method of using it. To him it was a terrible thing that they should be wasting by the extravagant use of coal the inheritance of those who were to come after them, and he therefore thought that anything which could be done to put a stop to it ought to be encouraged. The writer of the paper had hardly given credit to the steam-engine trials which he had referred to in his address the other evening. There was no doubt the engine was in the best order on that occasion, and it was worked by a very skilled person, who did not hesitate to display his great interest in the trial by turning up his sleeves and himself performing the duties of stoker. He (Sir Frederick) thought that the theory of the gas-engine was a good one, and that its results when worked with cheap gas would be satisfactory he did not doubt. In proof of this he had recommended its adoption instead of steam in a case where it was very desirable to reduce the fuel consumption. He looked forward most hopefully to the outcome of the subject brought before them.

Mr. FLETCHER asked Mr. Dowson whether he had contemplated the possibility of saving the ammonia which would be obtained in carrying out the system he had described.

Major-General WEBBER, C.B., who said he had watched the progress and development of the matter in question with considerable interest, did not think Mr. Dowson had given himself sufficient credit for the results he had obtained. He had worked in the direction of reducing nitrogen to a minimum without increasing the expense of manufacture. In this process of manufacture the apparatus converted the three fuels coal, water, and air into the results which were given in the analysis. He had not attempted to get rid of nitrogen, but to obtain the maximum quantity of hydrogen, and he was very much to be congratulated upon the effective mode he had adopted for the purpose. He might justly be called the pioneer of gaseous fuel. In Paris in 1881 one of these generators was at work under the gallery during the whole of the Exhibition, and it was not considered a source of danger, nor yet of inconvenience, to the number of valuable exhibits by which it was surronuded. The idea that danger would result from placing the generator in the basements of buildings in our towns was, therefore, entirely got rid of. The speaker described the successful manner in which an engine driven by this gas worked electric light machinery by night and farm machines by day, in a country place where the expense of coal was too great for steam to be used. Such a success as this was, in his opinion, worth all the written evidence which could be placed before them.

Professor HELE SHAW said that when the system was first described at the British Association meeting at York, in 1881, he asked a question as to whether if gaseous fuel were used for domestic purposes serious danger might not possibly result where carbonic oxide was used in large quantities. Mr. Dowson then replied that he proposed, when using it for such a purpose, to adopt means to enable the presence of carbonic oxide to be detected. This was another example of preconceiving a danger which might never happen, for they had now the experience of several years at the Gloucester Asylum and elsewhere to show that no inconvenience resulted, and he congratulated Mr. Dowson on the result. He felt certain that Mr. Dowson had given his figures honestly. He had also always stated that for an ordinary boiler this gas should not be used. The suggestion that gas should be generated in the boiler itself was a valuable one, and suggested a new departure. Water-gas would then be employed in a most satisfactory and economical manner. He asked for information as to the probable aggregate horse-power of the engines now working with the author's gas.

Mr. WILLIAMS asked whether any instances had been met with in which danger had resulted from the use of this gas. The danger from carbonic oxide was very great, and he had read of instances in which it had caused death without there being any smell or other indication of its presence. He understood that in the United States its manufacture was on this account restricted by the law in several parts of that country.

Mr. DOWSON, in replying, said he would be extremely sorry to be in any way unfair to the steam-engines. All he desired to do was to point out the different conditions under which they worked when on trial and on ordinary occasions. Experimentally, when he had worked the gas apparatus himself, he had brought down the consumption of fuel to 1·1 lb. per indicated horse-power per hour, but he had preferred to give the examples mentioned in his paper, as they referred to engines doing practical work under ordinary conditions. He thanked General Webber for his appreciative remarks, but must be careful not to take more credit than was his due. Sir William Siemens was unfortunately no longer with them, but it must not be forgotten that it was mainly due to him that the question of gaseous fuel had come prominently forward in this country. In answer to Mr. Fletcher's question as to the recovery of ammonia, he said he had not given the subject any serious thought. The quantity of ammonia was infinitesimally small when anthracite coal was used, so that it would hardly pay to recover it. Mr. Dowson proceeded to say that he knew of no one injured by this gas, and that it was no doubt a satisfaction to find that in such an institution as the County Asylum at Gloucester, which possessed a competent medical staff, who were necessarily exacting about the hygienic conditions, the use of this gas had been carried on for five years without any trouble at all having occurred. In concluding, Mr. Dowson acknowledged that there was a danger in the use of carbonic oxide, as there was also in using gunpowder, electricity, and other things if they were improperly handled. All that was necessary was to recognise the danger, and then take precautions accordingly.

The PRESIDENT expressed his deep interest in the matter under discussion, and congratulated Mr. Dowson on the success which had attended his investigations. He added that up to the time of his death the late Sir William Siemens was actively engaged on the subject, and the prize given by him at the Smoke Abatement Exhibition for the best method of utilising fuel was awarded to Mr. Dowson.

MONDAY, SEPTEMBER 10TH.

Mr. W. H. PREECE, F.R.S., presiding.

The special subject for the day's discussion was *Applied Electricity*, and the first paper was read by Mr. W. ANDERSON, M.Inst.C.E., upon *The Application of Electricity to the Working of a 20-ton Travelling Crane.* One of the travelling cranes in the foundry of the Erith Ironworks was originally constructed to be worked by hand, but preparations had been made to apply wire rope driving at some future time.

The crane is 39′ 6″ span, and consists of a pair of wrought-iron girders resting on end carriages running on an elevated line of rails. The gearing for hoisting longitudinal and for cross traverse is secured to the top of the main girders; the hoisting chain passes from the barrel at one end over a pulley at the other, then back to the pulleys in the cross traversing carriage, which runs between the main girders, through a falling block, and thence to an anchorage under the barrel at the extreme end of the main girders. By this arrangement the crane occupies a moderate height, and the hook can come within three feet of each wall.

The inconveniences and wear attending the employment of rope-driving gear induced the writer to try whether electricity might not be used with advantage. Messrs. Elwell Parker, of Wolverhampton, were communicated with, and these gentlemen undertook to supply the dynamo and a motor suitable for the peculiar requirements of a heavy crane. The dynamo, which was intended to give 50 ampères at 120 volts with 1,200 revolutions, was fixed in the main boiler-house of the works, and was driven by a small horizontal engine by means of a link belt. The leads from the boiler-house up to the conductor in the foundry are of 6 B. W. G. copper wire, while the conductor is formed of an angle-iron bar $2'' \times 2'' \times \frac{1}{4}''$, extending the whole 350-feet length of the shop, and has one face roughly ground and protected from rust by vaseline. The return current travels along one of the rails on which the crane runs. The motor, which is shunt wound, and constructed for 100 volts and 50 ampères, is fixed on the working platform of the crane beside one of the main girders. Its driving spindle carries a steel pinion which gears into a double helical spur wheel keyed on to a shaft which runs longitudinally on the top of the girder, and is connected by nests of three bevel wheels, with friction clutch connections to the three shafts which command the several movements of the crane, the means of using the hand-power being still retained.

Two sets of speeds are arranged for each of the movements, namely—

Hoisting .	. slow 3·4 ft. per min.,	fast 10 ft. per min.
Cross traverse .	,, 25 ,, ,,	,, 105 ,, ,,
Longitudinal traverse	78 ,, ,,	,, 213 ,, ,,

To provide against undue strains upon the motor an automatic magnetic cut-out is fixed on the crane, and for the purpose of varying the power and speed to meet the requirements of the foundry a set of resistance coils is provided, governed by a special switch by means of which different resistances can be introduced into the armature circuit of the motor, or the current can be cut off altogether, but so that it must be done by steps, and not suddenly. The connection between the motor and the conductors is by means of brushes pressed against them by elastic attachments. The handles for operating the several movements, the break lever, the switch, and the automatic cut-out are all collected together, so that a single attendant can readily work the crane from one spot.

The crane was set to work in June last, and has continued to act satisfactorily ever since. The advantages are very great in the facility of adaptation, as it is so easy to transmit the power from any point. The main boilers being always under steam, the crane is available at a moment's notice. The duty realised is about sixty-five per cent. of the power developed in the driving steam-engine. As far as can be judged at present, there is no special wear to apprehend. The conductors act satisfactorily, though a considerable length is in the open air, and the dust, heat, and smoke of the foundry do not appear to affect the working.

When first proposed, the writer was not aware of the existence of any other electric crane, but he has since learned that Messrs. Mather and Platt, of Manchester, have had one working satisfactorily for some time, and that there is one also in France.

A brief discussion followed. Several members, including Mr. J. L. STOTHERT and Sir FREDERICK BRAMWELL, F.R.S., asked questions as to the details of the working of the crane, and in reply Mr. ANDERSON said he thought there was not a weak point in it. The crane worked perfectly well, and without the least trouble.

In the absence of Mr. R. E. CROMPTON (owing to the sudden death of his eldest brother), Mr. GISBERT KAPP read that gentleman's paper upon *Recent Developments in Cowles's Aluminium Process.* The paper gave an account of the works erected at Milton, near Stoke-upon-Trent, and the writer stated that recent experience in America, at the works at Stockport, Ohio, showed conclusively that great economies were to be expected by increasing the size of the furnaces and the strength of the electric currents employed to work them, but no current larger than 3,000 ampères had been used up to the time the Milton Works were planned, where a dynamo giving a current of 5,000 ampères at 60 volts had been erected.

The discussion dealt principally with the details of the process which had been described by the paper, and Mr. KAPP, in his reply, stated that although he knew the cost of manufacturing aluminium at Milton, he was not at liberty to inform the section upon the point, but he might say it was exceedingly cheap.

Professor G. FORBES, F.R.S., read a paper upon *Electric Lighting in America*, drawing attention to the directions in which this industry had been developed in America. In landing in England they were particularly struck everywhere with the dimness of lighting in the streets. In America they could go to no single town without seeing abundance of arc lighting in the streets. He did not speak simply of the influential towns, such as New York, Philadelphia, or Boston; but in many out-of-the-way places in the most distant parts of the States, where gas had never penetrated, there the electric light had fixed its position, and was being used frequently; and not only the electric light, but other developments in the same way. But the progress made recently with arc lighting was not so striking to the Englishman as before, inasmuch as it was thoroughly established in America at the time of the British Association's visit to Montreal; but the progress had been with incandescent lights. The chief progress, he stated, in central station work had been in three directions—(1) arc lighting; (2) incandescent lamps with 3-wire system; (3) incandescent lamps with converters (Gaulard-Gibbs system). The number of arc lights was now about 300,000. The greatest progress had been by the work which Mr. Westinghouse had done in America. In electric lighting we in England had been stopped a great deal by what he might almost call the iniquitous Electric Lighting Act; and he regretted extremely, in the interests of the public and electric lighting generally, the Act passed this year, which had not yet put electricity on the same footing as gas. Those who had the matter at heart must regret that the Act had been passed, and so delayed the due recognition of the value of electric lighting. But he must say he did not think that the Electric Lighting Act was the only thing that had delayed their progress, because he saw that in electric traction and other developments of electricity the Americans had gone ahead with great energy indeed; and he certainly did not put it down to the want of capacity of our inventors. The best dynamo machines were all designed originally in England; the best arc lamps were in England; but with inferior machines and lamps in the States, he had noticed that they were determined, so long as the something they had would work well, to make it work well in the meantime, and to take up anything better whenever it might present itself. This go-aheadness was not in the inventor in the States, so much as in the men of capital who were also technically instructed—in fact, it was technical instruction which had developed enterprise in the States. Professor Forbes proceeded to detail some of the leading features of the Westinghouse central stations, and mentioned that there were at present 2¾ million incandescent lamps in use in the States. The general view, based upon experience in America, was that there was no danger of a breakdown ever happening in a properly organised station, with proper apparatus correctly laid down. He attributed a great part of the manufacturing success of American electric lighting plant to the fact that they fixed upon the types of machines they were going to make, they stuck to those types alone, laid down machinery enabling them to produce those types cheaply, and having thought out the system thoroughly at the beginning, they did not require to make a completely new type of machine for every order that came in. Thus they could manufacture their machinery cheaply, and in such a way that every part of the machine was replaceable.

Mr. H. EDMUNDS read the next paper, the subject being *A System of Electrical Distribution.* The author described the Edmunds system of electrical distribution, as now in actual use by the Cadogan Electricity Supply Company in London.

By this system groups of cells are placed in various portions of the district to be lighted, each group being divided into a given number of sections. If the group be divided into four sections it is arranged that three of these sections shall be sufficient to supply the local demand, while the fourth is being charged by a line from the central station. At given intervals the section which has been charged is removed from the main charging circuit, and switched into the local one, through which it discharges itself, its place in the charging circuit being taken by one of the other three, which, in its turn, is removed, and replaced by the next, and so on. Thus each section is kept charged, the charge never being allowed to fall below a certain point. Thus the great desideratum is achieved, viz., *constant supply*, quite independent of any accident on the line or at the central station. These changes are brought about automatically, by an instrument called a "distributor," consisting of a revolving shaft carrying cams, which in their rotation cause levers to rise and fall, and thus make and break the necessary contacts at the proper intervals. A polarised switch is attached, to prevent the current from entering the cells in the wrong direction, and also a voltage regulator, which keeps the batteries out of the charging main when they are fully charged, and connects them to it when they become exhausted, while a simple form of meter registers the amount of current consumed from day to day.

Mr. W. BAYLEY MARSHALL read a paper written by Mr. W. LOWRIE, upon *The Measurement of Electricity in a House-to-house Supply.* The paper described a method designed by the author and his colleagues for the purpose of measuring alternate currents as used for house-to-house distribution, with the converter system. As was well known, with such a system it was possible to get a current first in one direction, then in the opposite direction, and any chemical effect of the one current was destroyed in the reverse action. Messrs. Lowrie, Hall, and Kolle proposed to insert in the main an accumulator having an electric motive force of 2 volts. This electric motive-force during one-half alternation aided the ordinary current, during the other half opposed it. Thus, if the original electric motive-force was 100 volts, this became, when aided, 102 volts; when opposed, 98 volts. If, then, there were a deficiency in the circuit deposition would at one time take place, due to the electric motive force 102 volts, and during the reverse action only 98 volts, leaving the action of 4 volts over one-half the time—that is, of 2 volts over the whole time; and that gave the means of exact measurement as required.

The three papers were taken together for the purposes of discussion, and the CHAIRMAN said the system of measurement as described by Mr. Lowrie was actually in use at the present time, but it had been kept very quiet. He was rather afraid that it was difficult to derive information from the paper, but it appeared to him that there was the basis of a system which gave some accuracy of measurement and was novel.

Sir WILLIAM THOMSON, who was indistinctly heard at the reporters' table, alluded to the great cost of accumulation which must be taken into consideration. If the 50 volt lamps had stronger durability that would be an important matter, but it would not be sufficient to determine them if the whole cost of renewing 100 volt lamps was small. In all other respects the 100 volt lamps were the more convenient.

Mr. SELLON, Mr. S. WALKER, Major-General WEBBER, and Mr. KAPP continued the discussion.

Professor FORBES agreed with Sir William Thomson's remarks respecting the accumulators; they were working extremely well, but unfortunately they were still too costly.

In proposing a vote of thanks to the authors, the CHAIRMAN said he desired to protest against the idea that the inaction in this country was solely due to the Electric Lighting Act of 1882. That Act was in no sense or shape an interference with the action of corporations. Some fifty or sixty corporations obtained Provisional Orders under the Act of 1882, but never carried out the provisions of those orders. The fact was that the system of electric lighting had not even yet become sufficiently advanced for corporations to justify themselves in investing the money of the ratepayers in electric lighting. It was impossible not to be impressed with the wonderful activity of the Americans, but he considered that in this country it was best to work slowly and with certainty, as was being done at the present time. In a year or two they would be able to learn all that was necessary in England, and they would go ahead and establish a system infinitely better than anything now existing. He should make it his duty to recommend to the Institute of Electrical Engineers to appoint a strong committee, to take into consideration the relative advantages of the 100 volt and 50 volt lamps, but he was himself favourable to the 100 volt.

Mr. R. PERCY SELLON read a paper upon *Electric Light Applied to Night Navigation upon the Suez Canal.* The author said that the largely increased traffic since 1878 gave rise to inconveniences and resulted in frequent delays. Hence shipowners put pressure upon the Canal Company to afford facilities to cope with the increased traffic. In 1885 the average time occupied in passing through the Canal (eighty-seven geographical miles long) amounted to from forty to forty-five hours.

To meet the general demand the Canal Company introduced various improvements, and in the year 1884 commenced experiments to determine the practicability of navigation during the night by means of the electric light.

Owing to difficulties incident to the case, these experiments occupied two years, resulting in an authorisation issuing from the Canal Company in December, 1885, permitting vessels of war and mail boats to navigate some portion of the Canal if provided with suitable electric lights.

In April, 1886, the s.s. *Carthage*, of the Peninsular and Oriental Steam Navigation Company, for the first time made the prescribed passage by night successfully, followed shortly by others.

The success of these results encouraged the Canal Company to extend the authorisation to vessels of all classes, and to throw open the whole length of the canal to them; and in February, 1887, this authorisation was made public, subject to certain regulations laid down by the Canal Company.

Mr. FRANK BRAIN, M.E., dealt with the subject of *Electricity as Applied to Mining*. This paper was written from the mining engineer's standpoint, briefly sketching the known applications of electricity to mine working up to the present date.

The writer regretted there was very little known to add to what had already been made public. He could not but express surprise that a power which it is apparent had now passed the range of experiment, and is developing itself economically and efficiently, should not have been made greater use of than appeared to have been the case hitherto.

Mr. NICHOLAS WATTS read a paper on *Miners' Electric Safety Lamps*, in which he described the following lamps: the Swan, the Schanschieff, the Pitkin, the Walker, the Portable Electric Syndicate's Lamp, and the Vaughton.

A paper by Mr. J. W. SWAN, on *An Automatic Fire-damp Indicator*, was taken as read, that gentleman not being present; and Mr. S. WALKER and Mr. CARPENTER joined in a very brief discussion on the three papers.

TUESDAY, SEPTEMBER 11TH.

The business of the section did not commence until twelve o'clock, owing to a joint discussion with Section A on *Lightning-conductors*.

Mr. W. ANDERSON, M.Inst.C.E., presiding.

Mr. E. A. COWPER opened the proceedings by reading a paper on *An Improved Seismograph*, remarking at the outset that in order to register the motions of the earth, N., S., E., and W., it was, of course, necessary to have a heavy weight as little as possible affected by the motion of the earth. Parallel motions, or "compound pendulums," had been used with good effect, but a simpler and more effective plan would be to place a heavy flat weight on a piece of glass with three small "steel bicycle balls" below, resting on another flat or slightly hollowed plate, so that when the vibrations of the earth ceased the weight would slowly return to its normal position. In place of glass plates, ground porcelain or metal plates might be used. The weight might be brought back to its normal position by a light pendulum, and then all the plates must be flat and of common plate-glass. Then two levers acted on from the centre of gravity of the weight, and multiplying the motions, would register, on long strips of paper, the vibrations, N. and S.' E. and W., the paper, of course, being driven by clockwork, and allowed to start as soon as the vibrations of the earth commenced. Then the vertical vibrations (which had always been the most difficult to obtain a record of) could be very thoroughly ascertained and recorded by the following simple arrangement: A light steel iron or steel tube, closed at the top, like a small gas-holder, was inserted in a tank of quicksilver, the centre space inside the gas-holder being occupied by an empty tube, so as to reduce the weight of quicksilver very materially. On exhausting the gas-holder with a "Sprengel pump" the tank would rise, owing to the pressure of the atmosphere below it, until the column of mercury balanced the atmosphere; thus the weight of the tank and mercury in it being, in fact, supported by the *atmosphere*, and the gas-holder being attached to the earth, might rise or fall, and yet scarcely affect the tank in any way, and a rod from the tank to a multiplying lever attached to the earth and recording apparatus would record the vertical vibration on a strip of paper moved by the clockwork.

Professor H. S. HELE SHAW read a paper, prepared by himself and Mr. E. SHAW, upon *the Friction of Metal Coils*.

A discussion upon details followed, in which Professor UNWIN, Mr. W. W. BEAUMONT, and the CHAIRMAN took part.

Mr. PERCY K. STOTHERT thought it might be of interest if he described the form of rope brake which had been applied to cranes of very large size—*i.e.*, fifty-ton concrete block setting-machines. Four lengths of three-inch circumference ropes were placed side by side and sewn together, and afterwards lapped round by spun yarn; one end of the band was attached to a fixed point on the crane, and the remainder passed four or five times round a cast-iron barrel on the second and third motton shaft; the other end being held in the crane-driver's hand, a very slight pull was sufficient to hold the full load, and an equally slight pressure in the other direction was sufficient to lower the fifty tons, the driver thus being able to lower at any required speed. The only objection to this method was that owing to the heat generated, the rope very soon burnt, and had to be frequently renewed, so he thought Prof. Hele Shaw's system of spiral springs could be applied to the lowering and suspension of these heavy bodies.

Professor M. F. FITZGERALD explained a number of *Steam-engine Diagrams*, and in the discussion several members expressed their opinion that he was pursuing his studies in a direction with most useful results.

Mr. W. W. BEAUMONT read a paper on *Efficiency of Steam at High Pressures*.

Professor UNWIN, Professor FITZGERALD, Mr. H. DAVEY, and others discussed the paper briefly.

Mr. H. C. VOGT dealt with the subject of *Revolving Sails, or Air-propeller*.

Several speakers characterised the scheme as a novelty, but agreed in the idea that it was thoroughly worthy of investigation.

The CHAIRMAN said he had determined to fit out a steamer in the manner described, in order to see the results which might be obtained.

ANTHROPOLOGICAL SECTION.

(*Continued from p.* 272.)

MONDAY, SEPTEMBER 10TH.

Lieut.-Gen. PITT-RIVERS, D.C.L., F.R.S., presiding.

A paper was read by Miss A. W. BUCKLAND on *Necklaces in relation to Prehistoric Commerce*. The object of this paper was to trace the geographical distribution of various forms of necklaces and beads, as indicating some sort of commercial intercourse between the races among whom they are found either in present use, or among the relics of the past.

Among the ancient cave-dwellers of Europe, teeth of men and animals, bored for suspension and intermixed with shells and pieces of bone, were used as necklaces, and similar necklaces are still worn by savages in almost all parts of the world; but in the Andaman Islands necklaces are made of pieces of human bone, and of bones of animals, not bored, but bound to cords, and wood is sometimes made to imitate bone. The same singular substitution exists in the Admiralty Islands, where also human bones are used as neck ornaments. Necklaces formed of discs of white, purple, and red shell, cut with much care and labour from large sea-shells, are used by natives all over America and across the various groups of the Pacific to Japan, China, and India, where they are worn by the Nagas. These shell discs, known in America as Wampum, form the money of the Red Indians, and are also used as money by the Solomon Islanders. Similar shell discs are found in ancient graves, not only in America, but in Europe; whilst in Africa, ostrich egg-shell discs of the same size and threaded in the same manner, with pieces of skin substituted for the dark shell, are made and worn by Bushmen, Niam-Niams, and other wild tribes in the interior. Similar ostrich egg-shell discs are found in ancient Egyptian and Etruscan tombs, showing prehistoric intercourse between Etruria and Egypt, or the interior of Africa.

The pendants accompanying these necklaces are almost always teeth or shells cut in the form of teeth. The beads used for necklaces and found among ancient relics are of various substances, such as bone, serpentine, gold, silver, bronze, tin and glass, and are often made so as to represent several discs or beads joined together. Beads of this kind are found in the Swiss lake dwellings, in Spain, in Britain, in Hissarlik and Mycenæ, and of a later date in Livonia and Abyssinia.

Beads of amber, which formed such an important article of commerce in prehistoric times, are found among relics of the Stone Age, and have also been discovered in tombs belonging to the Bronze Age, in all parts of Europe, in Egypt and India, several trade routes being known, whereby amber found its way from the Baltic to the Mediterranean. Of glass beads the most remarkable are those known as adder-stones, still used as a charm to cure cattle diseases. Beads of this kind of one particular pattern known as chevron beads have been found in various parts of Europe, in Great Britain, in Egypt, in the Pelew Islands, and also in ancient graves in Canada and Peru. Similar glass beads are dug up in Ashantee and highly valued, forming part of the royal jewels. Beads of the same shape, and from the markings upon them, probably of the same kind, appear adorning the necks of monarchs on the sculptured slabs brought by Layard from Assyria.

There is also a melon-shaped bead of various materials, very widely distributed, being found in ancient graves in Mexico, as well as in Assyria and all over Europe.

Many peculiar glass beads are found in Ireland, resembling those of Egypt and Greece, although perhaps of native manufacture copied from older types, and it may be fairly said that the history of necklaces is the history of commercial intercourse both in prehistoric and in modern times.

Major C. R. CONDER, R.E., communicated a paper on *The Early Races of Western Asia.*

Mr. J. THEODORE BENT discoursed on *Discoveries in Asia Minor.*

A note on *The Definition of a Nation* was read by Mr. J. PARK HARRISON, who said that he did not propose to go into the archaic meaning of the word "Nation," but simply to elicit an opinion as to the growing misuse of the term at the present day. He referred to the definitions by Johnson, Todd, and Latham, and also to that by Dr. Worcester, in the American Dictionary of 1881. They all, excepting Todd, omit any reference to race or language. As regards language, it is admitted by ethnologists that it is no test of race. Numerous populations are known to have entirely given up their own tongue and adopted the language of their conquerors. This was so with the earliest races in Great Britain and Ireland, when subjugated by the Kelts; whilst as instances of voluntary change of language, the Scandinavian people in Ireland, who at the time of the Conquest, were found to be a third of the entire population, learnt Celtic, and styled themselves "Irish," an example subsequently followed by the earlier English settlers in Munster and other parts of Ireland.

The definition of the term nation in the dictionary of the French Academy also omits race and language, and is by far the best, and possesses the greatest authority. It is this—"The entire population born or naturalised in a country, and living under the same government." This definition applies to England as well as France, both of which countries contain a population composed of four different races, none of whom by themselves are, or ever were sufficiently numerous in either country to constitute a nation.

There is consequently no Saxon, Danish, Keltic, or Iberian nationality in the British Isles. The several races were merely offshoots of great nations. Their proper nationality was lost when they separated from the parent stocks—very much as individual emigrants lose their former nationality when they obtain letters of naturalisation in a foreign country.

Sir JOHN LUBBOCK said it was convenient to speak of the people of our country as English, but as a matter of fact they were an extremely composite race. In different parts the population was made up of elements in very different proportions. The East of England was ethnologically similar to the East of Scotland rather than to the West of England, and the West of England was ethnologically similar to the West of Scotland rather than to the East of England. In considering the qualifications of the race inhabiting these islands they found some were more Saxon, some more Celtic, others more Iberian in blood, but there was something in which the people of those islands differed from the Saxons, Celts, or Iberians of the Continent, and the reason of this was that they came in very small boats, and without women, and men of the tribe not unnaturally intermarried with the women of the island. The result was they had in this country a composite race entirely different from any other race in the world, except in their own colonies, where they found the race reproduced. He thought all the great races of the world had occupied this country with the exception of negroes, and one or two other races confined to the torrid regions. They saw cropping up amongst them even the Australian and the Mongolian types.

Dr. E. B. TAYLOR considered, as anthropologists, they wanted a more accurate sense in which they could use the words family, clan, tribe, nation, etc.

Professor SAYCE briefly dealt with the subject from a linguistic point of view.

Dr. J. BEDDOE deprecated the use of the word "nation" in an anthropological sense, as the definition belonged rather to politics than to anthropology, and these two they were not desirous of mixing.

Dr. EVANS and other gentlemen joined in the discussion, and the PRESIDENT said he thought they would all agree that a nation was a people who, having a great and glorious history, had the firmness and determination to maintain it.

Mr. J. W. BLOXAM, M.D., in the absence of the author, Mr. J. S. Stuart Glennie, M.A., read an abstract of a paper on *Pelasgians, Etruscans, and Iberians; their Relations to the Founders of the Chaldean and Egyptian Civilisations.*

A paper entitled *Notes on the Hyksôs, or Shepherd-Kings of Egypt,* was read by the Rev. HENRY GEORGE TOMKINS.

In the discussion which ensued, Professor A. H. SAYCE said he could no longer subscribe to the opinion that between the Hyksôs and the Hittites there could be any racial connection.

TUESDAY, SEPTEMBER 11TH.

Lieut.-General PITT-RIVERS, F.R.S., presiding.

The first paper read was by Miss R. W. BUCKLAND, on *King Orry's Grave, Isle of Man.* The authoress gave a description of a visit she paid last year to the ancient monument in the Isle of Man known locally as "King Orry's Grave," a name which was repudiated by antiquaries as misleading, but which having crept into guide-books, and even into archæological works, might perhaps be retained for the present. This monument possessed certain peculiarities, sufficiently uncommon to render it deserving of especial notice. It did not seem easy at present to trace the plan of the monument as described by Oswald, but the tall monolith remained in position, and some of the chambers, especially at the west end, were intact, although the covering stones were gone. The authoress, who also forcibly dealt with other monuments in the Isle of Man, contended that these monuments belonged to a date far earlier than that assigned to them by those who would refer them to King Orry and his successors.

A paper on *Sun-myths in Modern Hellas,* by J. THEODORE BENT, was then read. The author said, The personification of the sun amongst the peasants of modern Greece compares well with the legends of classical times; his beauty, power, and strength endow him with regal attributes, and he is supposed at night-time to seek his kingdom, and live in a palace where his mother tends upon him. We have also the Sun's wife and the Sun's daughter, and can compare the Macedonian legend of Heliojenni with the Homeric myths of Perse and her children Circe and Aïtes. The Sun, as messenger, may be compared with the words of the dying Ajax.

The connection between sun-worship and that of the prophet Elias is very marked in modern Greece. Elias looks after rain, and is the Greek St. Swithin. Churches to him are always found on sites of ancient temples to Apollo. The Macedonian ceremony of Perperouna has a connection with other prayers for rain offered up to St. Elias. In a MS. from Lesbos this idea of union between St. Elias and a power over the elements is clearly shown. Taygetus, in Laconia, shows too the same connection.

There is a connection between sun-worship and St. George; the κάρα fires are lit on his day, and the connection is noticeable not only in the islands, but in Macedonia, where a curious swing ceremony is performed on St. George's Day, in honour of the Sun's bride having been swung up to heaven on that day. Also there is a close connection between St. George and St. John, the universal day for lighting fires, on the eve of the summer solstice.

Mr. J. HARRIS STONE, M.A., F.L.S., F.C.S., communicated a paper on *The Ancient Inhabitants of the Canary Islands,* of which the following is an abstract: The author stated that the name *Guanche,* though generally used for the old inhabitants of all the seven islands of the Canary group, should properly be only applied to the ancient inhabitants of Teneriffe. The ancient inhabitants of these islands were ignorant of the use of metals, and up to 1402, when the conquest first began, had to all practical intents remained apart from the civilisation of that day. They were a branch of the great Berber race, and probably also a tribe of that white dolichocephalic race of cromlech-builders which at a very early period swept through Europe. Their connection with the ancient Egyptians was noticeable in many traits and customs. The ornamentations in caves and on pottery which the author had come across in his travels in each island of the archipelago were Egyptian in character. The method of embalming the dead, particularly the practice of removing the entrails by a slit made with the *tabona* and the wrappings of the corpse, was very similar to that employed by the lower class of Egyptian embalmers. Though the ancient inhabitants of all the islands had so much in common, there were so many specific differences in their languages, manners, and customs that the conclusion was almost forced upon the investigator that they must originally have been peopled by more than one tribe of the same race.

The author had examined a large number of skulls in collections in the islands, and found them very European in contour and general appearance. In a large proportion of those in the collections in the islands he had noticed a peculiar indentation in the frontal bone, usually the left, and to his surprise found that of the twenty-six skulls at the Royal College of Surgeons, no less than fifteen possessed this mark, and of these ten on the left frontal bone.

The ancient inhabitants are now quite extinct as a separate race, but the author in his travels had noticed several traits, manners, and customs of the present inhabitants which were clearly, in his opinion, derived from the old race. The food *gofio* and its method of making and eating; the number of cave dwellings and villages; the still prevalent inter-insular jealousy; the size and great physique of the men of the Purpurariæ; the confiding, generous, hospitable character of the Conejeros; the use of the vaulting pole; the general absence of bigotry and religious intolerance: the preference to this day of the Gomeros to carry baggage on the head; the abomination of butchers; the torchlight fishing; the method of laying-out the dead; the wit of the Palmeros; the cleverness with which buildings are constructed with stones without mortar; the honesty of the Canarios; the unusual beauty of the peasant-women, were points alluded to by the author in illustration of his assertion.

The position of women was considered at some length, the author bringing forward many facts to show that they held a far higher position in the social scale than was usual among ancient nations.

Canon TRISTRAM said he had listened to this paper with much interest, as he was just fresh from the Canaries, having spent twelve weeks there. He had paid considerable attention to the subject which had been brought before them by Mr. Stone. He agreed with the author in everything, except when he said the "Guanche" had gone. He must allow that the inhabitants of the Canaries were free from all the vices which characterised his countrymen, and possessed all the virtues they could not find in Spain. Who were the European aborigines? what were they? and did any of them remain? He thought, with Mr. Stone, many of them did remain, and though the land might be lost, yet the race was not. While in the islands he visited every village, and wherever he went he found the "Guanche" the most truthful and honest people in the world. In the three islands he visited he never heard a muleteer utter an oath. He could not agree with the author that there was the slightest Egyptian trace in the inhabitants of these islands. No more Egyptians, he thought, than negroes. There was not the slightest trace of their having heard anything of Christianity or Mohammedanism. In conclusion, he asked if any reason had been found why the ancient people of the islands did not use boats.

Other speakers followed, and the author, in answer to Canon Tristram, said he had thought over the question why boats were not used by the ancient people, but he could give no satisfactory reason.

The Rev. HENRY GEORGE TOMKINS discoursed on *Worlebury, an Ancient pre-Roman Stronghold at Weston-super-Mare.*

The last paper was read by Mr. F. HAVERFIELD, on *Pre-historic Objects Found at Broos, in Hungary, by Miss Von Torma.*

In connection with this section there was an anthropological laboratory for the use of members.

CUSTOMS OF SAVAGE RACES.

LECTURE DELIVERED BY SIR JOHN LUBBOCK, M.P., F.R.S., TO THE WORKING-CLASSES OF BATH.

THE subject on which I shall have the honour of addressing you this evening is one of such vast extent, that I shall make no apology for entering on it at once, without any introductory remarks. I do not propose to describe the arms or implements, houses or boats, dress or food of savages—all no doubt very interesting, but which time will not permit me to deal with. My object will rather be, if possible, to illustrate the mental condition and ideas of the lower races of men.

Our empire contains representatives of almost every race of men, and every stage of human progress. To understand their wants and ideas, is not only an intellectual exercise, but a political problem of great national importance. Even those who consider that man was civilised from the beginning, and who look upon savages as the degenerate descendants of much superior parents, must still admit that our own ancestors were once mere barbarians, and may find therefore much interest in this study; but it no doubt appears far more important to those who think that the primitive condition of man was one of savagery, and that the history of the human race has, on the whole, been one of progress. No one, of course, supposes that every people must necessarily progress; but those which do not advance will assuredly be replaced, sooner or later, by more worthy races. Nor certainly do our modern savages in all respects reproduce the condition of our ancestors in early times; on the contrary, even the Australians have now a system of complex rules and stringent customs which have grown up gradually, and cannot have existed originally; it does, however, seem that from the study of modern savages we can gain a fairly correct idea of man as he existed in ancient times, and of the stages through which our civilisation has been evolved. At the same time the study is by no means easy, because many things which seem natural and obvious to a savage appear to us absurd and inconsequential. Moreover, if we often find it far from easy to understand savages, they naturally have much greater difficulty in understanding us. All over the world nations on first seeing white men have taken them for ghosts or spirits. Our weapons, tools, animals, in fact all our belongings are at first a source of great wonder. An Australian tribe, for instance, when they first saw a waggon drawn by oxen were much puzzled as to what the oxen could be. It afterwards appeared that some thought they were spirits, because they had spears on their heads, while others maintained that they were the wives of the white men because they carried the burdens, which among Australians is the special duty of women. Again, the modes of salutation among savages are sometimes very curious, and their modes of showing their feelings quite unlike ours. Kissing seems to us so natural an expression of affection that we should expect to find it all over the world, yet it is unknown to the Australians, the New Zealanders, the Paponans, and the Esquimaux and other races. I mentioned this fact about the negroes in one of my books many years ago, never supposing that it would give any offence, and was surprised to receive a most violent anonymous letter from a negro of St. Domingo on the subject. He abused me in unmeasured terms, and ended by saying that he would like to drink my heart's blood. The Polynesians and the Malays always sit down when speaking to a superior: in some parts of Central Africa it is considered respectful to turn the back to a superior.

Captain Cook asserts that the inhabitants of Malliedo, an island in the Pacific Ocean, show their admiration by hissing; the Todas of the Neilgherry hills in India are said to show respect by raising the open right hand to the brow, resting the thumb on the nose; it is asserted that among the Esquimaux it is customary to pull a person's nose as a compliment; a Chinaman puts on his hat where we should take it off, and among the same curious people a coffin is regarded as a neat and appropriate present for an aged person, especially if in bad health. Among the Yombas of West Africa, who take great care of their teeth and scrub them well at least three times a day, an old tooth brush is regarded as a touching present, not being so much intended for actual use indeed, but rather as conveying a sort of implied message that as the sender took the greatest care of his teeth and used his tooth-brush continually, so his friend was also in his thoughts morning, noon, and night. (Gollmer, Jour. Anthr. Hist., 1884, p. 176).

A mistake made by Dampier led to very serious results. He had met some Australians, and apprehending an attack, he says, "I discharged my gun to scare them, but avoided shooting any of them, till finding that we were in great danger from them, and that though the gun had a little frightened them at first, yet they had soon learnt to despise it, tossing up their hands and crying pooh, pooh, pooh, and coming afresh with a great noise.

I thought it high time to charge again and shoot one of them, which I did." Thus this wretched savage lost his life because Dampier did not remember that pooh, pooh, or puff, puff, is the name which savages, like children, apply to guns.

Mr. Taplin, a missionary to whom we are indebted for an excellent account of the natives of Australia, tells a curious story of this kind against himself. He asked the native word for "sins," but as the Australians do not use the letter "s," but replace it by "th," they misunderstood him and gave him the word "*Yrothelum*" which means thin, and he used this for a considerable time before he found out his mistake. I must, however, let him tell it in his own words. "When," he says, "I asked the word for sin, they gave the one for 'thin,' and so I was led into representing that it was hateful to God for men to be thin: that they would be condemned for it. So they came to the conclusion that it was pleasing to God for people to be fat. In fact, I had been telling them that all lean people went to hell, and fat people to heaven." (Rev. G. Taplin, "The Narrinyeri. Account of the South Australian aborigines," page 86.) Some ideas, indeed, which appear to us inexplicable and fantastic, are very widely distributed. For instance, medicine; our system seems so natural: send for doctor, get prescription, pay him, take medicine. By no means. In some cases a sorcerer is sent for, who frightens evil spirits by making a noise. In others, a wizard comes with a charm on a board. In others, a doctor drinks his own medicine. In China, they pay the doctor while well.

In many parts of the world a man is strictly forbidden to speak to his mother-in-law. Again, probably every Englishman who had not studied other races would be astonished to meet with a nation in which, on the birth of a baby, the father and not the mother was put to bed and nursed; yet though this custom seems so ludicrous to us, it prevails very widely.

Commencing with the Abipones of South America, Dobritzhoffer says that "no sooner do you hear that a woman has borne a child than you see the husband lying in bed, huddled up with mats and skins, lest some ruder breath of air should touch him, and for a number of days abstaining religiously from certain viands; you would swear it was he who had had the child. . . . I had read about this in old times, and laughed at it, never thinking I could believe such madness . . . but at last I saw it with my own eyes." Other travellers mentioned the existence of a similar custom in Kamskatka, in part of China, in Borneo, in the North of Spain, in Corsica, and in the South of France, where it was called "faire la Couvade." The reason probably was that the father and child being regarded as intimately connected, it was supposed that any exposure of the one to cold, wet, or other unwholesome conditions would be injurious to the other.

Again, it might have been thought that forms and ceremonies were especially characteristic of civilised life; but here again the actual fact is the very reverse of what might have been not altogether unnaturally expected.

> "Custom hangs on them with a weight
> Heavy as frost, and deep almost as life."

The salutations, ceremonies, and legal proceedings of savages are, in fact, most tedious and complex. Eyre mentions that in their intercourse with one another the natives of Australia are extremely punctilious. Captain Burton states that the Egbas or West African tribe spend at least an hour every day in troublesome ceremonies and have a great variety of salutations suitable for every possible occasion.

Another subject on which savages entertain ideas different from ours is that of relationships. It used to be supposed that the original family was founded on the Patriarchal basis—that the father was lord and head of the family; and that the ideas of relationships were founded, like ours, on marriage and descent through the male line. We regard a child as related equally to its father and its mother. We make no difference between a father's brother and a mother's brother on the one hand; a father's sister and a mother's sister on the other. Recent researches, however, especially those of Bachofen, Maclennan, Morgan, and Tylor, have not only modified, but I must say, with all respect to the justly high authority of my friend, Sir H. Maine, revised our ideas on these subjects. Herodotus long ago observed that the Lycians "had this peculiar custom, wherein they resemble no other men, they derive their names from their mothers." So far, however, from this being peculiar, it is, as a matter of fact, very general. Among most savage races when a woman marries she does not become one of her husband's clan, but remains still a member of her own. Now, the children cannot belong to both. Consequently if they are regarded as belonging to the mother's clan, they cannot be included in that of the father. But among the lower races it is most usual that descent is traced through the mother. Hence a man's children do not belong to his clan, but his sister's children do; and hence again, what appears to us the singular anomaly that among many races a man's heirs are not his own, but his sister's children. But though in this respect the woman occupies an important position, she is, on the whole, greatly to be pitied. The Hindoo maxim "never strike a wife even with a flower" is, no doubt, comparatively speaking, of modern origin. In fact, the original idea of marriage was one mainly of possession. The wife was the property of the husband. In many cases, no doubt, she was a war captive. Hence, I have suggested, arises the very prevalent custom of marriage by capture. Originally a stern reality, it became to be a mere symbol. All over the world we find that even after all the arrangements have been satisfactorily and amicably concluded, the bridegroom makes a pretence of carrying off the bride by force. Thus in the Phillippine Islands, when a man wishes to marry a girl, her parents send her before sunrise into the woods. She has an hour's start, after which the lover goes to seek her. If he finds her and brings her back before sunset, the marriage is acknowledged; if not, it is broken off.

In some parts of Australia when a man marries, each of the bride's relations gives him a good blow with a stout stick, by way I suppose of a warm welcome into the family.

Among the Kalmucks of Central Asia, again, the marriage ceremony is very romantic. The girl is put on a horse and rides at full speed. When she has got a fair start the lover sets off in pursuit; if he catches her she becomes his wife, but if he cannot overtake her the match is broken off; and we are assured, which I can well believe, that a Kalmuck girl is very seldom caught against her will.

If time allowed I could show you that this idea of capture in marriage occurs almost all over the world. Hence no doubt the custom of lifting the bride over the doorstep, which occurs or did occur among the Romans, the Redskins of Canada, the Chinese, the Abyssinians, and other races. Hence also perhaps our custom of the honeymoon, and hence may be after a wedding, things are thrown, as McLellan has suggested, in mock anger after the departing bride and bridegroom. It is remarkable how persistent are all customs and ceremonies connected with marriage. Thus our bride cake, which so invariably accompanies a wedding, may be traced back to the old Roman form of marriage by confarreatio or eating together, and is found also in other parts of the world, as, for instance, among the Iroquois of North America. It must we know be cut by the bride, because it is the duty of the wife to prepare food for her husband.

The prevalence of marriage by capture naturally led to the impression that a woman who was captured was relieved of all responsibility. It was no part of her duty to resist—which would indeed have been useless. On the contrary, the very fact of her capture itself constituted a legal marriage. This, I have ventured to suggest, explains what would otherwise be a great difficulty, namely, the position assigned to Helen in the Iliad. From our point of view her acceptance of Paris as a husband would be a great blot on her character. Yet not only among the Trojans generally, but by the venerable Priam and the virtuous Hector, she is always treated with affection and respect. The point seems to me of interest, because it throws light upon what from any other point of view seems inexplicable in the great Greek epic.

Again, we recognise only one kind of marriage, but in many parts of the world there are two or more totally distinct kinds of marriage, in which the relation, rights, and position of the husband towards the wife are altogether different. On the whole, it is satisfactory to see that as races progress the position of woman rises too.

It has always seemed to me that one of the clearest proofs of the low mental power of savage men is that afforded by arithmetic. For instance, in no single Australian language is there any word for "five." They said, "One, two, two, one, two, two, many." The fingers are greatly used as a help in these simple calculations, and all over the world we find the word "hand" standing for "five" in reference to our five fingers; indeed, if we had had six we should probably have had a duodecimal notation, which would have been in many respects a great improvement on our present system. Even our own word "five" is a case in point, though it is so much worn by use that its original form is almost unrecognisable. The original Indo-European word for "hand" is found little altered in the Persian "Penze." In Greek "Penze" becomes πεντε, in German "funf," whence our "five." The Punjab is the country of "Five rivers" from *Penge* "five," and *ab* "water," a root which we find again in many Celtic names, as for instance in Aberdeen, Aberystwith.

As might naturally be expected, none of the lower races have made any great advance in art; they have in many cases made a beginning, and those beginnings are very far indeed from being without interest.

The earliest works of art which we possess are rude sculptures and drawings, some of them far from deficient in spirit, which have been found in caves in Western Europe, and which appear to belong to the period when the Mammoth and Woolly-haired Rhinoceros still lived in England. Some of them indeed clearly appear to be representations of the former animal.

Books and writing have always appeared very mysterious to savages—and no wonder. On one occasion a "missionary sent a native to one of his colleagues, with some loaves of bread and a letter stating their number. The messenger ate a part of the bread, and the theft was consequently discovered. Another time when he had to deliver four loaves, he ate two of them, but hid the accompanying letter under a stone while he was engaged, believing that his conduct would not be revealed this time, as the letter had not seen him in the act of eating the loaves.

The Minatarrees (a North American tribe) once seeing Mr. Catlin intent over a copy of the New York *Commercial Advertiser*, were much puzzled as to what he could be doing, but at length concluded that his sight was weak and that was a cloth for sore eyes. One of them eventually bought it at a high price.

(To be continued.)

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

My visit to M. Agassiz—as the date indicates—occurred long before he left Switzerland for America, but I found that he spoke English freely. I was then the proud proprietor of a grand and decidedly original theory of the origin of mountains, and improved the occasion by submitting it to him.

I started my theory by assuming, in the ordinary gratuitous, matter of course fashion, that the earth was once an intensely heated sphere of fused matter, which has since cooled down and become solid. This being taken for granted as usual, my great deduction logically and necessarily followed. This was, that in such slow cooling of silica, the silicates, etc., would crystallise, and that the size of the crystals would be, and as we find they become in artificial crystallisation, proportionate to the whole mass and the slowness of cooling; therefore, when this world of ours first solidified, those parts of its surface where the quartzites and similar material prevailed, presented on a large scale a group of pyramidal eminences, corresponding to those we find on a small scale in drossy cavities and other places, where such material has been fused and slowly cooled. These pyramidal crystals were the great mountains of the earth.

This idea seemed to be confirmed by the fact that the highest mountains of the Alps, etc., were mostly composed of silicates, etc., with crystalline proclivities, and I had measured and recorded by means of a simple instrument the visual angles of a large number of the well-known "*aiguilles*" and summits of the Alps, many of which—such as the *Silberhorn* of the Jungfrau and the *aiguilles* of Mount Blanc—are remarkably geometrical and crystal-like in their form, and appearance. The first blow to my grand theory was presented by Mont Blanc itself, which instead of appearing as the master crystal of the group, is a rounded mass, its summit receiving the name of the "dromedary's hump."

This, however, I parried by making an ascent, and thereby learned that Mont Blanc actually has a similar structure to the pyramidal aiguilles around it, and that the rounded appearance is due to the snow that fills up all their hollows, leaving only the summits of the pyramids visible just above the snow such summits being the *Grands Mulets*, the *Rochers rouges*, etc., etc., that are seen in the course of the ascent.

I still believe that such is the real structure of this mountain, though I am not aware that it has been so regarded by any other observer.

Agassiz listened attentively to my exposition of the grand theory, used some complimentary expressions in reference to its ingenuity, etc., and then proceeded to demolish it by referring to what I saw around me, to the block on which we stood, and the material on the great moraine over which I had travelled that morning, all of which showed that even if such crystallisation had ever occurred the pyramids would have been obliterated by weathering and glaciation long ago. He admitted, however, the possible existence of something like crystalline cleavage planes having produced the curious uniformity that I had observed in the summit angles of different mountains composed of similar material.

This conversation showed that Agassiz at that time had strong faith in the potency of glaciation as a shaping agent of the earth's surface. Subsequent researches have justified this, so far as the Arctic and temperate zones are concerned.

The scene presented from the Hotel des Neufchatelois was very grand and characteristic. We stood upon a wide expanse of ice, having the appearance of a solidified river of great width, with great blocks of stones floating on its surface, some standing on stalks like gigantic mushrooms, others, as already described, forming the great ridge of the medial moraine.

Looking up the ice river, the bold wedge-shaped promontory of rock, the *Abschwung* formed the middle foreground, and diverging upwards from this were the two tributary ice streams of nearly equal width, the Finsteraar and the Lauteraar glaciers, which by their confluence form the *Unteraar* glacier, on the medial moraine of which we stood.

Rising from all sides of all these ice rivers were pyramids and pinnacles of snow-clad rock. Above the Lauteraar glacier were the many glistening peaks of the Shreckhorn (12,383 ft.) and the Lauteraarhorn. To the left above the Finsteraar glacier stood the massive Finsteraarhorn (14,106 ft.) and its snow-capped satellites, and on either side of the wider stream at our feet were similar peaks; nothing but frozen desolation visible everywhere around, although it was the 20th of August, and the sun-rays were painfully scorching, as so frequently is the case on the high Alps.

On one of these snow peaks, the one showing the fewest dark spikes of rock among the snow, thus presenting a cone of nearly unspotted whiteness, and named accordingly the *Point de Niege* or *Schneehorn*, we saw some dark moving specks like beetles crawling over the snow. This was a section of the students that had made the ascent, and were then on their way down. I was surprised on their arrival to see several Alpine flowers that they had collected from amidst this snowy desolation.

Presently they started again as our guides over the glacier, which differs materially from those that are more familiar to the Alpine tourist, those of Chamouni, Grindelwald, etc. These are in steeply sloping valleys and abound in crevasses, broken up angular masses of ice, and general irregularities. The Aar glacier, at the part chosen by Agassiz, and for a long distance both above and below, has but a small slope, and thus the action of the sun upon its surface has time to produce some of its characteristic effects, which in steeper glaciers become obliterated before they are fully developed.

One of the first of these that we were shown was a fine glacier table, a great block of stone perched upon a cone of ice. Originally this stone had fallen from one of the rock slopes flanking the glacier, and in its fall had been projected beyond the lateral moraine, so as to stand alone as a small island on the ice. In this position it shaded the ice immediately below it, which thus retained its original level while all around was thawing down. The block and pedestal as we saw it presented at a distance the appearance of a gigantic mushroom.

The time required for effecting a notable difference of level will be understood by the following:—Agassiz covered portions of the ice with different protecting substances, and observed the result at the end of 16 days. A piece of woollen cloth stood not quite 8 ins. above the naked ice; an umbrella made a difference of $8\frac{3}{4}$ ins.; a wooden plank, 11 ins.; a covering of turf, $11\frac{3}{4}$ ins., and of snow the same. Thus the general "ablation" or thinning down amounted to about 1 ft. in the 16 days.

M. Desor covered a space of 6 square metres with turf on 15th July, and on 13th September found that the glacier had sunk at an average rate of nearly $1\frac{1}{2}$ ins. per day. This of course varies with the season and weather.

We were shown how to obtain our bearings by means of a glacier table. The cone of ice on which it stands is irregular, the slope of one side much greater than that of the other. The longest slope is always on the north side and the steepest on the south.

The reason of this appears on a little reflection. The sun at midday is due south, and during its most vigorous working hours it is more or less southerly, and therefore casts a due north and northerly shadow. It is the shadow of the block of stone that protects the ice and forms the cone on which the glacier table rests.

For simplicity sake let us regard the work of the sun at midday. Being on the south side of the block, and below the zenith its rays must to some extent undermine the ice base, while the north side of the base is completely in shadow. This goes on until such undermining causes the block to topple over to southward, when it starts afresh to produce another glacier table. In this way a huge block may actually travel across a glacier. Agassiz saw one that was 15 ft. long, 12 ft. wide, and 6 ft. high, slide 30 ft. on falling. It reduced to powder the ice over which it passed.

GASEOUS FUEL.

A PAPER READ BY MR. J. EMERSON DOWSON, M.INST. C.E., BEFORE THE MECHANICAL SCIENCE SECTION OF THE BRITISH ASSOCIATION.

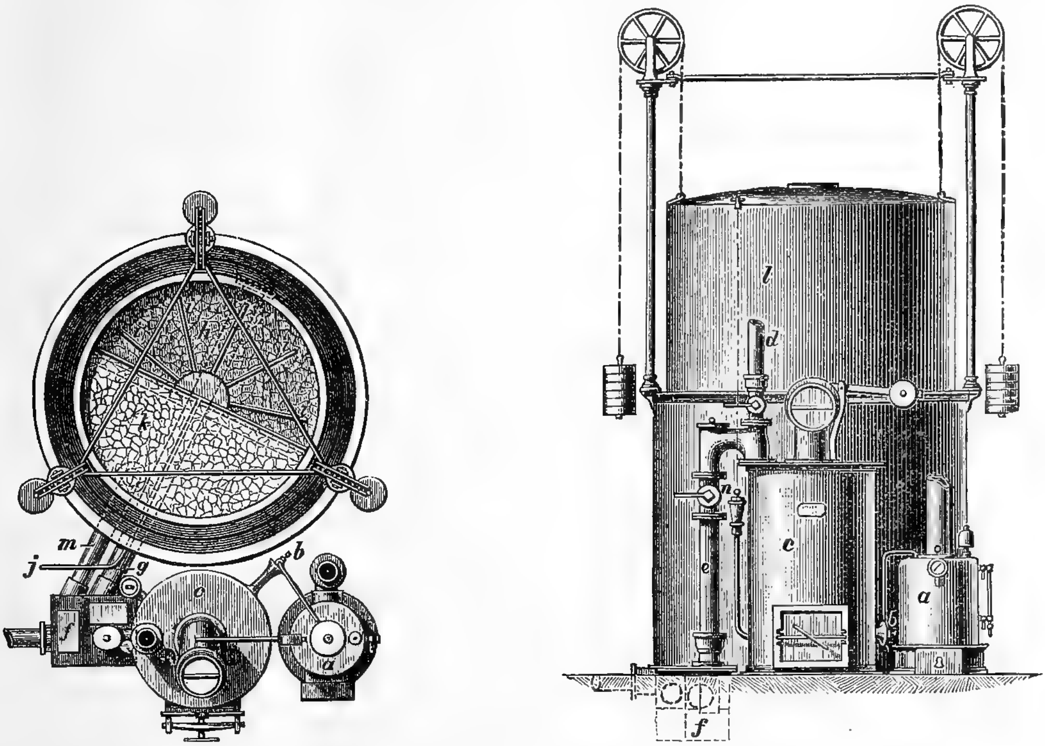
At the York meeting of the Association, in 1881, I had the privilege of explaining for the first time an apparatus with which I had succeeded in making a cheap fuel-gas, and I gave the economical results of working some gas engines with it. An abstract of my paper will be found in the Transactions of Section G. Since then I have gained a much wider experience in connection with this subject. My apparatus has been considerably improved, and the gas made in it has been much used, not only for driving engines but for heating in many industrial processes. I propose, therefore, to give a short account of the development which has taken place, and of some of the more important results obtained:

Like other generator gas, mine is made by passing steam and air through incandescent fuel, and gas so made can be taken direct from the generator and burnt in a furnace without being purified or cooled. For such work large flames are used, and it is comparatively easy to deal with them. When, however, the gas is required for a gas engine, or for small burners, the conditions are very different. The gas must be clean, or troublesome deposits will occur in the pipes and cocks, and it must pass through a gasholder to insure uniformity of pressure in the distributing pipes. It must also be cool, and this is especially the case for gas engines, as within certain limits the cooler and denser the gas, the greater is the energy in the limited volume which can enter the cylinder. It is also essential that when small jets of gas are used, as in small burners, the gas should be fairly strong and of uniform quality, or the flames will not burn steadily. To any one accustomed to the manufacture of ordinary lighting gas, these remarks may perhaps seem too elementary, but it should be remembered that generator gas is usually required in large quantity, and that to avoid large gasholders, it should be made as quickly as it can be consumed. In one case I have had to provide plant to make gas at the rate of one million cubic feet per day, or about 90,000 cubic feet per working hour, and without expensive appliances the cooling and cleaning of so large a volume of gas is not so simple as it may at first sight appear.

The original invention dealt with the generator only, but I have since found it necessary to devise a complete set of gas plant, to meet the requirements of practical work. In nearly all cases it is important that the apparatus should occupy as little room as possible, and the accompanying figs. 1 and 2 show the arrangement usually adopted. The steam boiler is small and specially made with a super-heating coil, so that dry steam enters the generator. The gas from the generator passes through water in the washer, and then through a scrubber containing coke moistened by water. The scrubber is placed inside the gasholder tank, so as to occupy as little ground space as possible. The rise and fall of the gasholder is made to regulate the supply of steam to the injector, so that to a certain extent the production of gas can be regulated automatically to suit a varying rate of consumption. In some special cases the gas is passed through oxide of iron to remove all traces of sulphuretted hydrogen, but for general purposes chemical purification is not necessary. The whole is very compact, and a plant large enough to drive an engine of 50 h.p. indicated, occupies a ground space of only 9 ft. by 10 ft. I have always taken the view, and it has been confirmed by practice in many places, that when the consumption of gas is regular there is no need for a large holder, provided the generator is well able to make gas at the maximum rate of consumption. In the case of engines, for instance, the gas plant is to the gas-engine what the boiler is to the steam-engine, and it is no more necessary to have a large reserve of gas than to have a large reserve of steam.

As regards the composition of the gas, it necessarily depends somewhat on the quality of the coal used, and on the fuel column being kept deep enough to insure a reduction of the carbonic acid. It has been analysed independently by Professor Wm. Foster and others, and, roundly speaking, the gas now made has the same composition as that made some years ago. I then thought that possibly in a large generator containing a great mass of fuel at a high temperature the percentage of hydrogen might be increased and that of the carbonic acid reduced. Trials since made have, however, shown that the average composition is much the same whether the gas be made at the rate of 1,000 c. ft. per hour in a small generator or at the rate of 15,000 c. ft. per hour in a large one. In 1881 I stated that for gas engines it was then necessary to use five volumes of the generator gas for one of ordinary lighting gas, to develop the same power. Theoretically, the comparative explosive force of the two gases is as 3·8 : 1, and it was evident that so long as practice required five to one, the weaker gas was not being used to the best advantage. Since then some important modifications have been made in the Otto engines, and I am glad to say that it is now necessary to use only four volumes of the generator gas. On this point, therefore, theory and practice are now fairly in accord. By calculation the calorific power of 100 litres of an average sample of the generator gas is 143,213 units of heat, while that of 100 litres of ordinary 16 candle-power lighting gas is 569,264 units. Tests made with a calorimeter and in other ways confirm these figures approximately.

In 1881 only one engine of $3\frac{1}{2}$ h.p. had been worked with this gas, and this showed a consumption of 1·46 lb. of coal converted into gas per indicated h.p. per hour. Since then a large number of engines have been worked with it, one indicating over 80 h.p., and many independent tests have been made. Details of these will be found in a paper of mine in the Proceedings of the Institution of Civil Engineers for last year, and on the present occasion it will be sufficient to give a few instances only. For more than four years Messrs. Crossley Brothers, the English makers of the Otto engines, have used this gas exclusively at their works for an average of about 150 h.p., and after a careful trial extending over thirty-five weeks they found that the fuel consumption averaged only 1·3 lb. per indicated h.p. per hour, including all waste, and the coal burnt in the generator every night and during Sunday (= 112 hours per week) when the fire was alight, although there was no work. At the time of this trial the construction of the generator rendered it necessary to draw the fire every two or three weeks, to remove the clinker adhering to the firebrick lining. Since then I have altered the generator, so that when the fire has once been lighted it need never be drawn; one of these generators has now



FIGS. 1 AND 2.—THE DOWSON COMPACT PLANT FOR MAKING GENERATOR GAS ON A MODERATE SCALE.

a. Steam producer and superheater; *b.* Injector; *c.* Gas generator; *d.* Chimney and waste pipe; *e.* Down pipe conveying gas to hydraulic box; *f.* Hydraulic box; *g.* Inlet pipe of gas-holder; *h.* Wet scrubber; *ii.* Water spray pipes; *j.* Water supply pipe; *k.* Dry scrubber; *l.* Gasholder; *m.* Outlet pipe of gasholder; *n.* Steam and air escape valve.

been running continuously for over a year, and Messrs. Crossley estimate that this saves about 20 tons of coal per annum. It is also worthy of note that at these large works, owing to the use of gas, there is no chimney except for the blacksmiths' shop. The returns sent me by eleven users of Otto engines working regularly in different places, and averaging each 35 h.p., also show an average fuel consumption of about 1·3 lb. per indicated h.p. per hour. Messrs. Ibotson, of the Colnbrook Paper Mills were supplied with a single cylinder Otto engine to indicate about 45 h.p. with this gas, on the guaranteed condition that the engine and gas plant could be worked continuously day and night, and that the fuel consumption should not exceed $1\frac{1}{2}$ lb. per indicated h.p. per hour. A trial was made extending over two weeks, the engine being indicated day and night at frequent intervals, and the result showed that the guarantee was in all respects fulfilled. The Otto engine makers in Germany have made exhaustive trials with this gas in connection with several of their engines, and have fully confirmed the results obtained by Messrs. Crossley in this country. Professor K. Teichmann, of the Royal Technical School of Stuttgart, and Mr. F. Böcking, Chief Engineer of the Rhenish Society for examining steam boilers, made a joint test of a twin-cylinder Otto engine worked with this gas. The engine developed a brake power of about 52 h.p., and the total fuel consumption including that used for the super-heating boiler was 1·6 lb. per *brake*, or barely 1·3 lb. per indicated h.p. per hour. Professor Witz, of Lille, a well-known scientific authority on the gas engine, has tested two Delamare-Deboutteville engines worked with this gas—one of 9 h.p., and the other of 25 h.p. effective. The first trial, of which full details were published in *Engineering*, gave a consumption of 89 c. ft. of gas, equal to 1·33 lbs. of coal per *brake* h.p. per hour. I have not exact particulars of the second trial, but I understand from the maker of the engine, Mr. Thomas Powell, of Rouen, that the result was even more favourable. Seeing that all these results have been obtained under practical working conditions, the record is certainly satisfactory, and I am pleased to add that I have also many letters testifying to the ease with which the gas-plant can be managed. This is an important point, for if the saving of fuel could only be effected in a complicated way, the apparatus could not be generally adopted. The total number of engines already made to work with this gas is 71, and the aggregate horse power is 2,390, or an average of nearly 34 horse power each.

I consider myself justified in saying that gas power is now fairly launched in competition with steam power, and to my mind there are reasonable grounds for supposing that eventually the former will to a great extent supersede the latter. In this view I am confirmed by the late Professor Fleeming Jenkin, who, in his lecture at the Institution of Civil Engineers, on "Gas and Caloric Engines," remarked—

"Since theory shows that it is possible to increase the efficiency of the actual gas engine, two—or even three—fold, then the conclusion seems irresistible that gas engines will ultimately supplant the steam engine. The steam engine has been improved nearly as far as possible, but the internal combustion gas engine can undoubtedly be greatly improved and must command a brilliant future."

It has been proved that the absolute efficiency of the gas engine—*i.e.*, the ratio between the indicated h.p. and the total quantity of heat generated by the fuel per minute—is already about double that of the best steam engine. As regards the mechanical efficiency—*i.e*, the difference between the gross indicated power developed in the cylinder, and the effective power given off on the brake—in the condensing steam-engine it is taken at about 80 per cent., and in the non-condensing engine at about 85 per cent. In the gas engine I showed, in my Inst.C.E. paper before referred to, that the average of several examples given was about 84 per cent. The Otto and other compression engines are of comparatively recent invention, and it is fair to assume that further improvements will yet be made, as the principles on which they should be based are now well understood. An important modification, for instance, has only recently been made in the Otto engine, the slide valves being entirely dispensed with.

We have seen that the results already obtained with this generator gas are good, but I cannot help feeling that still better results can and will be obtained, when the engine is really designed to give the best effect with a gas of this kind. It is well known that in the Otto engines each new charge of gas is diluted with a portion of the products of combustion from the previous charge, and, for reasons I need not now discuss, this answers very well with ordinary lighting gas. But as generator gas such as mine has only about one-fourth the explosive power of the other gas, it is a disadvantage to dilute it with products of combustion. Sooner or later this point will no doubt receive due attention, especially as the economical use of gas engines of high power must depend on their being worked with cheap gas. Looking to the probable extension of gas power, it is, in fact, most important that the best possible engine should be made for the fuel gas.

For gas engines, as now made, it is important that the generator gas should be as clean and free from sulphur compounds and ammonia as ordinary lighting gas. With this in view the best fuel to use is anthracite, as it does not yield tar or other condensable products which foul the pipes and valves. It is also suitable because it does not cake, and because it makes a dense fire, free from holes. Good qualities of anthracite yield but a small percentage of clinker and of sulphur compounds, and no ammonia. With some special precautions ordinary gas-coke can also be used. The quality of gas-coke varies, however, very much in different localities, and this is doubtless due in some measure to the different kinds of coal from which the coke is made, but also to the varying heats to which it is subjected in the retorts of different gas works. Some coke yields very large quantities of clinker, and is quite unfit for use in such an apparatus as mine. Other samples yield less clinker, but owing to the comparatively low temperature to which they have been subjected in the retorts, they retain hydro-carbonaceous bodies which vaporise in the generator, and are afterwards troublesome to remove from the gas. As before mentioned, these difficulties are not met with when the hot generator gas can be taken direct to a furnace; but when it is necessary to cool and clean the gas, as for engine work, special precautions must be taken.

Several trials have shown that when the gas apparatus is worked with anthracite the actual fuel consumption is about 13 lb. per 1,000 c.ft., including that used for producing the steam required, but to cover all sources of waste, as well as inferiority of quality, I usually allow

15 lb. per 1,000 c. ft. passed into the holder under ordinary conditions of temperature and pressure. On this basis the yield of gas is a little over 149,000 c. ft., or, allowing for the presence of 50 per cent. of nitrogen and carbonic acid, say 74,500 c. ft., of combustible gas per ton of fuel consumed.

(To be continued.)

THE ARCHÆOPTERYX.

THE oldest known bird was found in the Mesozoic (Jurassic) strata, at Solenhofen, in Bavaria. The history of its remains is curious. A single feather was first found in 1860, and caused much talk. Then, in 1861, a whole specimen came to light, and this, after much cogitation of learned geologists and naturalists, was christened *Archæopteryx macrura*, from its long tail (*archaios*, ancient; *pterux*, wing; *makros*, long; *oura*, tail). There was much competition among the varied distinguished museums as to which should have the honour of possessing the ancient specimen, and at length our British Museum carried off the prize, paying £700 for the privilege. A still more perfect specimen (of which we give an illustration) was found in 1877, at the Pappenheim Quarries; this was offered to the British Government, who were very desirous of having it, but in recollection of the previous specimen, for which they had paid £700, they refused to purchase it, and it was then sold to the German Museum, at Berlin, for about £1,000; and unscientific observers were much struck with the enormous price paid for so insignificant-looking a creature. Scientific men then concerned themselves with the position of the animal in the zoological world; and Huxley created an order all for itself, the *Saururæ* (*saura*, a lizard; *cura*, tail), for no other bird was found which could be classed with it. From the remains of the specimen, now in the Natural History Museum, South Kensington, it seemed evident

THE ARCHÆOPTERYX. (AFTER DAMES.)

that the body could not have been all covered with feathers, but must have had a smooth skin; this was gathered from the accurate impression left by the wing and tail feathers, while no impression was left of feathers elsewhere, except a circlet surrounding the neck, like that of the Condor. The size was about that of a rook, but its structure seemed half to resemble a bird, half a reptile. The presence of feathers, which denote hot blood, and the anchylosed metatarsals proclaimed it a bird, but the reptilian characters, which have now disappeared in process of evolution in modern birds, were decidedly present in three forms.

(1) True teeth, which can be easily distinguished in our illustration, were embedded in distinct sockets.

(2) It possessed a lizard-like tail.

(3) The hand resembled that of a lizard, though the phalanges of the digits in number agreed with birds. Taking the various parts of its body into consideration, it became regarded as an example of the now known fact that there can really be no definite line drawn in the animal kingdom, and that things seem to glide into one another from the simplest forms to the highest structures.

Some dispute and discussion on the point, however, arose, and Dr. W. Dames, a German man of science, published in 1884 a monograph on the subject, in which he maintained that the archæopteryx was by no means an animal occupying an intermediate position between birds and reptiles, but that it was a distinct bird of the Carinate class; and that in the latest-found specimen examined by him a well-preserved coating of feathers covering the body was noticeable.

It is not improbable that birds may have existed long before the time indicated by the records discovered, and we should be cautious in not inferring their non-existence in strata because we find no actual proof of their presence. For, as Sir Charles Lyell says, "The powers of flight possessed by most birds would insure them against perishing by numerous casualties to which quadrupeds are exposed during floods," and "if they chance to be drowned, or to die when swimming on water, it will scarcely ever happen that they will be submerged so as to become preserved in sedimentary deposits," the hollowness and lightness of their bones would cause them to float a considerable time; probably bones and all would become the food of hungry animals.

In the valley of the Connecticut river, in the United States, are, however, certain footprints which have been thought to be the impressions of birds. The strata in which they have been found are Triassic sandstones, and if the traces are really those of birds, then their ancestry can be traced to the beginning of Mesozoic times, or even into Palæozoic ages; but some think them to be impressions left by Deinosaurian reptiles which have hopped about on two hind legs. On this point geologists are divided in opinion.

DURABLE BOOKBINDING.

ABOUT a year ago (Scientific News, vol. i., p. 85) we called attention to the causes of decay in leather-bound books, and offered hints as to likely remedies. It may be of use to those who have suffered in this way if we quote the specification and estimate adopted by the Library of the Yorkshire College, Leeds. The specification aims at securing such permanence as can be given by the best materials and the most approved methods of binding. It has been in use for three years, and though this is too short a term to justify a very confident opinion, all the indications favour the belief that the books so bound will prove really durable. It will be seen that no leather except the best morocco is used at all. The choice of leather or cloth is determined mainly by the amount of wear to which the book is subject. By comparison with a number of binders' accounts, it appears that the prices here given would not have been considered unreasonable for ordinary binding in cloth or half-calf, with no stipulation as to materials or workmanship.

Specification for Bookbinding.

Collation.—Each book to be carefully examined, and notice of any imperfections to be sent to the Librarian.

Sewing.—The books to be sewn single-sheet-on, *i.e.*, each section to be sewn the full length, and on best quality of broad tape.

Forwarding.—Each back to consist of two boards glued together, the tapes being placed between the two boards and firmly pressed. Fast backs, raised bands, silk head-bands, edges washed with colour, and burnished.

Finishing.—No paste-washing to be used in finishing the books. Books to be lettered with author's name, short title, and date, gold fillet on the raised bands, blind fillet on each side of band, and on sides. End-papers not to be fastened down.

Plates.—Double plates to be mounted on guards.

Cloth Joints.—Folios and quartos to have cloth joints.

Materials.—The boards to be of best Buckinghamshire millboard. The cloth to be Winterbottom's first quality, of approved colour and pattern. The leather to best morocco, dyed with natural dyes, and supplied by Messrs. J. J. Flitch and Son, Leeds.

Estimate.

	Full Cloth.	Half-Morocco.
Crown 8vo	1s. 6d.	2s. 9d.
Demy 8vo	1s. 10d.	3s. 2d.
Royal 8vo	2s. 2d.	3s. 9d.
Imperial 8vo	2s. 6d.	4s. 3d.
Crown 4to	2s. 9d.	4s. 9d.
Demy 4to	3s.	5s. 2d.
Royal 4to	3s. 4d.	5s. 8d.
Imperial 4to	4s.	6s.
Crown folio	4s. 4d.	6s. 6d.
Demy folio	4s. 9d.	7s. 3d.
Royal folio	5s. 2d.	7s. 9d.
Imperial folio	5s. 6d.	8s. 6d.

The Electric Light in Fishing.—Recent experiments have been made on the Welsh coast to determine the application of the electric light to fishing in the night. The nets were let down to the depth of three fathoms; the one furnished with an Edison-Swan glow-lamp, and the other in the ordinary conditions. The first when raised was found full of fish, whilst the second was empty. At the depth of six fathoms the same result was obtained. In another experiment the nets were both illuminated, but the one was let down to the depth of five fathoms and the other was placed at the surface. Both contained a large quantity of fish, but those caught at the depth of five fathoms were not the same as those obtained from the surface.

General Notes.

The Centenary of the University of Montpellier.—This will be celebrated in 1889-1890 with all due solemnity.

Culture of the Vine in Australia.—*Cosmos* looks with alarm on the increase of vineyards in Australia, the profits of which are considerable enough to occasion disquiet to the French vine-growers.

Mechanical Theory of Lightning.—M. Charles Moussette (*Comptes Rendus*) is of opinion that lightning is a projectile, the luminous track described being merely the trajectory of a globular " thunderbolt."

A Physiological Laboratory for Bombay.—According to the *Medical Press*, the University of Bombay is still sadly in need of a physiological laboratory, an essential element in imparting a thorough medical education.

The Meteorite of Bahia.—This enormous meteorite, described by Mornay and Wollaston in 1816, and estimated to weigh between six and nine tons, has lately been conveyed to Rio, and safely lodged in the National Museum.

The Electric Treatment of Disease. — Among electricians in America it is currently asserted that workmen engaged among the machines for the production and the distribution of the electric light are found singularly free from rheumatism and neuralgia.

Supposed Submarine Earthquake in the Baltic.—In the morning of August 17th, the inhabitants of Rûgen saw two enormous waves approaching from the north-west which broke on the shore, doing considerable damage to the vessels at anchor. The sea was otherwise calm, and there was no wind.

A Canal across Jutland.—According to *Cosmos*, the Danish Government has just granted a concession for a canal which will intersect the north part of Jutland. It will leave the North Sea in the Jammer Bay. The new canal will save ships from having to double the north point of Jutland, Cape Skagen—a true cape of tempests.

The Climate of Assab.—According to a medical contemporary, Assab, at the southern extremity of the Red Sea, has the honour of being the hottest place in the world, its mean temperature exceeding that of Aden by 3°. For four successive months the thermometer at 9 a.m. stood above 90° F. in the shade, and rarely fell below 88° F.

The Rainfall of the Season.—Contrary to the popular impression, the rainfall for the year 1888 is, so far, not in excess of the average, and, in certain parts of Britain, falls even below it. The unsatisfactory character of the summer is due, not to the weight of rain, but to the deficiency of sunshine, the low temperature, and the excess of wind.

A Low Death-Rate.—The mortality in the townships of Barton and Monton, a few miles to the west of Manchester, has been only a little above five in the thousand, whilst in Manchester it has exceeded twenty-six. As there is no perceptible difference in the climate, the high death-rate of Manchester must be due to human neglect or error, and must be capable of reduction.

Centenarianism.—*La Nature* records the death, at Muro, in Corsica, of a man aged 113 years three months. Antonio Giovani Marchetti was born at Zilia, on May 1st, 1775. He became a soldier in 1793, and served under the first Napoleon from the siege of Toulon to Marengo, where he was very severely wounded. He settled afterwards at Muro, and was married four times.

Production of Milk in the United States.—According to the *Journal de l'Agriculture*, there are in the United States 21 millions of milking cows, and their total yearly yield of milk is 294 million hectolitres. Two-thirds of the produce is converted into butter and cheese. The value of this production exceeds that of the wheat grown in the United States, and nearly equals that of the maize.

Botanical Statistics.—According to Mr. J. G. Baker, F.R.S. (*Midland Naturalist*), before the war of secession in the United States, the Southern States had almost a monopoly of the trade in raw cotton. Last year the value of the raw cotton exported from India was between fourteen and fifteen million pounds sterling. In 1840 China had a monopoly of the tea trade. In 1883-4 the value of the tea imported from India was over four million pounds sterling.

A Variable Star (?)—Professor H. Fol reports having seen from the balcony of the Grand Hotel at Toulon, on August 24th last, a little before 9 p.m., a star more brilliant than those of the first magnitude and having a very red lustre. It was in the upper part of the constellation Virgo and at the same height above the horizon as Antares. It had no apparent movement, and seemingly no diameter. The observer after watching for some minutes went in to fetch a map of the stars, but on his return it had disappeared.

Photographing the Heavens.—After fifteen months' delay, the Treasury have at last sanctioned the provision of two telescopes to enable Greenwich and the Cape of Good Hope observatories to take their share in the international scheme for charting the heavens by photography. There will now be five British and colonial observatories taking part in the work, as instruments were ordered some months back for Oxford University, Sydney, and Melbourne observatories; but their construction has been delayed by the tardiness of our Government in arriving at a decision.

Ruins of an Ancient City in Russia.—It is announced that on the right bank of the Volga there exist the ruins of a large city extending over a space of nearly two miles in length, by rather more than half a mile in width. A deputation from the Commission of Archives has recently visited the localities, when there were found a great quantity of Arabian, Persian, and Tartar coins and medals, among a crowd of objects of various kinds indicating a very advanced civilisation as prevalent among the ancient inhabitants. Numerous blocks of marble and ruins of waterworks enable the plan of the ancient city to be to some extent ascertained.

The Hydrophone.—Commandant Banaré has devised an apparatus in place of the syren, and has named it the hydrophone. It is well known that in foggy weather ships make use of a deep whistling sound, produced by a syren, to prevent collisions. This whistle is heard very well at considerable distances, if the wind be not contrary, but it is often insufficient. M. Banare collects on one ship, by means of a special microphone, the sound-waves transmitted by the water, and emanating from a vibrating body placed on board of another ship. Experiments have been made at Brest between two ships, one of which was at anchor, and then between two vessels, both in motion. In the former series the noise of the screw of the moving ship was heard plainly. In both series the success was decisive.

Two Eclipses of the Moon Observed at Babylon.—M. Oppert communicated recently to the Academy of Sciences the translation of a cuneiform inscription narrating two eclipses of the moon observed at Babylon in the year 168, of an unknown local era and in the year 232, of the era of Arsaces, corresponding to the year 256 B.C. The inscription describes the two phenomena with every detail. Two phrases relating to the planets Mercury and Venus could not be deciphered. If we compare the eclipse of the year 232 with one of the ancient eclipses calculated by Professor Oppolzer, we find that all the particulars related by the inscription are verified. According to M. Faye, observations of this kind are important for improving the theory of the movement of the moon.

The Effects of Coal-smoke.—The injurious action of coal-smoke upon vegetation seems to be the joint effect of two factors which have not been separately estimated. On the one hand there is the visible, opaque matter, consisting of particles of carbon, which acts by obstructing the pores of plants and by diminishing the total intensity of the sunshine. This factor can be reduced by what is commonly called "smoke-consumption." On the other hand, we have the transparent, invisible sulphurous acid gas, which blights all vegetation. Against this part of the mischief smoke-consumption is powerless. The only hope lies in minimising the quantity of fuel burnt. This may be effected in manufacturing establishments by obtaining the full duty out of every pound of coal, and in households by the sacrifice of the open fire, which wastes at the very least seven-eighths of the heat generated.

Chinese Cookery.—The *Journal d'Hygiène* reports that a missionary during his stay in China had often seen the pupæ of the silkworm used as an article of diet. He has personally tried this dish, and finds it savoury and nutritious, and well adapted for invalids.

After having reeled off the silk the larvæ are stoved to free them from moisture. The outer coating is easily removed, and there are then seen small yellow masses resembling the *ova* of the carp. They are then fried in butter, lard, or oil, and seasoned with chicken-broth. When the whole has boiled for four or five minutes, it is bruised with a wooden spoon, and kept well stirred to prevent it from adhering to the bottom of the pan.

The mandarins, and in general the wealthy, add yolk of egg in the proportion of 1 to 100 pupæ. This addition causes it to exhale an exquisite odour, and to take the colour of cream. The poor merely add salt, pepper, and vinegar.

Earthquake in Iceland.—Captain Brown, of the Icelandic trading steamer Princess Alexandra, of Glasgow, brings intelligence of a reported earthquake or volcanic eruption in Iceland. Shortly after leaving Reykjavik on the afternoon of August 24th, the steamer got into a thick sulphurous atmosphere, which continued for three hours, the distance run during the time being thirty miles. After emerging out of this atmosphere, which was very stifling, the steamer got into very disturbed water, and the compasses on board became unsteady, moving from point to point. The steamer then encountered a strong east-north east wind, with a clear atmosphere, and her course was altered to a southerly direction in order to get clear away from the effects of the volcanic disturbance. This course was kept for seventy miles, when the steamer got into smoother water. Captain Brown is of opinion that the disturbance of the sea, which resembled the waters of the Pentland Firth during a storm, was caused by an earthquake, which had extended its influence seaward for thirty miles.

The Public Health.—The Registrar-General's return for the week ending September 8th shows that the deaths registered during that period in twenty-eight great towns of England and Wales corresponded to an annual rate of 17 8 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Bristol, Brighton, Portsmouth, Nottingham, Wolverhampton, and Sunderland. In London 2,475 births and 1,316 deaths were registered. Allowances made for increase of population, the births were 264, and the deaths 130, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 17·5 and 16 4 in the two preceding weeks, further declined last week to 16·0. During the first ten weeks of the current quarter the death-rate averaged 16·2 per 1,000, and was 4·1 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,316 deaths included 26 from measles, 19 from scarlet fever, 18 from diphtheria, 32 from whooping cough, 11 from enteric fever, one from an undefined form of continued fever, 131 from diarrhœa and dysentery, three from cholera and choleraic diarrhœa, and not one from small-pox or typhus; thus 241 deaths were referred to these diseases, being 43 below the corrected average weekly number. The death of a journeyman tailor, formerly of Whitechapel, whose age was stated to be 103 years, occurred on the 4th inst, in the Hand-in-Hand Asylum at Hackney. In Greater London 3,249 births and 1,630 deaths were registered, corresponding to annual rates of 30·7 and 15·4 per 1,000 of the estimated population. In the Outer Ring 33 deaths from diarrhœa, seven from measles, six from scarlet fever, and five from whooping-cough were registered. Of the fatal cases of diarrhœa, six occurred in Stratford, four in Tottenham, three in Bromley, three in Willesden, and three in Leyton sub-districts. The deaths from measles included three in Tottenham and two in West Ham sub-districts; and four of the six fatal cases of scarlet fever occurred in West Ham sub-district.

SURFACE TENSION.

We here lay before our readers the abstract of a paper read before the Microscopical Society of Belgium, as reported in *La Nature*, from which source we also borrow the accompanying illustrations.

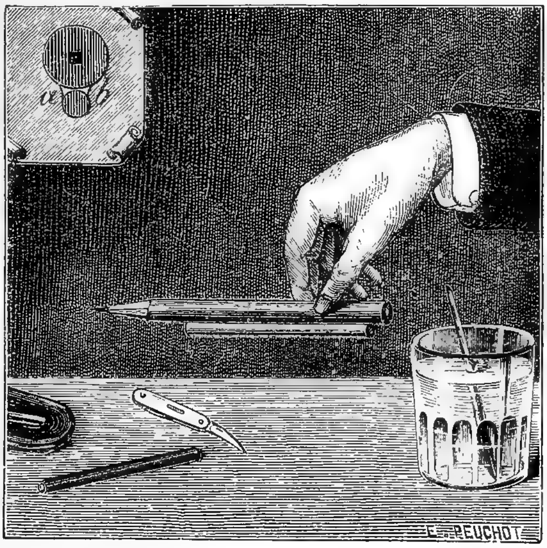


Fig. 1.

Let us consider a glass containing water; is the liquid everywhere constituted alike? This has been believed or a long time, but the belief is being abandoned. To form a clear idea on this subject, let us examine the forces which act upon the particles. In the first place,

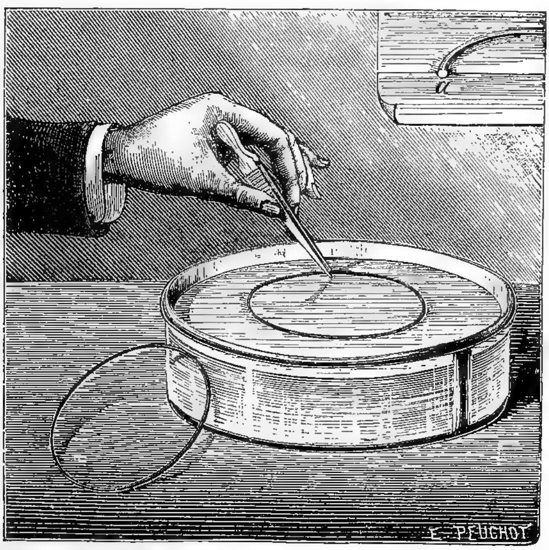

Fig. 2.

there is attractive force; for if we plunge a pencil into the water, and then withdraw it, there will be a drop hanging to the pencil. If we imagine a horizontal plane dividing the drop, all the particles situate above such plane must be regarded as sustained by those which are above, without which there can be no equilibrium. This cohesion is evidently due to attractive forces. On the other hand, there are repulsive forces which tend to sever the particles. If we leave the glass of water to itself, the liquid will ultimately entirely evaporate. Is not this a proof that if there be forces tend-

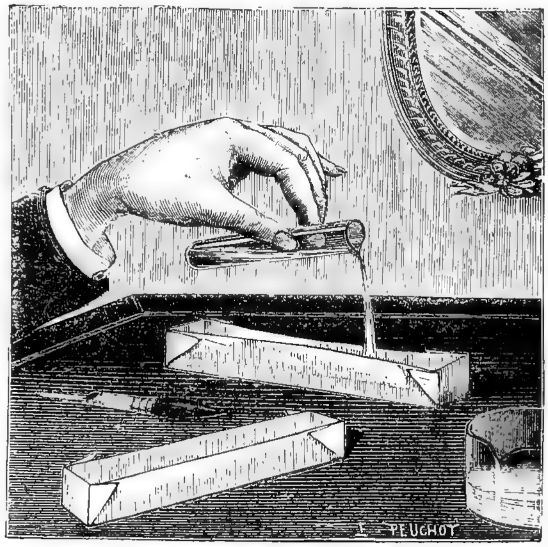

Fig. 3.

ing to approximate the particles of liquid to each other, there are others in virtue of which these particles diverge from each other?

On studying the constitution of liquids from this point of view we have arrived at the following result: an

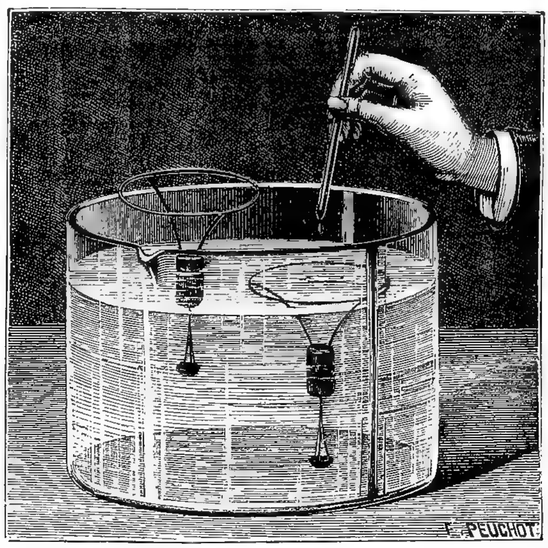

Fig. 4.

equilibrium cannot exist in a liquid between the attractive and repulsive forces, unless there is, in the immediate proximity to the free surface, a tendency to the mutual separation of particles, combated incessantly by the attractive forces.

But is not this state of the superficial layer comparable to that of a thin elastic membrane which we stretch by exerting a certain effort, whilst its cohesion is at each moment opposed to any further extension? This is why we may say that the free superficial stratum of a liquid is submitted to a contractile force or tension in virtue of which it possesses a tendency to become as small as possible.

But what is the thickness of the stratum which is the seat of this tendency? Plateau and Quinete have found by different methods that the thickness of this superficial stratum does not exceed $\frac{1}{20000}$ of a millimetre in thickness. And what is the intensity of the contractile force? It varies from one liquid to another, and in one and the same liquid it generally decreases as the temperature rises. At 59° Fahr. the tension of distilled water is about 7·5 milligrams per millimetre of length; olive oil has, under the same conditions, a tension of 3·6, petroleum of 2·6, absolute alcohol of 2·5, and ether of 1·88 milligrams.

But we must now demonstrate the existence of the contractile force by some very simple experiments.

First Experiment.—Let us take two pencils, one of which must be of very light wood and not more than three or four millimetres in thickness. We apply them to each other, so that they may touch in a horizontal straight line. In the space close to this line of contact we put a few drops of pure common water, so that the parts bordering on the line of contact may be well wetted. There will then be formed, adhering to the two pencils, a small liquid mass, of a concave curvature, which is shown in section in fig. 1, *a b*. Then the pencil of light wood can remain suspended to the other, by reason of the tension of the concave surfaces *a b* which prevail on either hand of the line of contact. For instance, if the length of the pencils is twelve centimetres, the weight which can be sustained will be $2 \times 120 \times 7{\cdot}5 = 1800$ milligrammes. The lighter pencil must therefore weigh less than 1·8 gramme.

Second Experiment.—We cleanse perfectly a ring of copper wire of about one millimetre in thickness and eight centimetres in diameter, and place it with care upon the surface of pure water in a capsule which has previously been well washed. The copper ring will float (fig. 2, section *a*), and this though its density is 8·8 times greater than that of water. This is because all the tensions of the liquid which prevail on the one hand and the other of the ring give a resultant acting from below upwards. A very simple calculation shows that the weight of the ring is about $\pi \times (\frac{1}{2}) \times \pi \times 80 \times 8{\cdot}8$ milligrammes $= 1{\cdot}73$ grammes. On the other hand, the maximum effect of the tensions is $2 \times \pi \times 80 \times 8{\cdot}5$ milligrammes $= 3{\cdot}77$ grammes. We see, then, that even if we disregard the thrust of the liquid, the effect of the surface tension is more than double the weight of the ring.

In the same manner we may float upon water needles, globules of mercury, a slender platinum ring, etc.

Third Experiment.—We procure a leaf of light unglazed paper (*e.g.*, silk-paper), say seventeen centimetres in length and three in width. All the edges are folded (fig. 3) so as to form a rectangle of fifteen centimetres in length and one centimetre in breadth; all the edges are turned up to the height of one centimetre, and four small folds are made following a diagonal of each of the squares formed by the first folds, and we thus obtain a small box, the long sides of which are made very flat. This being done, the apparatus is set upon a table; all the inner surfaces are well moistened by means of a brush, and water is poured in to the height of 4—5 millimetres. Immediately, the tension of the liquid surface draws together the long sides which are opposite to each other, and the vessel becomes closed automatically.

Fourth Experiment.—Take a cylindrical cork (fig. 4) of, *e.g.*, two centimetres in thickness and four in length; in the centre of one of the ends we insert a very fine iron wire, six or eight centimetres in length, and having at its lower end a hook or a small basket suitable for receiving a load. To the opposite end of the cork is fixed a system composed of a ring of fine wire ten centimetres in diameter, and supported by two ends of the same wire which are inserted into the cork in such a manner that the plane of the ring may be perpendicular to the axis of the latter and placed concentrically with respect to it.

This being done, the small apparatus is plunged into water contained in a vessel of sufficient depth; if the load be suitable, the cork will remain upright, and will only project eight or ten millimetres above the level (fig. 4). If the entire system be made to descend vertically into the water and be left to itself, the ring will not again leave the water; it will merely rise a little above the level, producing a bi-concave meniscus. Here the result of the surface tension gives rise to a resultant acting from above downwards and sufficient to counterbalance the increase of the thrust. If the load be suitable, this resultant, augmented by the weight of the system, very little exceeds the upward thrust of the liquid. It is then sufficient to bring near the water a little wadding soaked in ether (which decreases the surface tension) to see the ring, in appearance, spontaneously rise out of the liquid and the system resume its original position of equilibrium.

(*To be continued.*)

PAPER BOTTLES.

ONE of the most interesting of the many uses to which paper has been put is the manufacture of paper bottles.

We have long had paper boxes, barrels, and car wheels, and more recently paper pails, wash basins, and other vessels; but now comes a further evolution of paper in the shape of paper bottles, which are already quite extensively used for containing such substances as ink, bluing, shoe dressing, glue, etc., and they would seem to be equally well adapted for containing a large variety of articles.

They are made by rolling glued sheets of paper into long cylinders, which are then cut into suitable lengths, tops and bottoms are fitted in the inside coated with a waterproof compound, and all this is done by machinery almost as quickly as one can count.

They are cheaper and lighter than glass, unbreakable, and consequently very popular with consumers, while the fact that they require no packing material, and are clean, handy, and economical, commends them to manufacturers. Unlike glass, they can be manufactured and shipped at all seasons; and being made by machinery, the supply is independent of labour troubles, which are additional advantages to manufacturers who use bottles.

FUNCTION OF THE HALTERES OR BALANCERS IN DIPTEROUS INSECTS.—It is contended that in the common fly and in its congeners these parts contain the organs of hearing.

Natural History.

THE KAGU.

THE Kagu, a small bird by no means as imposing as its dignified appellation, *Rhinocetus jubatus*, has given rise to some discussion as to its true position in ornithological classification. Professor Parker, F.R.S., published a long paper on its osteological formation, in the Transactions of the Zoological Society, in which he asserted that it constituted a type of a distinct family belonging to Professor Huxley's order, *Geranomorphæ*, closely allied to the *Psophia* (trumpeters) and *Eurypygae* (bitterns). A writer in the "Standard Natural History" makes it the type of an entire family, *Rhinocetidae*, but Mr. Bartlett, Superintendent of the Zoological Gardens, agreed with Professor Parker in ranking it with the sun bittern (*Eurypyga helias*), whence he allied it again to the herons, cranes, rails, and plovers, an opinion which is, we believe, now universally accepted.

The Kagu (to call it by its native name) was first described by some French naturalists, about the middle of the present century, in a memoir on the Ornithology of New Caledonia, an island in the South Pacific, east of Australia, which had then been recently colonised by the French. In December, 1861, Dr. George Bennett, of Sydney, New South Wales, received a present of a living Kagu from his friend, M. D. H. Joubert, one of the settlers in New Caledonia, who had had it in his possession for a short time. This bird, together with another which was subsequently presented to him, Dr. Bennett forwarded to the Zoological Society in London, where they arrived safe and well on the 22nd of April, 1862, the first specimens of their kind to reach this country alive. At that time the Kagus were very numerous in New Caledonia, and Mr. Ferdinand

Joubert, son of the above-mentioned gentleman, writing from Kai, in the interior of the island, remarked that these birds were particularly plentiful in all the neighbourhood of Kai and in the district of the Boh Mountains. Unfortunately, however, they were discovered to be excellent for the table, and were forthwith snared and shot in great quantities by both natives and settlers, with the natural result that some twenty years later their numbers had decreased to such an extent that they were only to be found in certain parts of the country, and are now so scarce that when a gentleman leaving Port de France, N. C., offered a large reward for a live Kagu to take back to France with him, not a single bird was to be found for miles around. The natives were in the habit of catching the Kagus by means of a strong string fastened to the ground with a loose slip knot, in which the birds would become hopelessly entangled, thus falling an easy prey to their captors.

M. Ferdinand Joubert called attention to the fact that there were two distinct kinds of this bird, one the "Bush Kagu," as he termed it, large and handsome and comparatively serene in disposition; the other, the "Grass Kagu," much smaller and darker, with dark stripes on its wings and tail, and so pugnacious that fights were of constant occurrence, despite the fact that the aggressive little "Grass Kagu" was invariably ignominiously defeated.

Dr. Bennett describes this bird as about the size of an ordinary fowl. The female is usually slightly the larger of the two, and rather more graceful in shape, with pale brown plumage, and with bill, feet, and legs of a pale orange colour. The plumage of the male bird is dark brown, with bars of a paler shade, the primaries and secondaries of the wings very dark brown, barred with black, the long pending crest on the nape of the head dark grey, the bill and legs vivid orange scarlet, and the iris orange. The voices of both birds are peculiar; the female utters a strange kind of growling scream, and the male a noise which is an extraordinary compound between a bark and a laugh, and which sometimes in their wild state is said to sound like a young puppy calling for its mother. Like most birds of the heron tribe, the *Rhinocetus jubatus* has the remarkable powder-down tufts, characteristic of the Ardeines, strongly developed, having the down tufts above and around its wings, and on its breast and back, thickly stored with powder. Mr. Bartlett remarked that when these birds bathed, the whole surface of the little pond was immediately covered with a sort of film, somewhat resembling French chalk. The markings of the Kagu's wing and tail feathers strongly resemble those of the sun-bittern, and although no eggs have hitherto been found in its native home, the one "obligingly" laid by the specimen in the Zoological Gardens (the adverb is Professor Parker's) bears a great similarity in both form and colour to that of the bittern, and is further proof of the relation of the two birds. The Kagu possesses a distinctive feature in the peculiar scroll-like membrane which surrounds the nostrils, which, closing entirely over the aperture when the beak is inserted into the soft earth and mud where the bird seeks its food, effectually prevents the entrance of any extraneous matter into the nostril. The female bird has a curious habit of crouching on the ground and covering herself with her wings, throwing them up in concave form over her back, so as to completely hide her head and body.

(*To be continued.*)

The Language of Crows.—According to Dr. C. C. Abbott, a well-known and trustworthy observer of bird-life, crows have twenty-seven distinct cries, calls, and utterances, each readily distinguishable from the others, and each having an unmistakable connection with a certain class of actions. Is it not fully time that the cant expression "dumb animals," peculiar as it is to England, should cease to be employed?

Vital Conditions of Bacteria.—A writer in the *Berichte der Deutschen Chemischen Gesellschaft* finds that air, and still more pure oxygen, promotes the multiplication both of the bacilli of anthrax and those of putrefaction. Ozone, however, is fatal to the latter, though it has no power over the former.

Structure and Function.—Some time back Mr. Waterhouse, of the British Museum, exhibited at a meeting of the Entomological Society some aquatic *Curculios* which swim with the same action and the same ease as a *Dytiscus*, though their legs display no structural adaptation to the purpose.

A Wasp at Dinner.—Mr. J. H. Emerton (*Cosmos*), whilst passing through a marsh covered with alders, observed the curious spectacle of a wasp hanging from a branch by one of its hind feet, and in this strange position tranquilly devouring a fly. The prey was held by its two anterior feet, whilst the other feet and the wings were disengaged. The rapid movement of the jaws and the antennæ whilst the fly was being turned to and fro caused the body of the wasp to keep gently swinging. When nothing remained of the fly beyond the wings and the shell the wasp let fall the remnants, drew herself up on the branch and took wing in quest of fresh adventures.

Experiment on the Treatment of the Potato Disease.—M. Prillieux (Paris Academy of Sciences) has treated a plot of early potatoes in which the disease had already shown itself in the form of black spots on the leaves, with "Bordeaux broth," a decoction of six parts of sulphate of copper and six parts of lime in 100 parts of water. The liquid was applied in the state of a fine dew by means of a "pulveriser." When the crop came to be gathered not one diseased tuber was found on the plants which had been treated. Adjacent plants of the same kind, but not treated, yielded 32 per cent. of diseased tubers.

Leafing of the Oak and the Ash.—Mr. J. Saunders, writing in the *Midland Naturalist*, informs us that this year a large number of trees were carefully observed in South Bedfordshire and North Hertfordshire, especially where they were growing in company, and in the great majority of cases oaks were before the ashes, the exceptions being about 10 per cent. He also considers that oak trees, upon the whole, leaf before the ash, and remarks that this season, in which the oaks have been less in advance than usual, has turned out exceptionally wet. We may here remark that there are contradictory versions of the old proverb concerning the leafing of these two trees. In some parts we are told:—

"If the oak's before the ash,
There will be nought but drip and splash;
If the ash is before the oak,
There will be nought but dust and smoke."

CUSTOMS OF SAVAGE RACES.

LECTURE DELIVERED BY SIR JOHN LUBBOCK, M.P., F.R.S., TO THE WORKING-CLASSES OF BATH.

(*Continued from p.* 304.)

CARVER astonished the Canadian Indians by allowing them to open a book wherever they pleased, and then telling them how many pages they were from the beginning. The only way they could account for this was by concluding that the book was alive, and told him whatever he asked. This belief in the mysterious character of writing has led to its being used in various parts of the world as a medicine. The Central Africans are a religious people according to their light, and have great faith in the efficacy of prayer. When anyone is ill they write a text out of the Koran on a board, wash it off, and drink it. In India charms are used in the same way, but now strong medicine is often openly put into the ink, a curious combination of medicine and superstition. It was soon observed that these charms were no protection from firearms, but that did not in the least weaken the faith in them, because the Mahomedan priest explained that as guns were not invented in Mahomet's time, he naturally provided no specific against them.

Another curious idea very prevalent among savages is their dread of having their portraits taken. The better the likeness, the worse they think for the sitter; so much life could not be put into the copy except at the expense of the original. Once, when a good deal annoyed by some Indians, Kane got rid of them instantly by threatening to draw them if they remained. Catlin tells an amusing but melancholy anecdote in illustration of this feeling among the same people. On one occasion he was making a likeness of a chief named Mahtocheega in profile. This, when observed, excited much commotion among the Indians. "Why was half his face left out?" they asked, "Mahtocheega was never afraid to look a white man in the face." Mahtocheega himself does not seem to have taken any offence, but Shonka, a hostile chief, took occasion to taunt him. "The Englishman," he said, "knows that you are but half a man; he has painted but one half of your face, and knows that the rest is good for nothing." This taunt led to a fight in which poor Mahtocheega was killed, and the whole affair was very unfortunate for Mr. Catlin, who had much difficulty in making his escape, and lived some time in fear of his life; nor was the matter ended until both Shonka and his brother had been killed in revenge for the death of Mahtocheega.

Those who have not devoted much attention to the subject have generally regarded the savage as having at least one advantage over civilised man—that, namely, of enjoying an amount of personal freedom greater than that of individuals belonging to more civilised communities. There cannot be a greater mistake. The savage is nowhere free. All over the world his daily life is regulated by a complicated set of rules, and customs as forcible as laws, of quaint prohibitions, and unjust privileges—the prohibitions generally applying to the women and the privileges to men. "The Australians," says Mr. Lang, "instead of enjoying perfect personal freedom, as it would at first appear, are governed by a code of rules and a set of customs which form one of the most cruel tyrannies that has ever perhaps existed on the face of the earth, subjecting not only the will but the property and life of the weak to the dominion of the strong. The whole tendency of the system is to give everything to the strong and old, to the prejudice of the weak and young, and more particularly to the detriment of the women. Moreover, if savages pass unnoticed many actions which we deem highly criminal, on the other hand they strictly forbid others which we regard as altogether immaterial. Thus the Mongols of Siberia think it wrong to touch fire with a knife; to use one for taking meat out of a pot; to cut up wood near a hearth; to lean on a whip; to pour liquor on the ground; to strike a horse with the bridle; to break one bone against another. The legal forms among savages are very long and tedious. But little consideration is required to show that this is quite natural. In the absence of writing, evidence of contracts must depend on the testimony of witnesses, and it is necessary therefore to avoid all haste which might lead to forgetfulness, and to imprint the ceremony as much as possible on the minds of those present.

Among the lower races of men, the chiefs scarcely take any cognisance of crime. As regards private injuries, everyone protects or revenges himself. Thus amongst the North American Indians even in cases of murder, the family of the deceased only punish the aggressor if they can. The chiefs and rulers do not feel called on to interfere. Since then crimes were at first regarded as mere personal matters, in which the aggressor and his victim alone were interested, every crime, even murder, might be atoned for by the payment of a sum of money.

Among the Anglo-Saxons every part of the body had a recognised value. Thus the loss of a front tooth was valued at six shillings, that of a beard was reckoned at twenty shillings, while the breaking of a thigh was only put at twelve, and of a rib at three, facts which show both the high value of money and also the importance attached by our ancestors to their personal appearance. Moreover these payments had reference to the injury done, and had no relation to the crime as a crime.

The religious condition of the lower races of men is one of the most interesting, but at the same time one of the most difficult parts of the whole subject. It is most difficult, partly because it is far from easy to communicate with men of a different race on such an abstruse subject; partly because so many men have no very clear ideas of what they really believe; and partly because even amongst those nominally professing the same religion there are often in reality great differences individually, as I shall endeavour to show you is also the case with nations, acquiring gradually higher and higher, and therefore truer ideas as they rise in the scale of civilisation. Even among races well known to us it is often very difficult to state what the orthodox opinions really are; for instance, it has long been a question amongst scholars what opinions orthodox Buddhists really entertain respecting the Deity and the condition of the soul after death. Moreover, as new religious ideas come into existence, they do not destroy, but are only superinduced upon the old ones; thus the religions of the ancestors become the nursery tales of their descendants, and the old Teutonic deities of our forefathers are the giants and demons of our children.

Savages generally assume that there is no motion without life. Hence they believe in spirits not only of animals, but plants, rivers, lakes, winds, and so on. In various parts of the world white men, when first seen, were taken for ghosts. For instance, some years ago a vessel was wrecked on the north coast of Australia, and all on board were drowned except a Scotch woman, named Thomson. She was kindly received by the natives, being taken for the ghost of a woman named Giom, who had recently died; and when she was teased by the children, the men would often say, "Let her alone, poor thing; she is nothing, only a ghost." This, however, did not prevent their marrying her to a man named Boroto. We must remember that ideas of spirits entertained by savages are very different from ours. They regard them as different indeed from, but scarcely more powerful or wiser than they are themselves. For instance, the nations of the Nicobar Islands used to put up scarecrows to frighten the spirits away from their crops. Even among a race comparatively so far advanced as the Greeks, the deities were regarded as liable to be wounded or even defeated by man. Mars himself, the very god of war, is described by Homer as being wounded by Diomede.

Various theories have been suggested to account for the deification of animals. I have ventured to suggest that it may be traced to the system of family names. We have seen that families are often called after animals, the bear, the bull, and so on. This leads to the idea—or at any rate various races have the idea, in a more or less definite form, that they are related to, or descended from the animal after which they are named. In many cases they will not injure or eat their namesake. They treat it with respect, which would gradually develop into reverence and worship.

The worship of inanimate objects is more difficult to account for. But, in fact, many savages regard everything as having life; and just as when a man died he went to the other world, so if a thing were destroyed, its spirit set out on the same long journey. Chapman mentions that the bushmen thought his waggon was the mother of his cart, and Hearne tells us that in his day the North Americans never hung up nets together for fear they should be jealous of one another.

Lord Iddesleigh, in a recent address, observed that as he stood by one of the mighty rivers of Canada, he almost felt as if the rushing waves were alive; and in fact rivers and seas are so active, and as we should say even now metaphorically, show so much life that we cannot wonder at the very general belief in a spirit of the waters, which we find prevalent in the most distant parts of the world. Among the Greeks if Neptune represented perhaps a deity ruling over the seas, Okeanos at any rate was the ocean itself. The Hindoos worship the Ganges; in North America the Mohawks believed that the spirit of Saratoga lake infallibly drowned any one who spoke while boating on it. The wife of a missionary once wishing to destroy this superstition got an Indian chief to row her across, and when they were in the middle, to his great alarm, began talking loudly. However, they got across, and when they were safe on the other side she laughed at him, but he was quite unshaken in his belief, and indeed I think had the best of it after all, for he replied gravely, "Madam, the Great Spirit is merciful, and knows that a white woman cannot hold her tongue." A belief in water spirits still lingers on in parts even of our own islands.

The heavenly bodies have long excited the wonder and admiration of mankind. Still, the worship of the sun, moon, and stars does not seem to prevail among the lower races of savages—such, for instance, as the Australians—and it was again abandoned among thoughtful races, perhaps on account of the regularity of their movements. We are expressly told in the case of Peru that the Inca Huayna Capa questioned the divine nature of the sun, because it did exactly the same thing every day. Now, he ingeniously argued, "If the sun were supreme lord he would occasionally go aside from his course, or rest for his pleasure, even though he might have no necessity for doing so."

The vestal virgins have made us all familiar with the worship of fire. Their duty was to keep the same fire perpetually burning. On the other side of the Atlantic, again, we find very similar institutions. In Peru "the sacred flame was entrusted to the virgins of the sun, and if by any neglect it was suffered to go out, the event was regarded as a calamity that boded some strange disaster to the monarchy." Very similar customs indeed prevailed among many races. The name vesta is merely a form of hestia, which in Greek meant a hearth; and vesta was the personification of the domestic hearth. We must remember that among savages it is a work of much difficulty to light a fire. Lucifer matches and other appliances make it now so very easy that we are apt to forget this. But with savages, and even until quite recently, it was very different. The commonest mode of obtaining fire was by rubbing one stick against another, and if any of you would endeavour to strike a light in this way, you would appreciate the labour it involves. Hence the fire, once obtained, was most carefully cherished. Indeed, it is said that some of the Australian tribes, though they had fire, did not know how to procure it, and, if theirs went out, were compelled to borrow a light from a neighbouring tribe. Hence. naturally, under such circumstances, it was jealously guarded, then reverenced, and at last worshipped.

We know that among many races, when a man died, his wives and slaves, sometimes, also, his horse and dog, were killed and buried with him, in order that their spirits might accompany him to the other world. But the preparation for eternity did not end here. Just as the survivors killed the wife and slaves, so they also "killed" his arms and implements, his clothes and ornaments, so that their spirits also might go with their master, and he might enter the other world as a great chief should. The Red Indian, Mr. Sproat tells us, quite understands that the things themselves remain in the grave, but believes that the phantoms of the things accompany the spirit of the dead. Even among the Greeks we know that a coin was put in the mouth of the dead, in order that he might have the wherewithal to pay the ferryman Charon; and the Chinese are said to burn paper-money with the dead—a process much to be commended from a banking point of view.

The language of poetry is another source of Divine origin. Thus the classical gods appear in the Vedic poems as mere names of natural objects. Jupiter is Zeuspater—the father Zeus; and Zeus is the Sanscrit word, Dyans—the Sleig or Heavens. When the original Indo-European said that "Dyans thundered," he meant no more than we do when we say that the heavens thundered. But gradually the word Dyans became more and more personified, until at last, under the Greeks and Romans, Zeus became a living deity, the lord of Heaven, the god of Thunder, and thus an extensive mythology gradually grew out of what were at first but poetical expressions. So far I agree with my friend Professor Max Müller, but I am only disposed to do so within comparatively narrow limits; and while admitting the explanation as applicable to certain cases, cannot regard it as having any very extensive application. In many cases the religious ideas of the lower races of men have been greatly influenced by the phenomenon of sleep.

> "Some say that gleams of a remoter world
> Visit the soul in sleep—that death is slumber,
> And that its shapes the busy thoughts outnumber
> Of those who wake and live—I look on high;
> Has some unknown omnipotence unfurled
> The veil of life and death? Or do I lie
> In dream, and does the mightier world of sleep
> Spread far around and inaccessibly
> Its circles?"
>
> —*Shelley, "Mont Blanc." Lines written in the Vale of Chamouni, Part* 3.

In sleep the body lies as it were dead; but the mind is often active, and the savage dreams as we do that when his body is asleep the mind wanders away to visit absent friends and distant regions. Hence he naturally concludes that he has a spirit which can leave the body. Hence also to him dreams have an importance and reality which we can hardly appreciate. Mr. M. Thurm tells us that when he was travelling in Guiana, his head boatman one morning insisted on thrashing one of the men because he dreamt he had been impertinent to him the night before. Hence to be unexpectedly woke up is in the eyes of some of the lower races of man a real danger. In a recent work on Burmah it is stated that an English magistrate rendered himself very unpopular by waking a native official in the middle of his siesta, or mid-day sleep. The natives argued in this way. The poor man always sleeps from 12 to 2. During this time his spirit wanders away, and often only comes back just before 2. It is now 1. Who can say where the spirit is? It may be miles away. It is barbarous to wake up a man's bod when the spirit may be at a distance. The poor wife was, it is said, terribly alarmed. In other cases dream thoughts were regarded as special inspirations, as in the beautiful verses of Job:—"In dreams, in visions of the night, when deep sleep falleth upon man, in slumberings upon the bed;" "Then God openeth the ears of men, and sealeth their instruction."

Our own sovereigns are still crowned on a stone, the Lia Fail or Stone of Destiny, which is said to have been the pillow on which the patriarch Jacob slept at Bethel when he saw "the ladder set up on the earth, and the top of it reached to heaven, and behold the angels ending and descending on it." It was carried to Ire-d, then to Iona, subsequently to Scone, and brought to England by Edward I., though some Irish antiquaries maintain that the true Lia Fail is the upright stone which stands on the hill of Tara. We all remember the significance attached by Joseph's parents and brethren to his dreams; as well as the political importance of Pharaoh's dream, which Sir Samuel Baker has recently attempted to explain by supposing that the Abyssinians had dammed up the Atbara river.

Moreover, the analogy between sleep, and that last long sleep death, could hardly fail to strike the savage. In classical mythology we are told that Mars the god of death, and Somnus the god of sleep, were both children of Nox, the goddess of the night. But as the savage every morning saw his friend awake from sleep, it was not unnatural that he should imagine that they might also arise from the tomb. Moreover, in confirmation of this the spirits of his departed relations often visited him in his dreams, and hence he readily adopted the idea that we have a soul which survives, or may survive, the body.

(To be continued.)

THE ELECTRICAL TRANSMISSION OF POWER.

A Lecture Delivered by Professor Ayrton, F.R.S., etc., before the British Association, on September 8th, and Re-delivered to the Working-Classes of Bath, on September 13th, 1888.

What is power, and why should we wish to transmit it? Power has one very definite meaning in science, and several rather vague meanings in practice. We speak of a powerful athlete, the power of the law, we sing of the power of love, we say knowledge is power, and so on, using the word in several different senses. Now in spite of the fact that a general audience feels a little anxious as to what troubles may be in store for it when a lecturer begins by being painfully exact, my telling you that by power an engineer understands the rate of doing work will not, I hope, make you fear that my remarks will bristle with technicalities.

When you walk upstairs you exert power, only perhaps the one-twentieth of a horse when you go up slowly talking to other people. But when you run upstairs because you have forgotten something that you intended to bring down, then your exertions represent perhaps the one-tenth of a horse power. You only get to the top of the stairs in either case, but the breathless sensation of running fast upstairs tells you that the more quickly you go the harder you are working. A person exercises power in the engineer's sense when he exerts himself physically, and the greater the exertion the greater the power. The exercise of power by the ruling classes, however, is unfortunately not necessarily accompanied by any exertion, physical or mental.

Probably the most familiar example of exerting power at a distance, that is of transmitting power, is pulling a handle and ringing a bell in another room. I pull the handle, exerting myself slightly, and as the result the bell at the other end of the platform rings. Were not this such a very familiar operation I would call it experiment No. 1. You have doubtless all of you performed this experiment several times to-day, and what is all-important with an experiment, performed it successfully.

And yet it was not until just one hundred years ago that it dawned on people that if one person, A, wanted to attract the attention of another person, B, the place where the bell ought to sound was where B was and not where A was. Indeed, in many English villages down to the present day, the knocker principle of attracting attention is alone resorted to, without the result which you may remember happened when Mr. Pickwick was staying in Bath at lodgings in the Royal Crescent, and Mr. Dowler undertook to sit up for Mrs. Dowler, but "made up his mind that he would throw himself on the bed in the back room and *think*—not sleep, of course. . . . . Just as the clock struck three there was blown into the crescent a sedan-chair with Mrs. Dowler inside borne by one short fat chairman and one long thin one. . . . They gave one good round double knock at the street door. . . . . 'Knock again, if you please,' said Mrs. Dowler from the chair. 'Knock two or three times, if you please.' The short man stood on the step and gave four or five most startling double knocks of eight or ten knocks apiece, while the long man went into the road and looked up at the windows for a light. Nobody came. It was as silent and dark as ever." But the tall thin man, you may remember, "kept on perpetually knocking double knocks of two loud knocks each like an insane postman" till Mr. Winkle, waking up from a dream "that he was at a club where the chairman was obliged to hammer the table a good deal to preserve order," met with the catastrophe which the readers of "Pickwick" will remember.

But if some houses can still dispense with mechanical or other methods of transmitting power, even to ring bells, factories cannot. The looms, the lathes, or whatever the machinery used in the factory may be, must either be worked by hand or foot, in the old style, or it must be connected with the steam, gas, or water engine, in the new. On entering a large factory you see lines of rapidly rotating shafting, and a network of rapidly-moving belting, all employed in transmitting power. As a contrast to this, I now throw on the screen a photograph of Sir David Salomon's workshop at Tunbridge Wells, in which every machine is worked by a separate electric motor, thus saving to a great extent the loss of power that usually accompanies the mechanical transmission. In America there are 6,000 electro motors working machinery; in Great Britain hardly 100.

But it is not only in transmitting the power from the steam, gas, or water engine of a factory to the various machines working in it, that electricity can be utilised. An incredible amount of power is daily running to waste in this and other countries because many of the rapid streams of water are too far away from towns for their power to have been hitherto utilised.

The holiday tourist, when admiring the splashing water dashing over the stones, hardly realises that the money loss is as if the foam were composed of flakes of silver.

If we take a low estimate that a large well-made steam engine burns only 2 lbs. of coal per horse power per hour, the coal consumption which would be equivalent to the waste of power at Niagara would exceed 150 millions of tons per annum, which at only 5s. or 6s. per ton means some 40 million pounds sterling wasted. And descending from big things to small, the river Avon flowing through Bath, which so far from being a roaring cataract, especially in dry weather, pursues its course with only a respectable, orderly swish, still represents a certain amount of lost power. It has been estimated that from 25 to 130 horse-power runs to waste at the Bathwick Weir behind the Guildhall, depending on the season. If we take as an all-round average that the fall at this weir represents 50 horse-power, and that a steam engine producing this power burns 150 lbs. of coal per hour, it follows that with steam coal at 16s. per ton, the price at Bath, the waste at Bathwick Weir represents an income of £450 per annum, not a princely fortune, it is true, but too large to be utterly thrown away as at present.

This state of things will, I hope, however, be shortly remedied, for as you will see from the large map on the wall, it is proposed to put up 81 electric arc lamps throughout the streets of Bath, and to supply the 50 horse-power required for these lamps by the fall at the Bathwick Weir, supplementing the fall with a steam engine at dry seasons.

The next large diagram shows the use that Lord Salisbury has made of the river Lea to electrically light Hatfield House and to supply electric motive power to the various machines working on his estate. The next diagram shows the course of the Portrush electric railway, 6½ miles long, which is worked by the Bushmill Falls, situated at about one mile from the nearest point of the railway. And lastly, this working model on the table, kindly lent me by Dr. E. Hopkinson, as well as the diagram on the wall, represent the Bessbrook and Newry electric tramway, a little over three miles in length, which is also worked entirely by water power, the turbine and dynamo which convert the water power into electric power being at about three-quarters of a mile from the Bessbrook terminus.

The newspapers of last week contained a long account of the spiral electric mountain railway that has just been opened to carry people up the Burgenstock, near Lucerne, and worked by the River Aar, three miles away, so that we see that electric traction, worked by distant water power, is extending. But splendid as are these most successful uses of water power to actuate distant electro motors, it is but a stray stream here and there that has yet been utilised, and countless wealth is still being squandered in all the torrents all over the world.

The familiarity of the fact makes it none the less striking that while we obtain in a laborious way from the depths of the earth the power we employ we let run to waste every hour of our lives many, many times as much as we use.

It is also a well-established time-honoured fact that large steam engines can be worked much more economically than small ones, and that therefore if it were possible to *economically* transmit the power from a few very large steam engines to a great number of small workshops there would be a great saving of power, as well as a great saving of time from the workmen in these many small workshops having only to employ this power for various industrial purposes, instead of having to stoke, clean, repair, and generally attend to a great number of small, uneconomical steam engines.

When delivering the lecture which I had the honour to give at the meeting of the British Association at Sheffield nine years ago, I entered fully into Professor Perry's and my own views on this subject, and, therefore, I will not enlarge on them now. You can all realise the difference between the luxury of merely getting into a train instead of having to engage post horses, of being able to send a telegram instead of employing a special messenger, or being able to turn on a gas tap and apply a match when you want a light instead of having to purchase oil and a wick, and trim a lamp. Well, a general supply of power to workshops is to the manufacturer what a general supply of light or a general supply of post-office facilities is to the householder; it is all part of the steady advance of civilisation that leads the man to go to the tailor, the shoemaker, the baker, the butcher, instead of manufacturing his own mocassins, and lassoing a buffalo for dinner. And in case any of you may be inclined to think that we have gone far enough in these new-fangled notions, and we are all perhaps prone to fall into this mistake as we grow older, let me remind you that, while each age regards with unjustifiable pride the superiority of its ways to those of its ancestors, that very age will appear but semi-civilised to its great-grandchildren. Let us accept as an undoubted fact that a general distribution of power would enable the wants of civilised life to be better satisfied, and therefore would greatly benefit industry.

There are four methods of transmitting power to a distance:—

(1) By a moving rope.

(2) By air compressed or rarified at one end of a pipe operating an air motor at the other end.

(3) By water forced through a pipe working a water motor.

(4) By electricity.

We have an example of the transmission of power through a short distance by an endless belt or rope in the machines geared together by belts on this platform, and in the rotatory hair brushes at Mr. Hatt's establishment in the Corridor, Bath. At Schaffhausen, and elsewhere in Switzerland, the principle is employed on a large scale. Spain and other countries use it in connection with the mining operations, and lastly wire ropes replace horses on many hilly tramways. Do not look, however, for the wire rope of the Bath Cable Tramways, for cable is only to be found painted on the sides of the cars.

For short distances of a mile or so there is no system of transmitting power in a *straight line* along the open country, so cheap to erect, and so economical of power as a *rapidly* moving endless rope; but the other systems give much greater facilities for distributing the power along the line of route, are much less noisy, and far surpass wire rope transmission in economy when the rope must move somewhat slowly, as in tramway traction, or when the distance is considerable over which the power is transmitted, or when the line of route has many bends.

In the same sense that an ordinary house bell may be considered as a crude example of the transmission of power by a moving rope, the pneumatic bell at the other end of the hall, which I now ring by sending a puff of air through the tube is a crude example of the transmission of power by compressed air. Compressed air is employed to work from a distance the boring machines used in tunnelling; the continuous vacuum brakes used on many of the railways are also probably familiar to you; and the pneumatic system of transmitting power to workshops is shortly to be tried on a fairly large scale at Birmingham.

But distribution of power by water pressure is the plan that has hitherto found most favour in this country. That little water motor at the other end of the platform rapidly revolves when I work this garden syringe, and serves as a puny illustration of the transmission by water pressure. Pressure water has been employed for years on a large scale at Hull, for distributing power; also by Mr. Tweddle as a means of communicating a very large amount of power through a flexible tube to tools that have to be moved about, but the grandest illustration of this principle is the vast system of high-pressure mains that has been laid throughout London.

The economy of this system is so marked, and the success that has attended its use so great that, did I not feel sure that electricity offers a grander system still, it would be with fear and trembling that I should approach the subject of this evening, the "Electric Transmission of Power." *Punch* drew six years ago the giant steam and the giant coal looking aghast at the suckling babe electricity in its cradle. That babe is a strong boy now, let the giant water look to its laurels ere that boy becomes a man. For the electric transmission of power even now bids fair to suppass all other methods in

(1) Economy in consumption of fuel.

(2) More perfect control over each individual machine, for see how easily I can start this electric motor, and how easily I can vary its speed.

(3) Ability to bring the tool to the work instead of the work to the tool. This rapidly rotating polishing brush, with its thin flexible wires conveying the power, I can handle as easily as if it were a simple nail-brush.

(4) In greater cleanliness, no small benefit in this dirty, smoky age.

(5) And lastly, there is still one more advantage possessed by this electric method of transmitting power that no other method can lay claim to—the power which during the daytime may be mainly used for driving machinery, can, in the easiest possible way, be used during the night for giving light. I turn this handle one way and the electric current coming by one of these wires and returning by the other, works this electric motor; now I turn the handle the other way, and the current which comes and returns by the same wires as before keeps this electric lamp glowing. It might be said that the transmission of power by coal gas which I have excluded from my test fulfils that condition, but so also does the transmission of power by a loaded coal wagon. In both these cases, however, it is fuel itself that is transmitted, and not the power obtained by burning the fuel at a distant place.

(To be continued.)

The British Association.

THE final meeting of the General Committee was held on the afternoon of the 12th inst. It was reported by Professor Williamson, as treasurer, that 1,984 tickets had been issued at this meeting to members and associates; there were 266 old life members who had attended the meeting. There was an accession of 36 new life members. Three hundred and ninety nine old annual members had attended, and 100 new annual members; 639 associates, 509 ladies, and 35 foreign members. The sum received for the tickets was £2,107. Professor Williamson added that the attendance of old life members and of old annual members had been decidedly above the average, and that showed that there was an increasing number who took a continuous interest in the work of the Association. One evidence of that continuous work is the number of committees that are appointed to investigate special questions and continue researches. To a large number of these committees, but not to all, grants of money are made, and all make reports to the annual meeting. Most of these are formally presented to the section concerned and thus do not come under general observation, but in the aggregate they bear testimony to an enormous amount of voluntary labour, and embody a mass of scientific information bearing upon problems in process of solution. The following money grants were now submitted to the General Committee by the Committee of Recommendation:—

MATHEMATICS AND PHYSICS.

Ben Nevis Observatory	£50
Electrical Standards	100
Electrolysis	20
Solar Radiation	10
Differential Gravity Meter	10
Nomenclature of Mechanics	10
Calculating Tables of certain Mathematical Functions	10
Seasonal Variations in the Temperature of Lakes, Rivers, and Estuaries	30

CHEMISTRY.

The Influence of the Silent Discharge of Electricity on Oxygen and other Gases	£10
Methods of Teaching Chemistry	10
Oxidation of Hydracids in Sunlight	10

GEOLOGY.

Geological Record	£80
Erratic Blocks	10
Volcanic Phenomena of Japan	50
Volcanic Phenomena of Vesuvius	20
Fossil Phyllopoda of the Palæozoic Rocks	20
Higher Eocene Beds of the Isle of Wight	15
Fossil Plants of the Tertiary and Secondary Beds of the United Kingdom	15

BIOLOGY.

Zoology and Botany of the West India Islands	£100
Marine Biological Association	200
Flora of China	25
Naples Zoological Station	100
Physiology of the Lymphatic System	25
To Improve and Experiment with a Deep-sea Tow Net, for opening and closing under water	10
Natural History of the Friendly Islands	100

GEOGRAPHY.

Geography and Geology of the Atlas Ranges	£100

ECONOMIC SCIENCE AND STATISTICS.

Precious Metals in Circulation	£20
Variations in the Value of the Monetary Standard	10

MECHANICAL SCIENCE.

Investigation of Estuaries by Means of Models	£100
Development of Graphic Methods in Mechanical Science	25

ANTHROPOLOGY.

Effect of Occupations on Physical Development	£20
North-Western Tribes of Canada	150
Editing a New Edition of Anthropological Notes and Queries	50
Calculating the Anthropological Measurements taken at Bath	5
Exploration of Roman Baths at Bath	100
Characteristics of Nomad Tribes of Asia Minor	30
Corresponding Societies	20
	£1,645

The Committee also recommended the appointment of a number of committees to whom grants are not made.

The President explained that already £300 had been given to the Marine Biological Association, and a further contribution of £200 would entitle the Association to certain privileges in the management. With respect to the Roman baths in Bath it had been felt that, having regard to the great value and interest attaching to them, it was most desirable that everything should be done for their preservation. Appreciating the active steps taken with that object at considerable cost by the Corporation, it was felt that it would be a gracious and proper thing on the part of the Association to express its gratitude for the cordiality of its reception by subscribing £100 towards the much larger cost incurred. It did not seem courteous to appoint a committee to interfere with the committee of the Corporation, and, therefore, the grant would be made to the Mayor for the Corporation.

The recommendations of the Committee were approved.

It was also resolved to memorialise the Government in favour of a permanent census sub-department, and the taking of the census every five years.

It was further resolved that the Corporation of Bath should be urged to lay bare a further portion of the Roman baths, and, with a view to the permanent preservation of the part already laid bare, that it should be protected from the weather.

The Committee then adjourned till Wednesday, Sept. 11th, 1889, at Newcastle-on-Tyne.

SECTIONAL MEETINGS.

FULL REPORT OF THE DISCUSSIONS.

[FROM OUR OWN REPORTERS.]

MATHEMATICAL AND PHYSICAL SECTION.

(*Continued from p.* 286.)

WEDNESDAY, SEPTEMBER 12TH.

Professor G. F. FITZ GERALD, M.A., F.R.S., presiding.

The report of the Committee on the *Nomenclature of Fundamental Units of Mechanics* was read, and Mr. P. T. MAIN presented A report on *Our Experimental Knowledge of the Properties of Matter*. Professor H. A. Rowland lectured on *Maxwell's Equations for Electro magnetic Waves*, and a discussion occupying some time ensued.

Major-General BABBAGE read a paper on the *Mechanical Arrangements of the Analytical Engine of Charles Babbage, M.A., F.R.S.* No discussion followed.

Professor JOSEPH KLEIBER, of St. Petersburg, instructed the section on *The Error of the Argument of Statistical Tables*, illustrating his lecture with numerous diagrams.

Mr. C. T. DIXON then read a paper on the *Fourth Dimension*, and Sen. C. TONDINI DE QUARENGHI discoursed upon *A Suggestion from the Bologna Academy of Science towards an Agreement on the Initial Meridian for the Universal Hour.*

This concluded the work of the section.

ECONOMIC SCIENCE AND STATISTICAL SECTION.

(*Continued from p.* 297.)

WEDNESDAY, SEPTEMBER 12TH.

Mr. INGLIS PALGRAVE again presided at this section.

Professor EDGEWORTH read a paper on *The Malthusian Theory*, which had been prepared by Mr. EDWIN CHADWICK. Local interest attached to this paper from the fact that Malthus lies buried in Bath Abbey.

Mr. GEORGE GIBBONS, of Tunley Farm, Bath, read a paper on *Dairy Industry*. He said the dairy industry was one of the oldest and most important with reference to occupation, and traced its development to the present time.

The reading of the paper was followed by a slight discussion, in which Mr. Botley, Mr. Macnight, Mr. Higgins (Shepton Mallett), and others took part.

MECHANICAL SECTION.

(*Continued from p.* 300.)

WEDNESDAY, SEPTEMBER 12TH.

Mr. W. H. PREECE, F.R.S., presiding.

Col. ROWLAND R. HAZARD read a paper on *Underground Railway Communication in Great Cities.*

Perhaps the most important physical problem, growing out of the concentration of great population in limited areas, was the construction, maintenance, administration, and uses of the public streets. These, absolutely indispensable for purposes of ordinary traffic, fulfilled many other requirements of public necessity or convenience, but should be so constructed as to provide for many others of capital importance, growing out of the multiplying wants incident to the demands of modern civilization.

The main thoroughfares of traffic should be reconstructed, substantially upon the plan of superficial subways and galleries, illustrated by a model and sketches shown. Between the lines of curb the substance of the street should be removed to a standard depth of twelve feet, and the excavation so made replaced by four centrally placed subways, the two interior ones being devoted to rapid transit or fast railway trains, operated at great speed between few stations. This form of railway service, essential to economy of time and the proper development of suburban population, was not now performed at all in any great city. The two exterior subways being devoted to "way" or slow trains, operated rapidly between frequent stations, for the convenience of every district on the line for shopping, and also for supplementing the more rapid long journeys of the express line.

These railways to be operated by electric-motors and solid trains, specially devised for the service and embodying provisions for safety and comfort to a degree which apparently precludes the possibility of serious accident. On either side of these centrally disposed railway subways were placed continuous galleries calculated for the housing, inspection, replacement, and repair of all pipes and wires of communication, sewers for local service, water mains and supplies, gas mains and service pipes, steam service pipes, pneumatic power, post, parcel, refrigerating and time tubes, electric wires for arc and incandescence lights for street and private use, for power, signals, telegraphs, telephones, etc., and all other essentials or conveniences which are more profitably generated or produced at some central station, and can be distributed or served only through the public domain, overhead or underfoot, and which from the want of such common accommodation were now used—if at all—to a limited extent, at great cost and inconvenience to the authorities, the corporation, and the public.

It was also imperative that the whole subway system should be adequately supplied with fresh air in movement, so that ventilation should be as perfect as in the best arranged dwellings. This was effected by closing the railway subways from any communication with the surface of the streets except through the station doorways, and ventilating the stations by shafts supplied with electric-exhaust-fans placed in the rear of the entrance buildings, the supply of fresh air being derived from similar shafts placed in the rear of the opposite building; by this means the air of the stations will be absolutely renewed as frequently as required. The railways from open cylinders from station to station, and the trains being of approximate cross-section constitute loose pistons always moving in the same direction; the effect is the establishment of a ventilating current within the subways dependent for its force upon (1) the approximation of cross-sections, (2) the speed of the trains, and (3) the integrity of the tunnels or subways.

As the products of artificial combustion will be excluded as far as possible, the requirements of ventilation are reduced to a minimum and perfectly performed.

Reference was made to a new material, "ferflax," composed of braided steel wire, and flax-fibre, chemically treated under hydraulic pressure, devised for the wall panels of the subways, and for the construction of the railway carriages, a compound building material not unlike horn in character, having a strength and flexibility somewhat exceeding steel wire netting; a toughness approximating horn, non-fragile and unbreakable by bending, not liable to shatter under shock.

The adoption of this system for the streets of every great city would effect an economic revolution. There would be rapid communication between distant points within the metropolitan areas; there would be rapid communication between frequent stops for the convenience of local traffic and shopping; the streets would be brilliantly lighted by electricity, every house on the line would have access to gas, steam, water, the telephone; telegraph, pneumatic tube, electric light, and compressed air at will. Small industries would flourish, because small and cheap power from remote stations would be everywhere available, while the surface of the streets could be maintained in a perfect state, with the minimum of cost, and with complete immunity from disturbance, other than for the repair of worn surfaces.

Sir FREDK. BRAMWELL said this obviously was a question which could only come into existence if it would pay. He desired to know what the cost per yard or mile of such an undertaking would be. No one could doubt the desirability of having this system. Would there be such a reward to those who undertook the work as to justify its structure?

Col. HAZARD said, in answer, it would be quite impossible to fix any exact sum, as labour and material varied so much in different parts. The cost would be very much less in London than in New York. The estimated cost would be somewhere about £400,000 per mile. After answering a question how the sewage would be dealt with in this system,

Sir FREDK. BRAMWELL said the paper dealt with two subjects. One was the question to which he had paid attention for some time past, for subways for pipes and for the means required to pass along the telegraph wires, and so on. The other was the question of underground railway communication. The gallant gentleman had referred to the obstruction in carrying out underground railways in England which was caused by legislative interference. He gave as an illustration the strenuous efforts which he and others had to put forth in obtaining a subway in Southwark-street. He did not think with the author as to the interruption of traffic caused by these subways, and gave it as his opinion that there need be absolutely no interruption to traffic during the working hours of the day. He referred further to what he characterised as "the hideous rectangularity" of the streets in America. He deprecated this on the score of peace to the mind and on the score of more ready communication from one point to another under certain circumstances.

After other gentlemen had spoken, the author enlarged upon Sir Frederick Bramwell's remarks on the rectangularity of streets in America, pointing out that owing to the way the streets were built they acted as tunnels, and the wind swept through them with tremendous violence.

Mr. W. H. DOUGLAS gave full particulars as to the construction of *an Annual Winding Clock.*

A discussion ensued, in which the CHAIRMAN thought this clock would prove a great boon to the public. It seemed to him to possess all the attributes for making it, in due time, a true time-keeper for the year. It seemed to be the general opinion that the temperature affected this clock, and that something would have to be done in improving this point.

Mr. H. DAVEY contributed a paper on *A New Form of Air Compressor for Variable Pressures*, and

Mr. A. WINTER read a paper on *Controlling the Direction of Rotation of a Dynamo.*

R. A. PROCTOR.

SCIENCE, in its most beneficent field of operation, that of morally elevating all mankind, has suddenly lost one of its ablest and most effective workers.

Richard Anthony Proctor was essentially and typically a man of genius. He was nobody's disciple, nobody's pupil, he belonged to no school, he followed no precedent, was the product of no course of academic or other course of education outside himself.

It is true that he studied and graduated at Cambridge, earning distinction there in mathematics, but he broke away from the established routine of collegiate advancement, and climbed the rugged mountain of physical science by a pathway which he not only hewed and paved for himself, but left open for the use of all who may choose to follow him.

In this latter consisted his highest and his peculiar merit.

He conducted original researches, and was exuberantly fertile in original suggestive speculation, but his work in these directions was not used as scientific capital to be invested in office or professorship hunting, was not merely buried in the "Transactions" of learned societies which are read only by experts, but all was freely spread abroad for the benefit of all, and in such wise that all might easily reach and use it.

Any man of average ordinary intellect and industry may learn the contents of science text-books, and "get-up" all that is required for passing examinations in science; and having done this may reproduce the matter of the books he has read and the lectures he has heard, and thus become an ordinary Professor of Science, or writer of ordinary treatises and hand-books for the use of ordinary academic students. This is so nearly mechanical that it ranks only a few degrees above the acquisition of dead languages—the translating of Homer etc.

But there is also another class of scientific students, those who do not merely *learn* science, but who assimilate it, who absorb it into their very souls as psychic nutriment, and thus become scientific in their essential nature. When these men teach they are not quoting, not copying nor reproducing the works of any master, however great, but are producing works of their own, as the true artist paints an original picture, though composed of elements common to all pictures. Proctor was an eminent example of such great masters in original scientific exposition.

Proctor boldly attacked one of the most difficult problems presented to the teacher of science, that of simplifying complex mathematical processes and results, and presenting them in such form as to be intelligible to the non-mathematician. No mere learning of lessons can enable a man to do this. He must master the whole subject in itself, must make it his own. The machinery of mathematical formulæ is absolutely necessary for the performance of certain quantitative scientific work, and must be used accordingly, but writers who pepper their pages with algebraic equations for the expression of simple laws that can be expounded in plain, ordinary language are either pedantic mental pretenders, or intellectual cripples that cannot traverse scientific ground without the aid of symbolic crutches; they are those who have learned to formulate, but cannot reason.

Proctor's popular treatises were by no means devoted to merely the rudiments of his subjects. He presented on the popular platform those more recondite questions previously regarded as appertaining only to the altars of the high-priests of science; he not only told his uninitiated readers that the sun is so many millions of miles distant from the earth, but struggled to teach them the details of the methods of determining the solar parallax, and in doing so detected a serious blunder made by the late Astronomer-Royal in reference to the transit of Venus, a mistake that was corrected only just in time to save our expeditions from a humiliating fiasco. He revelled in thus unravelling mathematical complexities, and even carried his mathematical propensities into his recreations, his whist and chess problems, and to the mathematical demonstration of the folly of the gambler. We believe that he acted imprudently in this, but he laughed at our ideas on this subject, which are that a man who works with his brain should play with his muscles, that the brain-worker should scrupulously abstain from intellectual recreations. Navvies should play at chess, philosophers may play at skittles, on the principle that recreation should afford rest to the hard-worked faculties, and exercise those that are otherwise left dormant. Like most of Proctor's friends, we feared that he would suffer cerebral collapse on account of his insatiable love of intellectual hard work.

It was not until we had seen him at home with his family, and wheeling his little sickly son on the Brighton pier, that this apprehension was removed. Then the wisdom of his second marriage became evident, the widower had found a helpmate who could win him away from severer studies to revel in music and pictorial art, in lively social converse, and the prattle of little children; for now there were three loving families, the first family of the widow, that of the widower, and those of the second marriage.

All who have had the pleasure of thus knowing Mrs. Proctor must deeply sympathise with her terrible affliction, as all such must have seen that the marriage was a genuine love-match, subsequently sustained by mutual respect and admiration.

In the days of his widowhood, when he lived at Clapham, we only met him on purely scientific ground, and was told by those who knew him more intimately that he was then a recluse and rather morose; but at Kew he was all the opposite of this, the difference due no doubt to his brilliant and gentle partner, than whom no one could be more suitable to such a man, nor no man more suitable than Proctor to such a woman.

His faith in the infallibility of mathematical results was curious, seeing that he had successfully refuted some of the accepted conclusions of very eminent mathematicians. His own mathematical self-righteousness maintained him in a perpetual Donnybrook, and those who only knew his controversies in their printed form commonly supposed him to be ill-tempered. This, however, was not the case; he was really as amiable as the habitual smile of his somewhat feminine features indicated.

We dwell upon this, knowing that considerable bitterness exists in the minds of many who have had controversies with him, and in this hope that all this will now be healed by making fair allowances for errors due to overwork and an earnest devotion to the purity of science, which occasionally led the great teacher into a somewhat Quixotic eagerness to defend it against the inroads of real or supposed fallacies.

INTERNATIONAL GEOLOGICAL CONGRESS.

THE opening of the International Geological Conference took place on Monday evening, the 17th inst., at the London University, Burlington Gardens, the committees on nomenclature and on the map of Europe having held sittings at the same place earlier in the day. At the evening meeting, which was attended by a large and distinguished company, a short address was delivered by the outgoing President, Professor Beyrich, of Berlin, after which a letter from Professor Huxley, the new Honorary President, who is now in the Engadine, was read, expressing his great regret that the state of his health did not allow him to be present. Sir Douglas Galton having in a brief, telling speech bade the strangers and foreigners welcome, and M. Capellini, Rector of the University of Bologna, having made a suitable reply, the new President, Professor Prestwich, assumed the chair, and delivered the opening address in French.

The following is a translation of Professor Prestwich's address:—

I deeply regret that on account of the present state of his health Mr. Huxley is not here to offer you a welcome to England. But if we need a voice, I ask you to believe that the unanimous voice of English geologists joins in this sentiment, and thanks you, our foreign colleagues, for having responded in a manner so flattering to us to the invitation of English geologists to meet this year in London. We have in this assembly, geologists representing Germany, Austria, Belgium, Denmark, Spain, France, Holland, Hungary, Norway, Portugal, Roumania, Russia, Sweden, Switzerland, as well as the United States, Canada, Mexico, the West Indies, the Argentine Republic, and Australasia. Eminent and illustrious men from all these countries honour us with their presence, and bring their knowledge to our assistance in discussing for the fourth time the questions with which the International Congress is concerned. The number of geologists present on this occasion indicates the deep and unbroken interest which they bring to it. Among the most permanent members of the organisation are the Secretaries of the Congress and of the Committees, to whose important and gratuitous services the

Congress is much indebted. We have unfortunately to deplore the death of one of these, M. Charles Fontannes, and we lose by this blow the advantage of his long experience and his valuable assistance.

As usual, our discussions are carried on in French, as in the diplomatic world, but it is to be hoped that friendly feeling will be better preserved here than sometimes happens in the other case, where councils have not always avoided strife. If I may be allowed to speak after a personal experience of about half a century, a most cordial feeling between us English geologists and our fellow-workers and friends beyond the sea has been the normal condition during those long years. May these open and friendly relations still remain the portion of science both now and in the future.

These friendly manifestations were, however, only occasional, and there was little personal exchange of ideas. But of late, instead of the discussion of disputed questions by each nationality separately, the happy thought has been hit upon of submitting questions which concern all to the arbitration of this General Council. In this way the various national centres of our science, each of which has its local shade of character and special experience, are able to combine their results in a much broader and more uniform manner than if each were separately to follow out its own ideas based on a more limited set of observations. Nevertheless, in giving to our science the uniformity of terms and of classification which are so necessary to it, we must be careful not to subject it to bonds which clasp it too tightly and which, instead of developing, may even retard its progress. It is advisable that the bonds should be sufficiently elastic to adapt themselves to the rapid development which we must expect in geological knowledge. It is very desirable, it is even highly necessary, that we should be in agreement with regard to the colours and symbols to be employed for the various beds, rocks, and irregularities which we find in the earth's crust, but petrology is still far from being established on firm foundations, and the synchronism of beds between even neighbouring countries is not always easy to determine with accuracy, and much less between countries far apart. Let us therefore endeavour to avoid the error of congresses of arrogating to themselves an infallibility which is very little in accord with the progress of science.

And now I would say in a few words what the Congress has already accomplished, and what remains to be done.

At Bologna M. Capellini gave the history of the Congress so well that there is no need for me to touch upon it, unless it be to remind you that the idea of the Congress had its origin in America at the Philadelphia Exhibition in 1876, and no doubt this idea, like that of the Exhibition itself, was only the expression of the desire which had been making itself felt for some time of treating certain questions of science and art, not only in what we might call a national family meeting, but in a cosmopolitan assembly—to deal with the great questions which concern all mankind as belonging to the whole civilised world, and, in order to discuss them, to make of the various nationalities a brotherhood founded on their interests and their common welfare.

Congress of Paris.—At the first Congress held at Paris in 1878, the primary questions of nomenclature and classification were sketched out, as well as the rendering of geological works uniform in the matter of colours and symbols, so that the signification should be alike for all countries.

The idea which was well received at first was to make use of the solar spectrum, and to adopt the three primary colours, red, blue, and yellow, for the three main divisions of Primary, Secondary, and Tertiary rocks; the subdivisions of the second order should be distinguished by shades of these colours, and those of the third order by cross-hatchings of the same colours. But this scale was afterwards found too limited, and at Bologna as at Berlin several modifications and complementary colours were introduced into it, still, however, keeping somewhat to the original idea. As a corollary, it was suggested that the labels of fossils ought to be, as is already the case in many museums, of the same colour as that used for the bed from which the fossils are derived, so that both the horizon and the period might be seen at a glance.

As to the question of rendering the nomenclature of the great divisions of the earth's crust uniform, it was felt that in the first place it is essential to be agreed upon the terms employed, and it was seen that a geological dictionary containing the etymology or source of each geological name, the synonymy in the other languages, a definition in French, and an illustrative figure as in technological dictionaries would be most useful. The publication of such a work, which ought to be at least in six languages, has been strongly supported. Finally the study of these questions was referred to International Committees to report upon to the meeting of the Congress at Bologna.

With regard to the classification of strata, memoirs have been received on the Pre-Cambrian strata, and on the Palæozoic rocks of North America, on the Carboniferous strata and the Permian, in different parts of Europe and in America, and on the relations of the horizons of extinct vertebrata in North America and in Europe. The two last memoirs were accompanied by valuable lists of invertebrata, plants, and reptiles of various countries. These memoirs have raised very important stratigraphical and palæontological questions with regard to the wide distribution of families and genera. Each of the faunas of the primary divisions of geological time has been in part recognised as occurring equally in the two great continents, in Europe and in North America — and Mr. Cope has been led to ask himself whether the organic types are natives of a special centre from which they have spread, or whether the same types of generic structure have appeared independently at different points of the earth; and in the latter case whether they are contemporaneous or of different periods. These synchronic appearances form a subject full of mystery from whatever side we view them. The geological record is at present too incomplete for us to solve the problem. In every country there are gaps which can only be filled by the aid of observations continued in other parts of the world. To encourage these observations is one of the most useful functions of the Congress. There has also been discussed the classification of the quaternary deposits in relation with the remarkable history of the grottoes of central France, the Glacial deposits and the Dunes of Holland, the Tertiary beds of Portugal, which are limited to the Miocene and Pliocene; the Tertiary eruption rocks of Hungary, from the point of view of discovering whether there is any relation between the mineralogical constitution and the relative age of different trachytic types.

The Congress has also dealt with questions of higher physics, such as those of the deformations and fractures of the earth's crust, the alignment of faults and of moun tain chains, the origin of volcanoes, and the probable causes of earthquakes, the structure of the Alps, and the foldings of the chalk.

Less in conformity with the fundamental objects of the Congress, but having nevertheless a relation to them, were the memoirs on the Felspars, on the alteration of superficial deposits, on the employment of the polarising microscope, on the propagation of heat in rocks, and other special subjects.

The Congress of Bologna.—In the fine volume constituting the account of the meeting held at Bologna is contained the report of the International Jury appointed to judge the competition for rendering the colours and geological signs uniform, for which the King of Italy had generously offered 5,000 francs to be given for the best memoirs deemed practically applicable.

Six memoirs were received, of which the three prize ones are published with coloured illustrations which leave nothing to desire. The authors of these were of opinion that though the solar spectrum is a very advantageous fixed base, the scale of colours was insufficient, and that it would be necessary to introduce complementary colours or such as had a relation to the primary ones. The divisions, in fact, of the sedimentary beds are so numerous that it would be necessary to employ not only these colours, but also many shades of the same colours or of different hatching, reserving rose-colour for the Archæan crystalline schists.

It was agreed to use for the eruptive rocks, strong and brilliant tints of red, green, or purple, the intensity of which would render them easily distinguishable from the colours of the primary sedimentary rocks and from the clear colour of the schists. It was desired too to discriminate between the acid and the basic rocks, both by their petrological composition and by their age, in using different shades of the same colours with coloured dots or by hatching of different kinds, and with the letters of the Greek alphabet. It is proposed to show thus by symbols the principal varieties of the granitic, porphyritic, trachytic, andesitic, basaltic, and other rocks; but the varieties are so numerous that it would be difficult to know where to place the limits, and according to one of these plans it would be necessary to use seventy-six signs and hatchings of different colours. You will be able to judge of the different methods proposed by the fine plates by which the reports are illustrated. The sections taken in the mountains of Switzerland and others which serve as examples produce an excellent effect. Conventional signs are also used to indicate the inclination and direction of beds, faults, fossiliferous places, cold, warm, and mineral springs, travertines, quarries, mines, etc. A geological map will thus be a veritable hieroglyphic chart possessing a universal meaning.

As a result of the discussions held at Bologna, and in order to make a practical application of them, it was decided to publish a Geological Map of Europe on the scale of $\frac{1}{1000000}$, in which the signs and colours definitely adopted by the Congress should be employed. This map, already far advanced towards completion, is under the direction of a Committee at Berlin.

With respect to the reports on the uniformity of Geological Terms, they have been received from nine national Committees, namely, Austria, Belgium, Spain, Portugal, France, Great Britain, Hungary, Italy, Russia, and Switzerland. Besides these there are eleven from individual members. One might well imagine that among so many opinions all would not agree; but from the good-will that every one has brought to the question, although some discord has occurred on points of detail, they were almost unanimous on essential matters, and a general agreement for Stratigraphic Terms has been arrived at, such as group, system, series étage, and for Chronological Terms, such as era, epoch, age, etc., leaving to future Congresses the consideration of certain other trifling points. This subject reminds me, gentlemen, of a difficult question which you have to face. If your resolutions are voted by the voices of all the members of the Congress, the result can scarcely help showing the effect of the variable number of the nationalities according to the country in which the congress is held. For example, at Bologna there were 149 Italian members and 19 English; at Berlin, 163 Germans and 11 English; here the numbers of English and foreign geologists present is still more considerable than at preceding Congresses. Therefore if all vote, the opinion of the place in which the Congress is held will predominate too much, unless you find means of placing limits to it.

Thanks to the fairness of the Council at Bologna, the greater part of the Resolutions were passed unanimously; some few having been referred back to the various Committees for further deliberation.

As to the stratigraphical divisions, it was resolved: (1) That the term "Group" shall be applied to each of the great divisions of the Primary, Secondary, and Tertiary rocks. (2) That the sub-divisions of these groups shall be called "Systems." Thus you have Primary Group, or Palæozoic, and Silurian System, Jurassic System. (3) To the first order of divisions of the systems, the term series will be applied (Oolitic series), to the divisions of the second rank the term "Etage," and to those of the third order the word "Assise." The unit of the stratified masses is the stratum or bed. With regard to a word much used in England, and dating from the primary time of geology, the word "Formation," the majority of the Congress decided not to employ it in the sense of the French "Terrain" as we generally do, but only in the sense of origin or mode of formation, so that we should say of a bed that it is a marine formation, or fluviatile formation, etc. We must, therefore, endeavour to find some other word to replace the habitual "Chalk Formation," London Clay Formation, etc.

For the Chronological divisions corresponding to those of the stratigraphy, it has been proposed that: (1) "Era" shall correspond to "Groupe," as "Primary" or "Secondary Era;" (2) "Période" to "Système," as "Silurian Period," Cretaceous Period;" (3) "Epoch" to "Series," as "Inferior Oolite Epoch;" (4) "Age" to "Assise," as "Portlandian Age."

On the subject of colours and symbols, the final decision was delivered to the committee of the geological map, and with respect to the rules to be followed in the nomenclature of species, it was resolved that the name given to each genus and each species shall be that by which they were earliest designated, subject to the condition that the characters of the genus and species have been published and clearly defined. The priority will not go back beyond Linnæus, 12th edition, 1766.

At the Bologna Congress there were only four special and local memoirs, and those were only produced in support of collections and documents which were exhibited.

Congress of Berlin.—The official account of this meeting has only been published a few days. I greatly regret that I have not been able to avail myself of it, for my address was already printed. I therefore confine myself to a mention of it, while for my information I had recourse to the independent notices of MM. Renevier, Klebs, Choffet, Frazer, Blanford. and Dewalque. At Berlin the Congress was especially engaged upon the geological map, the committee of which, profiting by the liberty accorded by the Bologna Congress, revised the colours for the sedimentary rocks in the following manner:—

1. Actual deposits (Alluvium, etc.)	Very pale cream colour.
2. Quaternary (Diluvium)	Naples yellow.
3. Tertiary	Different shades of yellow.
4. Cretaceous	Green tints and hatchings.
5. Jurassic	Blue tints.
6. Triassic	Violet tints and dots.
7. Permian and Carboniferous	Grey tints and hatching.
8. Devonian	Brown tints.
9. Silurian	Greenish-grey tints.
10. Archean	Rose tints.

And for the ten divisions of the eruptive rocks different tints and dots of strong and brilliant red.

With respect to the letters used in addition to the tints, it was decided to employ Latin initials for the sedimentary rocks and Greek initials for the eruptive rocks. It is on the basis thus described that the large and beautiful geological map of Europe in course of preparation at Berlin will be coloured.

As to the stratigraphical uniformity, the Congress adopted in the main the resolutions passed at Bologna. The French and Portugese committees, however, proposed to replace the word "Group" by "Series" for the three great divisions of the earth's crust, so that in place of "Primary Group," &c., we should have "Primary Series." The word "Group" will then take the place of the divisions of systems, as "Oolitic Group" (instead of "Series"). This substitution will, perhaps, recommend itself to many among ourselves.

Further, on the proposition of substituting for the present different terminations, a system of terminations, in *ique*, the Committees were not unanimous. Instead of Eocenic System, &c., we should have the terms Eocenic, Siluric, &c. Is it essential to alter these ancient terms of the science? It is all very well to have such terminations for actual things, such as the crystalline and eruptive rocks, *e.g.*, granitic or porphyritic rocks, but can one submit, or is it necessary to submit, series of strata which have no character in common, to the same narrow rule, because they are all included under the same ideal name of classification? This question will no doubt be discussed, and it is for you, gentlemen, to judge what is the most fitting solution.

Among the other questions, gentlemen, which you will have to consider, is that of the classification of the Cambrian and Silurian strata. Accordingly as these two great systems have been taken in a descending or an ascending order, the division between the two has been placed lower or higher, because the breaks in the two groups are few and the palæontological connection is little interrupted. In England, Sedgwick, who began from below, found no break till he reached the Mayhill sandstone, while Murchison, who began from above, met with no check till he reached the lower limit of palæozoic life: he even hesitated. Thus, in the countries where Murchison's work is best known and where his lead has been followed, the partisans of one side have surmounted stratigraphical barriers, while the partisans of the other side have neglected palæontological arguments. In this country, their stratigraphical birthplace, the Cambrian and Silurian have been but little spread out, and it is only since the death of their founders that the palæontological proofs have increased sufficiently to indicate their distinctive character. These two systems are found elsewhere (especially in America, where there is now some discussion as to their association with a Taconic system) either more developed or with special characteristics which may enable us to determine more precisely their mutual relations. Here, too, gentlemen, the knowledge which you bring from all parts of the world may assist us to unravel this complicated question.

Amongst the other subjects which the previous Congresses have not fully discussed are:—

(1) The connection between the Carboniferous and the Permian.

(2) Between the Rhaetic and the Jurassic.

(3) Between the Tertiary and the Quaternary.

In the case where there has been no interruption of the layers or discordant stratifications, the systems pass from one to the other without an apparent break, like the colour of the solar spectrum; but, as everybody knows, if a link be missing, the sequence is broken and the line of separation of the divided layers is settled. If, for example, the Caradoc were missing from the Cambrian-Silurian, or if the Pliocene were missing from the Tertiary, there would exist between these formations a gap which would give the necessary break.

Apart from the international questions, the Congress of Berlin had several special memoirs under consideration, but as yet the details are not before us; besides, whatever may be their importance, they are less interesting for the moment than the international subjects under discussion. One of these special memoirs refers to a vast palæontological project, and the Congress has nominated a Commission of distinguished palæontologists to contribute to its realisation. The proposed work is on the plan of Bronn's "Enumerator and Nomenclator," and of Alcide d'Orbigny's "Prodrome;" but such is the progress that palæontology has made, that about fifty large volumes would be needed for the complete enumeration of all the known animal and vegetable fossils. A work of this nature would form a useful addition to the great polyglot dictionary of geological terms projected at Bologna.

These then, gentlemen, are some of the subjects which you will have to consider. You have to review, and where possible to finally decide, questions already discussed, and to examine the new points raised. Amongst them is the fundamental problem of the crystalline schists, a subject remarkable for the great progress made in it during the last few years, and for the new aspect which it has recently assumed; for it is clear now that it is not merely a chemical metamorphosis by heat, but that the subject also includes questions of weight, pressure, and of sliding movements which necessitate for their explanation the combined efforts of the physicist, the chemist, the petrologist, and the stratigrapher.

Although the majority of the subjects under consideration at the present Congress are eminently practical and positive, they include theoretical points of the greatest interest. The classification of the formations, and their synchronism, rests as much upon stratigraphy as upon palæontology. In order to determine their relations, the identities as well as the difference of the fossil species must be noted, and it must be ascertained whether the sequence in distant countries follows the synchronic or merely the homotaxic arrangement. In one case it can scarcely be hoped that the same species will be found; in the other the identity of the species may be taken as a contrary proof, provided one does not agree with Edward Forbes that the species have had more than one centre of origin. To resolve these questions we must trace the dawn of life, the appearance, the duration, and the disappearance of the species, and of the source from which they came. Must we believe in the evolution of the species, or must we regard them as buds of short duration and the genera or families as the branches or permanent shoots. If I have permitted myself to discuss these problems of fact and of theory, it is not to venture on an opinion but only to indicate the vastness of the field, and how much collaboration and time will be occupied in making all the necessary studies. It must not be thought that the work of the Congress is completed when the fundamental questions have been discussed; unanimity established on the international facts will but clear the way, and the cosmopolitan theories already discussed, together with those which may arise, will provide ample materials for the future labours of the International Congress.

Dr. T. Sterry Hunt, of Montreal, then proposed a vote of thanks to the President for his address, Dr. von Zittel, of Munich, seconding the motion. The formal passing of the vote of thanks brought to a close the proceedings,

At 9 o'clock Professor and Mrs. Prestwich held a reception in the Library, in which has been arranged a large and valuable exhibition of objects of geological interest, mainly illustrative of the questions to be discussed before the congress. Contributions to the exhibition in the form of maps, rocks, fossils, &c., have been received from geologists all over Europe, as well as from many well-known English scientists. Dr. Geikie sent a number of maps illustrative of the peculiar geological structure of the North-west Highlands, together with a collection of rock specimens from the same district. Professor Heim, of Zurich, exhibited a very interesting collection of rocks and fossils from Switzerland, showing the contortions of the strata effected by pressure; and Dr. H. J. Johnston-Lavis, of Naples, sent some equally interesting specimens of more or less stratified limestones (in different stages of metamorphism) ejected from Monte Somma. A large series of Precambrian rocks from North Wales were contributed by Dr. Hicks; and a series of Monian rocks and slides, illustrating the various methods of metamorphism and their results, with regard to Anglesey rocks, by Professor Blake. Professor Prestwich, the president, sends a collection of plants and marine fossils from the coal measures of Coalbrook Dale, together with some peculiar types of flint implements from the Quaternary river drifts of France and England. From the office of the Geological Survey of Italy a large number of maps and rock specimens were sent; and Professor Judd showed a very interesting collection of samples from the borings in the Nile Valley conducted by the Royal Society. Dr. G. J. Hinde exhibited a number of specimens of siliceous rocks from the carboniferous strata of Yorkshire. Ireland, Wales, and Spitzbergen, showing their derivation from the remains of siliceous sponges. A very large and remarkable series of palæolithic implements from various localities, British and foreign, were contributed by Dr. John Evans; and an unusual collection of objects illustrating the stone-age deposits of Crayford were sent by Mr. Spurrell. Mr. Mark Stirrup brought together a series of boulders found in the coal measures of Lancashire, and there was also exhibited a large collection of wonderfully preserved fossil plants from the Eocene formation of the Isle of Mull. Some interesting specimens of spheroidal concretions occurring in granite, and others of Itacolumite, or flexible sandstone, were sent by Dr. Hatch and Mr. R. D. Oldham respectively. The exhibition was too large to be described at all exhaustively, but the foregoing remarks will supply an indication of its scope and interest.

The entire arrangement and organisation of the exhibition were in the hands of Dr. Hinde and Mr. J. Teall, together with several voluntary assistants.

NOTICES.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Sept. 10th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	53·5 degs., being 3·4 degs. below average.	6·5 ins., being 0·5 ins. below average.	277 hrs., being 87 hrs. below average

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

Nearly allied to the glacier tables described in my last are the glacier cones, but their history is rather more complex and very interesting. The glacial ice river is a paradoxer, some of its doings contradicting point blank the orthodox proceedings that are predicated as those of ordinary rivers. Thus on the glacier heavy masses float and even rise above the general level, while such filmy trifles as a fallen leaf or dead butterfly sinks to considerable depth, because it is filmy.

A dead butterfly falling on a glacier digs its own grave, and then raises a monument to its own memory, the height of such monuments varying from 6 to 8 inches to 6 and 8 feet, with about the same diameter at the base.

But what have butterflies to do on glaciers? the reader will ask. The answer is that their business there is simply to die. They are carried by the wind from the fields and gardens below, are killed by the cold, and fall upon the ice. They are even found on the nevé far above the glacier. When I ascended Mont Blanc, two were found on the Grand Plateau at an elevation of about 12,000 feet, and were kept as memorials of the ascent by the junior guides who found them. They are commonly found in making such ascents.

Most of my readers will remember Franklin's celebrated experiment of placing pieces of cloth upon snow exposed to winter sunshine, how they thawed the ice beneath and sunk to depths varying with their colours. The loose superficial structure of a butterfly coated with microscopic feather scales is a remarkably good absorber of radiant heat, and being exposed to the summer sunshine acquires a high temperature.

As the heat thus absorbed readily passes through so thin a film as the butterfly's outspread wings, the ice below them is more rapidly thawed than that of the less absorbent naked ice around, and thus a hollow is formed under the butterfly, into which it sinks, while heavy masses of rock protect the ice below them and, as already explained, stand above the general level on moraines and ice cones.

Let us now consider how the butterfly sinks, and the necessary consequences that follow such sinking. On a glacier with so little slope as the Unteraar the hollow under the butterfly remains filled with water, and the butterfly rests lightly on the bottom of this little pool. The thawing action continues as at first, so long as the depth is small enough for the radiant heat to pass effectively through the water.

After this another and very different action commences. The temperature of water in contact with ice is 32° Fah. When raised any temperature between 32° and a fraction above 39°, its density increases proportionately, and therefore the water thus warmed will sink below other water remaining at 32°.

The watery grave of the butterfly when exposed to the rays of the summer sun is superficially warmed, but immediately the temperature of the surface water exceeds 32°, it sinks, and cooler water rises to take its place. The warmer water in its downward course strikes and thaws the ice walls and bottom of the grave, and thus continually digs it wider and wider and deeper and deeper, but this widening and deepening does not occur equally on all sides. The south wall of the grave is in shadow from about 6 a.m. to about 6 p.m., most deeply so at midday, when the sun is working the most effectively. The solar grave-digging is therefore the most vigorously conducted on the north side of the excavation, both as regards walls and bottom. It is thus elongated northwards, and deepened on the north side. This proceeds to such an extent that the bottom of the grave becomes a rather steep incline, from due north upwards to due south, in the direction of the longer axis of the now elliptical pool.

We were shown several of these in various stages of development. Into those that were far advanced we thrust our alpenstocks, which, after a little preliminary reeling, stood aslant, pointing due south with remarkable accuracy, and also pointing upwards with a respectable approximation to sun's meridian attitude at the place and season. This is easily understood when we reflect upon the action above described. The stick falls to the lowest point it can attain; in doing so its lower part occupies the deepest end of the elliptical pool, and it leans against the longest incline of the wall, which extends from north to south.

These pools have accordingly received the name of meridian-holes (*trous meridionales*). By their aid a traveller in a fog, and without a compass, may at once find his geographical bearings.

It is easy to understand that this kind of excavation may be carried on much further. So long as the water can freely circulate, the warmer water will continue to sink from the surface, and, when it is cooled down to freezing point by its work of thawing, will rise again, and this circulation may continue to any extent. In some instances it does so continue for a long time, and thus the little meridian hole grows to a deep, wide pit in which some of the meridional features become partially obliterated, but the elliptical form remains. On the Unteraar glacier I saw several of these quite large enough to justify the name given to them by our merry mentors, who called them *Baignoires*, or bathing tubs, and invited us to use them freely. Agassiz describes examples reaching a length of 10 to 12 ft., a breadth of 3 to 4 ft., and depth of 20 ft. He calls them "*Wasserbecken*," water basins.

The ablation or thawing down of the glacier described in my last necessarily supplies a large quantity of superficial water. During the summer day-time the glacier is alive with rills and streamlets of varying dimensions, flowing along furrows of their own making, but their course is usually short, in many glaciers very short. They usually flow on until they reach a crevasse or chasm, such as abound on the steeper glaciers; then pitch down this to contribute to the waters of the subglacial tunnel which traverses the bottom of every glacier.

But the Unteraar glacier being so nearly level has but few crevasses, and these are far between; therefore it becomes easily possible for such rills to encounter a baignoire. Two opposite results follow from this. If the water of the streamlet is moderately clear it deepens the pit, and may go on thus deepening it until it forms a deep well in the ice, that may even reach to the bottom of the glacier. This occurs when the quantity of clear water is great. Such wells are named *trous de cascade*, as when fully developed, and reaching the bottom of glacier, all the water they contained in their bathing-tub stage is drained away, and flows under the ice. Thus the baignoire is converted into a deep hole with perpendicular crystal sides, down one part of which an eroding cascade is falling. Agassiz measured the depth of one of these near to the Hotel des Neufchatelois, and found it 260 metres (853 feet) deep, thus affording a measure of the thickness of the ice at that part.

If the rill that falls into the baignoire carries with it much sand and gravel the butterfly's monument is erected. How this comes about may in the meantime stand as a physical problem for my readers to work out, and compare their solution with that which I shall supply next week.

GASEOUS FUEL.

A Paper Read by Mr. J. Emerson Dowson, M.Inst.C.E., before the Mechanical Science Section of the British Association.

(Continued from page 309.)

To determine the working cost of a gas engine driven with this generator gas, compared with a steam engine and boiler, the more simple and direct way is to take in each case the weight of fuel used per h.p. per hour, as it is no more necessary to determine the volume of gas consumed than it is to know the volume of steam used. We have already seen that with this gas the fuel consumption of several Otto engines doing practical work in different places averages only $1\frac{1}{3}$ lbs. per indicated h.p. per hour. The wages of the attendant, the cost of repairs, and the other working expenses are about the same as with a steam engine of equal power. The great difference is in the consumption of fuel, and to make an exact comparison I have taken the returns last published by the Manchester Steam Users' Association, for all engines indicating under 100 h.p., for which the net fuel consumption is given. The details of these returns will be found in Appendix II. of my Institution of Civil Engineers paper before referred to, and from these it appears that the average fuel consumption is 7 lb. per indicated h.p. per hour. If, however, an average be taken of 5 engines, each indicating 20 h.p., the fuel consumption will be over 11 lb. per indicated h.p. per hour. It is instructive too to note what Sir Frederick Bramwell said on the fuel consumption of steam engines in actual work, in his address (January, 1885) as President of the Institution of Civil Engineers. He said:—"In an investigation instituted last year by the Corporation of Birmingham, when considering whether they should approve of a proposal to lay down power-distributing mains throughout their streets, it was found on indicating some six non-condensing steam engines, taken indiscriminately from among users of power, and ranging from 5 nominal h.p. up to 30 nominal h.p., that the consumption in one instance was as high as 27·5 lb., while it never fell below 9·6 lb., and the average of the whole was as much as 18·1 lb. per indicated h.p. per hour."
